APPLICATIONS IN CHEMISTRY

Foreword 3
Abbreviations 5
Amyloids 9

- **Kinetics of Amyloid Fibril Formation of Human Calcitonin,** *Miya Kamihira, Hazime Saitô, and Akira Naito* 11
- **Polymorphism of Alzheimer's Aβ Amyloid Fibrils,** *Oleg N. Antzutkin* 19

Chemical Shifts and Spin-Couplings 29

- **^{13}C, ^{15}N, ^{1}H, ^{2}H, and ^{17}O NMR Chemical Shift NMR for Hydrogen Bonds,** *Shigeki Kuroki* 31
- **NMR Chemical Shift Map,** *Isao Ando and Tetsuo Asakura* 37
- **NMR Chemical Shifts Based on Band Theory,** *Hiromichi Kurosu and Takeshi Yamanobe* 43
- **Modeling NMR Chemical Shifts,** *Julio C. Facelli* 53
- ***Ab Initio* Calculation of NMR Shielding Constants,** *Peter B. Karadakov* 63
- **Crystal Structure Refinement Using Chemical Shifts,** *Ulrich Sternberg, Raiker Witter, and Anne S. Ulrich* 71
- **The Theory of Nuclear Spin–Spin Couplings,** *Hiroyuki Fukui* 79

Fibrous Proteins 85

- **Investigation of Collagen Dynamics by Solid-State NMR Spectroscopy,** *Göran Zernia and Daniel Huster* 87
- **Solid-State NMR Studies of Elastin and Elastin Peptides,** *Kristin K. Kumashiro* 93
- **Structural Analysis of Silk Fibroins using NMR,** *Tetsuo Asakura and Yasumoto Nakazawa* 101

Field Gradient NMR 107

- **NMR Diffusometry,** *William S. Price* 109
- **Field Gradient NMR of Liquid Crystals,** *István Furó and Sergey V. Dvinskikh* 117
- **Field Gradient NMR for Polymer Systems with Cavities,** *Yuji Yamane and Sunmi Kim* 123
- **NMR Measurements Using Field Gradients and Spatial Information,** *Shingo Matsukawa* 129
- **Theory and Application of NMR Diffusion Studies,** *Torsten Brand, Eurico J. Cabrita, and Stefan Berger* 135

Host–Guest Chemistry 145

- **Solid-State NMR in Host–Guest Chemistry,** *John A. Ripmeester and Christopher I. Ratcliffe* 147

Imaging 155

- **Mapping of Flow and Acceleration with NMR Microscopy Techniques,** *Elke Kossel, Bogdan Buhai, and Rainer Kimmich* 157
- **Industrial Application of *In situ* NMR Imaging Experiments to Steel-Making Process,** *Koji Saito* 163
- **Biomedical NMR Spectroscopy and Imaging,** *Toshiro Inubushi and Sigehiro Morikawa* 173

Electron Spin Resonance Imaging in Polymer Research, *Shulamith Schlick* 179
NMR Imaging: Monitoring of Swelling of Environmental Sensitive Hydrogels, *Karl-Friedrich Arndt, Manfred Knörgen, Sven Richter, and Thomas Schmidt* 187

Inorganic Materials and Catalysis 195

Exploiting $^1H \rightarrow ^{29}Si$ Cross-Polarization Features for Structural Characterization of Inorganic Materials, *Piotr Tekely* 197
Solid State NMR Characterization of Solid Surface of Heterogeneous Catalysts, *Feng Deng, Jun Yang, and Chaohui Ye* 205

Isotope Labeling 213

Recent Developments in Stable-Isotope-Aided Methods for Protein NMR Spectroscopy, *Shin-ya Ohki and Masatsune Kainosho* 215
Structural Glycobiology by Stable-isotope-assisted NMR Spectroscopy, *Yoshiki Yamaguchi and Koichi Kato* 223

Lipid Bilayer and Bicelle 231

Development and Application of Bicelles for Use in Biological NMR and Other Biophysical Studies, *Charles R. Sanders* 233
Nuclear Magnetic Resonance of Oriented Bilayer Systems, *Akira Naito, Shuichi Toraya, and Katsuyuki Nishimura* 241
Solid-State Deuterium NMR Spectroscopy of Membranes, *Michael F. Brown, Silvia Lope-Piedrafita, Gray V. Martinez, and Horia I. Petrache* 249
Solid State ^{19}F-NMR Analysis of Oriented Biomembranes, *Anne S. Ulrich* 261

Membrane-Associated Peptides 269

Solid-State NMR Studies of the Interactions and Structure of Antimicrobial Peptides in Model Membranes, *Marise Ouellet and Michèle Auger* 271
Anisotropic Chemical Shift Perturbation Induced by Ions in Conducting Channels, *Jun Hu, Eduard Chekmenev, and Timothy A. Cross* 279
NMR Studies of Ion-Transporting Biological Channels, *James F. Hinton* 285

Membrane Proteins 289

Site-Directed NMR Studies on Membrane Proteins, *Hazime Saitô* 291
Structure of Membrane-Binding Proteins Revealed by Solid-State NMR, *Satoru Tuzi, Naoko Uekama, Masashi Okada, and Hitoshi Yagisawa* 299
Solid-State NMR of Membrane-Active Proteins and Peptides, *John D. Gehman and Frances Separovic* .. 305
Magnetic Resonance Spectroscopic Studies of the Integral Membrane Protein Phospholamban, *Gary A. Lorigan* 313
NMR Studies of the Interactions Between Ligands and Membrane-Embedded Receptors: New Methods for Drug Discovery, *David A. Middleton* 319
Photosynthetic Antennae and Reaction Centers, *H.J.M. de Groot* 327
Insight into Membrane Protein Structure from High-Resolution NMR, *Philip L. Yeagle and Arlene Albert*. 335

New Developments 345

Fast Multidimensional NMR: New Ways to Explore Evolution Space, *Ray Freeman and Eriks Kupče* 347
High-Sensitivity NMR Probe Systems, *P.J.M. van Bentum and A.P.M. Kentgens* 353
CRAMPS, *B.C. Gerstein and H. Kimura* 363
Mobile NMR, *B. Blümich and F. Casanova* 373
Rheo-NMR, *Paul T Callaghan* 383
Analytical Aspects of Solid-State NMR Spectroscopy, *Cecil Dybowski* 389

^{3}H NMR and Its Application, *John R. Jones and Shui-Yu Lu* 395
On-line SEC–NMR, *Tatsuki Kitayama and Koichi Ute* 399

NOE and Chemical Exchange 407

The Nuclear Overhauser Effect, *Mike P Williamson* 409
Solute–Solvent Interactions Examined by the Nuclear Overhauser Effect, *J.T. Gerig* 413
Chemical Exchange, *Alex D Bain* 421

NQR & ESR 429

Separated Detection of H-Transfer Motions in Multi-H-Bonded Systems Studied by Combined ^{1}H NMR and ^{35}Cl NQR Measurements, *Ryuichi Ikeda* 431
EPR: Principles, *Bruce R. McGarvey* 439
Zero Field NMR: NMR and NQR in Zero Magnetic Field, *David B. Zax* 445

Organo Metallic Chemistry 453

Organoboron Chemistry, *Bernd Wrackmeyer* 455
Organogermanium Chemistry, *Bernd Wrackmeyer* 459
Organotin Chemistry, *Bernd Wrackmeyer* 461

Paramagnetic Effects 465

^{1}H and ^{13}C High-Resolution Solid-State NMR of Paramagnetic Compounds Under Very Fast Magic Angle Spinning, *Yoshitaka Ishii and Nalinda P. Wickramasinghe* 467
Paramagnetic Effects of Dioxygen in Solution NMR—Studies of Membrane Immersion Depth, Protein Topology, and Protein Interactions, *R.S. Prosser and F. Evanics* 475

Protein Structure 485

TROSY NMR for Studies of Large Biological Macromolecules in Solution, *César Fernández, Gerhard Wider* 487
NMR Insight of Structural Stability and Folding of Calcium-Binding Lysozyme, *Makoto Demura* 497
NMR Investigation of Calmodulin, *Tapas K. Mal and Mitsuhiko Ikura* 503
Analytical Framework for Protein Structure Determination by Solid-State NMR of Aligned Samples, *Alexander A. Nevzorov and Stanley J. Opella* 517
Determining Protein 3D Structure by Magic Angle Spinning NMR, *Ovidiu C. Andronesi, Henrike Heise, and Marc Baldus* 527
^{19}F NMR Study of *b*-Type Haemoproteins, *Yasuhiko Yamamoto, Satoshi Nagao, and Akihiro Suzuki* 531

Polymer Structure 539

NMR in Dry or Swollen Temporary or Permanent Networks, *Jean-Pierre Cohen Addad* 541
Crystalline Structure of Ethylene Copolymers and Its Relation to the Comonomer Content, *Qun Chen* 545
Isomorphism in Bacterially Synthesized Biodegradable Copolyesters, *Naoko Yoshie and Yoshio Inoue* ... 551
Two-Dimensional NMR Analysis of Stereoregularity of Polymers, *A.S. Brar and Gurmeet Singh* 557
Quantitative Analysis of Conformations in Disordered Polymers by Solid-State Multiple-Quantum NMR, *Hironori Kaji* 563
Polymer Microstructure: The Conformational Connection to NMR, *Alan E. Tonelli* 567
Solid-State NMR Characterization of Polymer Interfaces, *Peter A. Mirau* 575
The Structure of Polymer Networks, *Andrew K. Whittaker* 583
^{1}H CRAMPS NMR of Polypeptides in the Solid State, *Akira Shoji* 591

Polymer Dynamics 605

Dynamics of Amorphous Polymers, *Fumitaka Horii* 607
Molecular Motions of Crystalline Polymers by Solid-State MAS NMR, *Toshikazu Miyoshi* 615

Dynamics in Polypeptides by Solid State ^{2}H NMR, *Toshifumi Hiraoki* 621

Polymer Blends 629

Polymer Blends, *Atsushi Asano* 631
Configurational Entropy and Polymer Miscibility: New Experimental Insights From Solid-State NMR, *Jeffery L. White* 637

Quantum Information Processing 645

Quantum Information Processing as Studied by Molecule-Based Pulsed ENDOR Spectroscopy, *Robabeh Rahimi, Kazunobu Sato, Daisuke Shiomi, and Takeji Takui* 647

Residual Dipolar Couplings and Nucleic Acids 655

New Applications for Residual Dipolar Couplings: Extending the Range of NMR in Structural Biology, *Rebecca S. Lipsitz and Nico Tjandra* 657
Refinement of Nucleic Acid Structures with Residual Dipolar Coupling Restraints in Cartesian Coordinate Space, *Nikolai B. Ulyanov, Zhihua Du, and Thomas L. James* 665
Conformational Analysis of DNA and RNA, *Gota Kawai* 671

Solid-State NMR Technique 677

Analytical and Numerical Tools for Experiment Design in Solid-State NMR Spectroscopy, *Niels Chr. Nielsen, Thomas Vosegaard, and Anders Malmendal* 679
Homonuclear Shift-Correlation Experiment in Solids, *K. Takegoshi* 689
Two-Dimensional ^{17}O Multiple-Quantum Magic-Angle Spinning NMR of Organic Solids, *Gang Wu* 695
A Family of PISEMA Experiments for Structural Studies of Biological Solids, *Ayyalusamy Ramamoorthy and Kazutoshi Yamamoto* 703

Structural Constraints in Solids 711

Rotational-Echo, Double-Resonance NMR, *Terry Gullion* 713
REDOR in Multiple Spin System, *Katsuyuki Nishimura and Akira Naito* 719
Torsion Angle Determination by Solid-State NMR, *Mei Hong* 727
Secondary Structure Analysis of Proteins from Angle-Dependent Interactions, *Toshimichi Fujiwara and Hideo Akutsu* 735

Telomeric DNA Complexes 741

Comparison of DNA-Binding Activities Between hTRF2 and hTRF1 with hTRF2 Mutants, *Shingo Hanaoka, Aritaka Nagadoi, and Yoshifumi Nishimura* 743

APPLICATIONS IN BIOLOGICAL SCIENCES

Abbreviations 755

Optimization of MRI Contrast for Pre-Clinical Studies at High Magnetic Field, *Yu-Ting Kuo, Amy H. Herlihy* 759
The Application of *In Vivo* MRI and MRS in Phenomic Studies of Murine Models of Disease, *Po-Wah So and Jimmy D. Bell* 769
Experimental Models of Brain Disease: MRI Contrast Mechanisms for the Assessment of Pathophysiological Status, *David L. Thomas, Louise van der Weerd, Mark F. Lythgoe, and John S. Thornton* 787
Experimental Models of Brain Disease: MRI Studies, *Louise van der Weerd, David Thomas, John Thornton Mankin choy, and Mark F. Lythgoe* 801
Application of MRS in Cancer in Pre-clinical Models, *Y.-L. Chung, M. Stubbs, and J.R. Griffiths* 823
Experimental Cardiovascular MR in Small Animals, *Jürgen E. Schneider and Stefan Neubauer* 835

Application of Pharmacological MRI to Preclinical Drug Discovery and Development, *Matthew D. Ireland and Steven C.R. Williams* 855
Application of MRI to Cell Tracking, *Kishore Bhakoo, Catherine Chapon, Johanna Jackson, and William Jones* 879

APPLICATIONS IN MARINE SCIENCE

Foreword 893
Abbreviations 895

Comprehensive Compositional Analysis of Fish Feed by Time Domain NMR, *Emil Veliyulin, Karl Østerhus, Wolfgang Burk, Trond Singstad, and Tore Skjetne* 897
Low Field NMR Studies of Atlantic Salmon (*Salmo salar*), *Ida Grong Aursand, Emil Veliyulin, and Ulf Erikson* 905
Water Distribution and Mobility in Fish Products in Relation to Quality, *Bo M. Jørgensen and Kristina N. Jensen* 915
Proton NMR of Fish Oils and Lipids, *R. Sacchi, M. Savarese, L. Falcigno, I. Giudicianni, and L. Paolillo* .. 919
Determination of Fatty Acid Composition and Oxidation in Fish Oils by High Resolution Nuclear Magnetic Resonance Spectroscopy, *Rosario Zamora and Francisco J. Hidalgo* 925
Resonance Spectroscopy to Study Lipid Oxidation in Fish and Fish Products, *E. Falch and M. Aursand* 933
Omega-3 Fatty Acid Content of Intact Muscle of Farmed Atlantic Salmon (*Salmo Salar*) Examined by ^{1}H MAS NMR Spectroscopy, *M. Aursand, I.S. Gribbestad, and I. Martinez* 941
HR MAS NMR Spectroscopy of Marine Microalgae, Part 1: Classification and Metabolite Composition from HR MAS ^{1}H NMR Spectra and Multivariate Analysis, *Matilde Skogen Chauton and Trond Røvik Størseth* 947
HR MAS NMR Spectroscopy of Marine Microalgae, Part 2: ^{13}C and ^{13}C HR MAS NMR Analysis Used to Study Fatty Acid Composition and Polysaccharide Structure, *Trond Røvik Størseth, Matilde S. Chauton, and Jostein Krane* 953
Post-mortem Studies of Fish Using Magnetic Resonance Imaging, *Emil Veliyulin, Alv Borge, Trond Singstad, Ingrid Gribbestad, and Ulf Erikson* 959
How is the Fish Meat Affected by Technological Processes?, *Loïc Foucat, Ragni Ofstad, and Jean-Pierre Renou* 967

Preface

It is a great pleasure for me to Introduce the handbook of Modern Magnetic Resonance, MMR. The various techniques which comprise MMR derive essentially from three sources, all of which were produced by physicists. Today they are widely used by scientists working in many diverse areas such as chemistry, biology, materials, food, medicine and healthcare, pharmacy and marine studies.

The first source of MMR studies is nuclear magnetic resonance, NMR. This provides details on the relative positions of nuclei, i.e. atoms, in a molecule. Consequently NMR provides structural information on samples which may be in the solid, liquid or gaseous state. Nuclear relaxation data yield dynamic information on the sample and the topology of the dynamic processes if the sample is undergoing a molecular change. Thus high and low resolution NMR studies provide information on all interesting aspects of molecular science. The protean nature of NMR is reflected in its many applications in chemistry, biology and physics which explore and characterize chemical reactions, molecular conformations, biochemical pathways and solid state materials, to name a few examples.

Magnetic resonance imaging, MRI, is the second source of MMR data. MRI provides a three-dimensional image of a substance, and is consequently widely employed to assess materials both *in vitro* and *in vivo*. The importance of MRI studies in many areas of science and medicine is shown by the recent award of the Nobel Prize to Lauterbur and Mansfield.

The third source of MMR results is due to electron spin resonance, ESR. This is a technique for detecting unpaired electrons and their interactions with nuclear spins in a given sample. Thus ESR data are often used to complement the results of NMR experiments.

Taken together NMR, MRI and ESR comprise the field of MMR, recent years have witnessed the fecundity of these techniques in many scientific areas. The present three volumes cover applications in most of these areas. Part 1 deals with Chemical Applications, Biological and Marine Sciences. Medical and Pharmaceutical Sciences are covered in Part 2. Part 3 provides examples of recent work in the Materials Science and Food Science.

I wish to express my gratitude to all of the Section Editors and their many contributors for their hard work and dedication in the creation of MMR. My thanks also go to Emma Roberts and the production staff at Springer, London, for their assistance in the realization of these volumes.

Part I, Section 1: Applications in Chemistry

Foreword to Application in Chemistry

Magnetic resonance has continued to be an emerging technique, to be applied to almost all fields of pure and applied sciences, including chemistry, physics, biology, materials science, medicine, etc. during past 60 years since its discovery. The applications in chemistry of this volume covers advanced studies on chemical aspect of magnetic resonance spectroscopy and imaging dealing with the state-of-the-art developments of new techniques together with those of basic concepts and techniques, consisting of 93 articles which are grouped to 25 chapters. They are alphabetically arranged for convenience of readers: amyloids, chemical shifts and spin coupling constants, fibrous proteins, field gradient NMR, host-guest chemistry, imaging, inorganic materials and catalysis, lipid bilayers and bicelles, membrane-associated peptides, membrane proteins, new developments, NOE and chemical exchange, NQR and ESR, organometallic chemistry, paramagnetic effects, protein structures, polymer structure, polymer dynamics, polymer blends, quantum information processing, residual dipolar couplings and nucleic acids, solid state NMR techniques, structural constraints in solids, and telomeric DNA complexes. The section editors are grateful to contributors to this section for their fine contributions.

Tetsuo Asakura, Hazime Saitô and Isao Ando

Abbreviations

AFM: atomic force microscopy

AHT: average Hamiltonian theory

Bicelle: bilayered micelles

BPPLED: bipolar pulse longitudinal eddy current

BPT: bond polarization theory

CC: coupled cluster

CD: circular dichroism

CHF: coupled Hartree-Fock

CNDO: complete neglect of differential overlap

CP-MAS: cross polarization-magic angle spinning

CODEX: centerband-only detection of exchange

COSY: correlated spectroscopy

CPMG: Carr-Purcell-Meiboom-Gill

CRAMPS: combined rotation and multiple pulse spectroscopy

CRINEPT: cross-correlated relaxation-enhanced polarization transfer

CRIPT: cross-correlated relaxation induced polarization transfer

CS: chemical shift

CSA: chemical shift anisotropy

CSI: chemical shift imaging

CTDQFD: constant-time double-quantum filter

CTOCD: continuous transformation of the current density

DARR: dipolar-assisted rotational resonance

DAS: dynamic angle spinning

DEPT: distortionless enhancement by polarization transfer

DD-MAS: dipolar decoupled-magic angle spinning

DECORDER: direction exchange with correlation for orientation-distribution evaluation and reconstruction

DFS: double frequency sweep

DFT: density functional theory

DIPSHIFT: dipolar chemical shift

DNMR: dynamic NMR

DNP: dynamic nuclear polarization

DOQSY: double quantum spectroscopy

DOR: double rotation

DOSY: diffusion-ordered NMR spectroscopy

DPMAS: direct polarization magic angle spinning

DQ: double quantum

DQDRAW: double quantum, dipolar recovery with windowless sequence

DRAW: dipolar recovery with windowless sequence

DSO: diamagnetic spin orbital

EFG: electric field gradient

EEHT: exact effective Hamiltonian theory

EHT: effective Hamiltonian theory

ENDOR: electron nuclear double resonance

EPSI: echo planar spectroscopic imaging

EPR: electron paramagnetic resonance

ESRI: electron spin resonance imaging

Et-NOESY: exchange transferred nuclear Overhauser effect spectroscopy

EXSY: exchange spectroscopy

FDR: frequency selective dipolar recoupling

FOV: field of view

FPT: finite perturbation theory

FC: Fermi contact

GE-HMQC: gradient enhanced-heternuclear multiple quantum coherence

GIAO-CHF: gauge-independent atomic-orbitals coupled Hartree-Fock

GC: gas chromatograph

HETCOR: heteronuclear correlation

HMBC: heteronuclear multiple bond correlation

HMQC: heteronuclear multiple quantum correlation

HOHAHA: homonuclear Hartmann Hahn

HSQC: heteronuclear single quantum correlation

HPDEC: high power decoupling

IGLO: individual gauge for localized orbitals

INADEQUATE: incredible natural abundance double quatum transfer experiment

INDO: intermediate neglect of differential overlap

INEPT: insensitive nuclei enhancement by polarization transfer

LC-NMR: liquid chromatography-NMR

LDA: local density approximation

LDBS: locally dense basis set

LORG: localized orbitals local origin

LG-CP: Lee Goldburg-cross polarization

MAOSS: magic angle oriented sample spinning

MAS: magic angle spinning

MCSCF: multi-configurational self-consistent field

MD: molecular dynamics

MI: molecular imaging

MOVS: magnetically oriented vesicle systems

MQMAS: multiple quantum magic angle spinning

MREV-8: Mansfield-Rhim-Elleman-Vaughan 8 cycle

MRI: magnetic resonance imaging

MRFM: magnetic resonance force microscopy

MSREDOR: multi spin REDOR

NMR: nuclear magnetic resonance

NMR-MOUSE: NMR-mobile universal surface explorer

NOE: nuclear Overhauser enhancement

NOESY: nuclear overhauser and exchange spectroscopy

NQR: nuclear quadrupole resonance

ODF: order-director fluctuation

ONIOM: Our own n-layered integrated molecular Orbital + molecular mechanics

ONP: optical nuclear polarization

PET: positron emission tomography

PFG: pulsed field-gradient

PGSE: pulsed gradient-field spin echo

Photo-CIDNP: photochemically induced dynamic nuclear polarization

PISA: polarity index slant angle

PISEMA: polarization inversion spin exchange at magic angle

PM5: parametric method 5

PSO: paramagnetic spin orbital

QC: quantum computation

QEDOR: quadrupole echo double resonance

QED: quantum electrodynamics

QCPMG: quadrupolar Carr-Purcell-Meiboom-Gill refocusing pulse

QIP: quantum information processing

QM/MM: quantum mechanics/molecular mechanics

QRI: quantum resonance interferometry

PFG: pulse field gradient

RACO: relayed anisotropy correlation

RDC: residual dipolar coupling

REAPDOR: rotational echo adiabatic passage double resonance

REDOR: rotational echo double resonance

RFDR: radio frequency driven resonance

RMSD: root mean-square deviation

ROCSA: recoupling of chemical shift anisotropy

ROCSA-LG: recoupling of chemical shift anisotropy-Lee Goldburg

ROE: rotating frame Overhauser experiment

RR: rotational resonance

SAIL: stereo-array-isotope-labelling

SASS: switching angle sample spinning

scBCH: semi-continuous Baker-Campbell-Hausdorff

SDC: superdense coding

SEC-NMR: size exclusion chromatography-NMR

SEDOR: spin echo double resonance

SELFIDOQ: separated-local-field double quantum

SFAM: simultaneous frequency amplitude modulation

SOPPA: second order polarization propagator approximation

SOS: sum-over-states method

SQ: single quantum

SQUID: superconducting quantum interference device

SSNMR: solid state NMR

STD: saturation transfer difference spectroscopy

STRAFI: stray field magnetic resonance imaging

STO: Slater-type orbital

TB MO: tight-binding molecular-orbital

TOCSY: total correlation spectroscopy

TORQUE: T one rho quenching

TRAPDOR: transfer of populations in double resonance

TPPM: two pulse phase modulation

TROSY: transverse relaxation optimized spectroscopy

VFMAS: very fast magic angle spinning

water LOGSY: water-ligand observation by gradient spectroscopy

WISE: wide-line separation

XRD: x-ray diffraction

ZQ: zero-quantum

Amyloids

Part I

Kinetics of Amyloid Fibril Formation of Human Calcitonin

Miya Kamihira[1], Hazime Saitô[1], and Akira Naito[2]
[1]Department of Life Science, Himeji Institute of Technology, Harima Science Garden City, Kamigori, Hyogo 678-1297, Japan; and
[2]Department of Engineering, Yokohama National University, Hodogaya, Yokohama 240-8501, Japan

Introduction

Amyloid fibril formation is one of the common phenomena associated with many serious diseases such as Alzheimer's disease, Parkinson's, bovine spongiform encephalopathy (BSE), scrapie, and so on. Independent of the constituent polypeptides, the amyloid fibrils exhibit highly organized filamentous structures which are typically ∼100 Å in diameter, as revealed by electron microscopy and atomic force microscopy. Mechanism of the amyloid fibril formation has been extensively studied by various spectroscopic techniques, related to misfolding of proteins. Especially, solid-state NMR spectroscopy has made a great contribution to determine the structures of the fibrils from several peptides/proteins at the molecular level. For example, Alzheimer's β-amyloid peptides, which consist of 40–42 amino acid residues, have gained insights into the three-dimensional (3D) structures in the fibrils as a double-layered cross-β structure with parallel β-sheets by accumulating the local and spatial conformational restraints [1–3]. Also, an 11-residue fragment of human transthyretin (TTR) in its fibrillar form which *in vivo* is allied with familial amyloid polyneuropathy and senile systemic amyloidosis, was revealed the complete 3D structures of the extended β-strand conformation, by establishing dihedral angles of the backbone and ^{13}C–^{15}N distances [4,5]. These results indicate that solid-state NMR spectroscopy is a powerful tool to determine the non-crystal, non-soluble, fibrillar structures.

In this chapter, a solid-state NMR application on the kinetics analyses of the amyloid fibril formation is described. Human calcitonin (hCT) is a thyroid hormone which regulates the mineral metabolism in the bones [6–8]. hCT contains 32 amino acid residues and its sequence is CGNLSTCMLGTYTQDFNKFHTFPQTAIGVGAP-NH_2 with a disulfide bond between Cys^1 and Cys^7 and a C-terminus amide. In a high concentrated solution, however, it is known to form the amyloid fibrils, which are typically 80 Å in diameter [9,10].

Properties of Fibril Formation of hCT

For concentrations above 15 mg/ml hCT, the solution changes in time into a turbid gel as the end fibrillated state, while for the concentrations below and around 1 mg/ml, the equilibrium state consists of a clear solution containing punctuate aggregates which may precipitate [11]. Long fibrils were observed from the gel (pH 3.3, 80 mg/ml) and short fibril aggregates were seen in the precipitates from a diluted solution (1.5 mg/ml, pH 7.5) [12]. Turbidity measurement showed absorption of the hCT solution increased gradually after a lag time which was dependent on the hCT concentrations [11]. As mentioned later, from the results, the kinetics of hCT fibrillation was proposed to be a double nucleation mechanism [11,13–15]. The fibrillation is also temperature-dependent and an apparent activation enthalpy for the reaction was obtained to be 20 kcal/mol at 10 mg/ml (pH 7.4) [11]. Also the rate of the fibril formation was found to be largely pH-dependent and in acidic solution it is much slower than that in neutral pH [11,12]. Solution NMR studies on hCT (80 mg/ml, pH 2.9) showed a gradual broadening of the peptide peaks, followed by a rapid broadening and subsequent disappearance of the NMR signals [16]. The phenomenon was not seen simultaneously and the peaks from the residues in the N-terminal (Cys^1-Cys^7) and in the central (Met^8-Pro^{23}) regions broadened and disappeared faster than those in the C-terminal region (Gln^{24}-Pro^{32}). Furthermore the peaks of Cys^1, Leu^{4,9}, Met^8, Tyr^{12}, Asp^{15}, and Phe^{16,19,22} disappeared faster than the others [16]. These results together with hydrogen–deuterium exchange of amide protons indicate that the amphiphilicity of hCT in the central region might cause a formation of α-helical bundles leading to the fibril formation [16].

Conformational Changes of hCT

To determine the fibrillation process further, the solid-state NMR methods were applied. For this purpose the conformation-dependent ^{13}C chemical shifts are efficient means to determine the secondary structures around the ^{13}C sites straightaway [17–21], especially in the case where the state changes as elapsed time. ^{13}C CP-MAS spectra of the hCT fibrils formed in 15 mM acetic acid solution (80 mg/ml) showed much narrower signals than those before dissolved in the solution (lyophilized powder) (Figure 1), suggesting that the fibril is conformationally more homogeneous than the lyophilized powder. Also

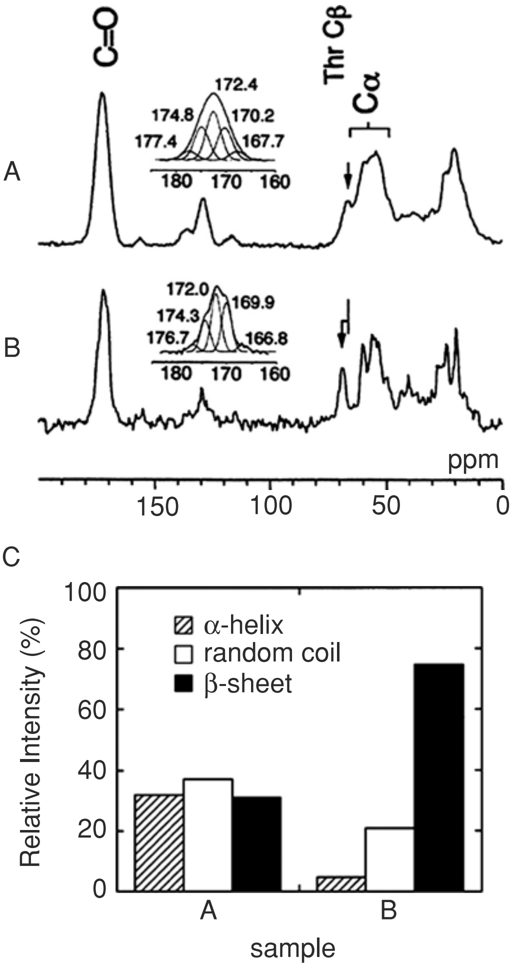

Fig. 1. ^{13}C CP-MAS spectra of lyophilized powder of hCT (Ciba-Geigy, Japan) (A) and the hCT fibrils obtained after 48 h from dissolution in 15 mM acetic acid solution (80 mg/ml) (B). The spectra were recorded on a Chemagnetics CMX 400 NMR spectrometer at the resonance frequency of 100.6 MHz (^{13}C). Insets show deconvoluted spectra of the carbonyl resonances using Peak Fit (SPSS Inc., Chicago, USA). The deconvoluted signals were assigned to be β-sheet (lower frequency than 172.2 ppm; black bars), random coil (172.2–174.5 ppm; open bars), and α-helix (higher frequency than 174.5 ppm; hatched bars) respectively (C).

it is noted that the peak positions have shifted. Deconvolution of the carbonyl signals clearly indicated that the β-sheet conformation gained largely during the fibril formation (Figure 1C). The signals which could be assigned to Thr C_β marked by arrows were also shifted from 65.7 (assigned to random coil) to 67.8 ppm (β-sheet) [18] (Figure 1A and B). Local conformations were examined using site-specifically ^{13}C labeled hCTs [12]. DD-MAS (single 90^o pulse excitation with a proton decoupling under magic angle spinning) and CP-MAS (cross-polarization with a proton decoupling under magic angle spinning) spectra were recorded, since in the CP-MAS spectra a fibril component was detected, while in the DD-MAS spectrum the solution component was mainly observed, especially for the carbonyl carbons in view of the long spin–lattice relaxation time compared with the recycle delay. During the fibrillation at pH 3.3, it was clarified that conformational transitions occur from an α-helix (in the solution) to a β-sheet structure (in the fibril), and from a random coil to a β-sheet structure in the central region, around Gly^{10} and Phe^{22}, respectively [12]. The C-terminus region (around Ala^{26} and Ala^{31}) also changed the conformation partially from a random coil to a β-sheet structure [12]. Further the existence of polymorphs of the fibrils was clearly shown in molecular level, depending on the pH (3.3, 4.1, and 7.5) in the solution [12,22]. It is suggested that at pH 7.5 hCT forms the antiparallel β-sheet by a favorable electrostatic interaction between Asp^{15}(−) and Lys^{18}(+), in addition to the hydrophobic interaction among the amphiphilic helices [12]. The fibrils at pH 3.3 may be a mixture of antiparallel and parallel β-sheet structures, because no attractive ionic interaction to fix the unique direction for the molecular association is present in this case to result in the presence of two conformations up to the C-terminus region [12]. Whereas the β-sheet formed at pH 4.1 is shorter than the others, suggesting probable ionic interactions of the side chain of Asp^{15} with the amino group of the N-terminus (Cys^{1}), rather than with the side chains of Lys^{18}(+) or His^{20}(+) [22]. Accordingly, it was demonstrated that the charged residues existing in hCT (amide nitrogen, Asp^{15}, His^{18}, and Lys^{20}) play a central role for determination of the molecular alignment of the hCT monomers. Indeed absence of the negative charge at Asp^{15} (mutated to Asn^{15}: D15N-hCT) did not make any differences in the local conformations of the fibrils from neutral and acidic solution [23].

Kinetic Analysis of hCT Fibrillation

When hCT solution was dissolved in 15 mM acetic acid solution (80 mg/ml, pH 3.3), it became a turbid, viscous gel in 2–3 days. Time course of the ^{13}C DD- and CP-MAS NMR spectra accumulated repeatedly, showed gradual increase of the CP-MAS signals, synchronously with decrease of the DD-MAS signals, after a certain time (Figure 2A). Although a MAS frequency of 4000 Hz was applied to the sample in a 5-mm o.d. rotor in a 400 MHz spectrometer, the observed increases in the CP-MAS signals were corresponding to the increases in turbidity and

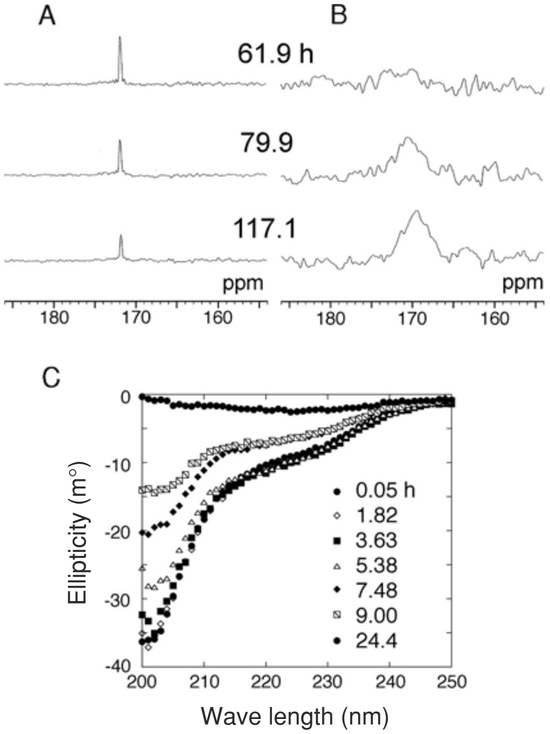

Fig. 2. Time course of ^{13}C DD- (A) and CP-MAS (B) NMR spectra of hCT monomers and fibrils, respectively [pH 3.3, 80 mg/ml (23.4 mM)] at 20 °C. The number of accumulations for the DD- and CP-MAS signals was 1000 and 2000, respectively. Magic angle spinning frequency of 4000 Hz was applied. Stacked CD spectra measured on an AVIV model 62DS using quartz cuvettes with path length of 0.02 cm (B). Sample concentration was 0.2 mg/ml (58.5 μM) in 20 mM phosphate buffer (pH 7.5). Temperature was controlled to 25 °C. The time when hCT was dissolved was regarded as 0.

viscosity by visual observation of the rest of the same solution located outside the magnet. The changes of the peak intensities in the DD- and CP-MAS spectra (Figures 2B and 3A) show a two-step reaction process: for the case of [1-^{13}C]Gly^{10}-hCT, the first and the second step may occur at ∼60 and 60–118 h, respectively. The chained changes in the DD- and CP-MAS spectra and the presence of the lag time suggest that this hCT fibrillation process could be explained by the two-step autocatalytic reaction mechanism, in which the first reaction is a homogeneous nucleation step and the second one is a heterogeneous fibrillation process to elongate and to mature the fibrils. Here, the components of hCT molecules observed by the DD- and CP-MAS experiments are defined as A and B forms, respectively. For an early stage, it is proposed that a formation of micelles which corresponds to the α-helical bundle [16], are reversibly formed from monomers with the same aggregation number $n_0(A_{n_0})$, as shown in Reaction (1) (Figure 4A and B),

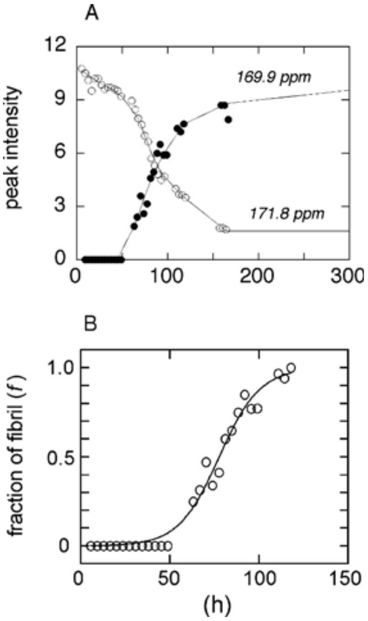

Fig. 3. A plot of [1-^{13}C]Gly^{10} peak heights in ^{13}C DD- (open circle) and CP-MAS (closed circle) of hCT (pH 3.3, 80 mg/ml) against the elapsed time (A). The time of dissolution was taken as 0. Acquisition was started 6 h after dissolution. The intensity of the CP-MAS signals was normalized as that observed at 119 h after dissolution as unity (B). The line in (B) shows the best fit to Equation (7) representing the two-step reaction mechanism.

$$n_0\text{A(monomers)} \leftrightarrow A_{n_0}\text{(micelle)}. \qquad (1)$$

Here, the hCT molecules in the monomer and the micelle states are supposed to give the same DD-MAS NMR signals as the other signals were not appeared. We consider the case where the total hCT concentration of A form ($[\mathrm{A_T}] = n_0[A_{n_0}] + c^*$) is always much higher than the critical micellar concentration c^*, then $[\mathrm{A}_{n_0}]$ can be expressed as $[\mathrm{A_T}]/n_0$. Under these conditions, the first reaction step is given by,

$$\mathrm{A}_{n_0} \xrightarrow{k_1} \mathrm{B}_{n_0}, \qquad (2)$$

where k_1 is the rate constant of Reaction (2) and B_{n_0} is the nucleus of fibril consisting of n_0 number of hCT. If f is defined as the fraction of the B form (fibril) in the system,

Fig. 4. Schematic representation of a proposed model for the fibril formation. hCT monomers in solution (A) make a homogeneous association to form α-helical bundles (micelles) (B) and simultaneously they change conformations to form β-sheet (C) which could be nuclei of the fibril for heterogeneous fibrillation process to grow the fibril (D).

the kinetic equation of Reaction (2) can be given by

$$\left(\frac{\mathrm{d}f}{\mathrm{d}t}\right)_1 = k_1(1-f). \tag{3}$$

The second autocatalytic fibrillation process can be given by

$$\mathrm{A} + \mathrm{B}_n \xrightarrow{k_2} \mathrm{B}_n + 1, \tag{4}$$

where k_2 is the rate constant of the Reaction (4) and B_n and B_{n+1} are the elongated fibrils with n and $n+1$ numbers of hCT molecules, respectively. In this process, each hCT molecule in B_n is assumed to act as catalytic sites to accelerate the change from A to B forms. Thus $[\mathrm{B}_n]$ can be replaced by

$$\begin{aligned}[\mathrm{B}] &= n_0[\mathrm{B}_{n_0}] + (n_0+1)[\mathrm{B}_{n_0}+1] + \cdots + n[B_n] + \cdots \\ &= af\end{aligned}$$

in the kinetic equation where a is the initial concentration of hCT in the solution. Although micelles are formed, individual hCT molecules (A form) could also react with B_n in the second autocatalytic step. As a consequence of the Reaction (4), $[\mathrm{A_T}] = a(1-f)$ can be used as [A], and [B] increases stepwise after a certain delay time. The relevant differential equation is given by

$$\left(\frac{\mathrm{d}f}{\mathrm{d}t}\right)_2 = k_2 af(1-f). \tag{5}$$

Then the overall kinetic equation for the two-step autocatalytic reaction may be expressed as

$$\frac{\mathrm{d}f}{\mathrm{d}t} = \left(\frac{\mathrm{d}f}{\mathrm{d}t}\right)_1 + \left(\frac{\mathrm{d}f}{\mathrm{d}t}\right)_2 = k_1(1-f) + k_2 af(1-f). \tag{6}$$

The differential equation can be integrated to provide

$$f = \frac{\rho\,\{\exp\left[(1+\rho)\,kt\right] - 1\}}{1 + \rho\exp\left[(1+\rho)\,kt\right]}, \tag{7}$$

Table 1: Kinetic parameters for the fibril formation of hCTs in various pH solution

Sample pH	Method (observed signal)	Concentration (mM)	k_1 (s^{-1})	k_2 ($s^{-1}M^{-1}$)	ak_2 (s^{-1})
hCT					
pH 3.3*	NMR (Gly^{10} C=O)	23.4	$2.71(\pm0.11) \times 10^{-8}$	$9.01(\pm0.81) \times 10^{-4}$	$2.11(\pm0.19) \times 10^{-5}$
pH 4.1	NMR (Gly^{10} C=O)	23.4	$3.86(\pm1.79) \times 10^{-6}$	$5.89(\pm2.94) \times 10^{-4}$	$1.38(\pm0.69) \times 10^{-5}$
pH 7.5*	CD (205 nm)	0.0585	$2.79(\pm0.04) \times 10^{-6}$	$2.29(\pm0.14)$	$1.34(\pm0.08) \times 10^{-4}$
pH 7.5*	CD (205 nm)	0.439	$6.44(\pm0.29) \times 10^{-8}$	$2.78(\pm0.19)$	$1.22(\pm0.08) \times 10^{-3}$
DFNKF†					
pH 7.5	NMR ($Phe^{2(16)}$ C=O)	23.4	$1.02(\pm0.35) \times 10^{-7}$	$7.28(\pm1.54) \times 10^{-3}$	$1.70(\pm0.36) \times 10^{-4}$

under the boundary condition of $t = 0$ and $f = 0$, where $\rho = k_1/k$ represents the dimensionless value to describe the ratio of k_1 to k and $k = ak_2$ is an effective rate constant of Reaction (4). After the peak height observed in the CP-MAS spectra was normalized as that observed at 119 h after dissolution as unity (Figure 3B), fitting of the data to the Equation (7) yielded the rate constants, k_1 and k_2, separately (Table 1). Almost the same values were obtained from increase of the intensities in the methyl signals in the ^{13}C CP-MAS signals as well [12] or from analysis of the decrease of the DD-MAS signals (data not shown). A proposed fibrillation process is illustrated in Figure 4. Similarly the rate constants for the fibrillation at pH 4.1 were obtained [22]. The fibrillation of hCT at pH 7.5 was examined using CD spectroscopy instead of NMR at low peptide concentrations (0.2 and 1.5 mg/ml), because the solution becomes a gel in a short time. Decrease of the intensity was observed as elapsed time (Figure 2B) and the same reaction mechanism was applied to it too (Table 1) [12]. Although the effective rate constant, ak_2, is affected by different initial concentrations, it is considered that the reaction rates should be compared as the rate constants, k_1 and k_2. This fact was justified by observing that the comparable k_2 values were determined in the two different initial concentrations (at pH 7.5; Table 1).

The most striking feature was that in the case of fibril formation of hCT the k_1 values were a couple of orders smaller than the k_2 and ak_2 values (Table 1). This suggests that the first homogeneous nucleation process is much slower than the second heterogeneous fibrillation step. Simulation of the Equation (7) reveals that if $k_1 \geq k_2$, the lag time disappears and as k_1 becomes longer the lag time increases gradually (Figure 5A). Basically, $ak_2(k)$ and the ratio of k_1 and $k(\rho)$ determine the reaction effectively. On the other hand, it became clear that if $k_2(k)$ increases by one order, the reaction attains to $f = 1$ by ~10 times faster (Figure 5B), while 10 times larger k_1 does not provide such big differences (Figure 5A). Accordingly,

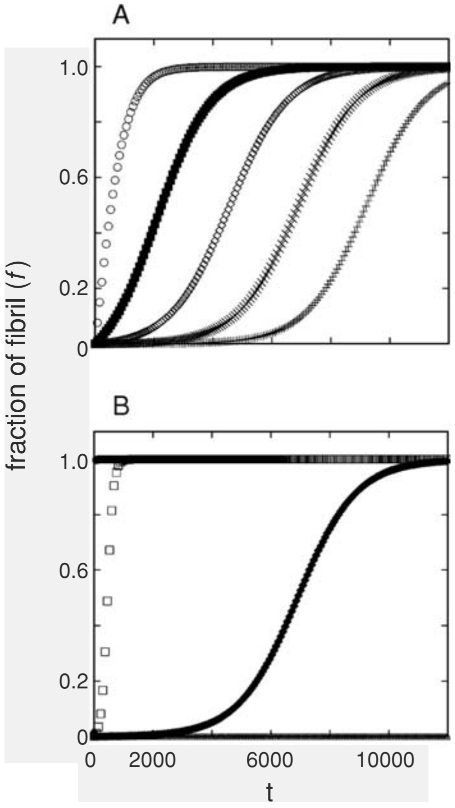

Fig. 5. A computational simulation of kinetics of the two-step autocatalytic reaction. The plot (A) shows at $k = 10^{-2}$ and ρ is varied for 10 (open circle), 1 (closed square), 10^{-1} (open diamond), 10^{-2} (×), and 10^{-3} (+) respectively, representing the effect of k_1 under fixed k_2 on the plot. Whereas the plot (B) shows the variation of k and ρ at the same time to demonstrate the effect of k_2 under fixed k_1: closed circle; 10^{-1}, open square; 10^{-2}, closed diamond; 10^{-3}, cross; 10^{-4}.

reflecting the large difference in the lag time, clear difference in the k_2 values appeared among the samples at pH 3.3 (and 4.1) and 7.5 (Table 1). Thus it is important to determine the rate constants for the first and the second reaction steps separately. The separation of k_1 from k_2 is also important to discuss the factor of fibrillation mechanism in the first step separately from that in the second step.

Mechanism of Fibril Formation

Recently many models have been proposed for the mechanism of amyloid fibril formations from several peptides/proteins [24]. The *double nucleation mechanism* explains the fibril formation starts with a homogeneous nucleation step from hCT monomers and afterward fibrillation continues with development of new fibrils from existing ones [11,13–15]. Formation of peptide micelles above a certain critical peptide concentration has been proposed in the *nucleated polymerization model* in which fibrils nucleate within these micelles or on existing nuclei (seeds) heterogeneously, following fibrils grow by irreversible binding of monomers to the fibrils ends [25–27]. Then the *nucleated conformational conversion model* describes that structurally fluid oligomeric complexes accumulate into nuclei or associate with existing ones where conformational conversion takes place as a rate-determining step [28]. The autocatalytic reaction mechanism we proposed, however, explains the conformational changes occurred together and the rate-limiting step that is characteristic to the amyloid fibril formation clearly. In the solution state, there also exist several different models. It has been proposed for the amyloidosis of β_2-microglobulin that there should be a monomeric amyloidogenic intermediate from a native monomer to assemble each other to form an early assembly intermediate, following it changes to a nucleus where the monomeric intermediates make an interaction together to elongate the fibril [29,30]. On the contrary, in a *mathematical model*, a rapid, irreversible commitment occurs to form either stable monomer/dimer or unstable intermediate, only which associates cooperatively into a multimeric nucleus (filament) [31]. Further, elongation of the filament may occur via addition of the unstable intermediate and by end-to-end association of the filaments [31]. We have also considered that many other fast reactions may exist during the process of a large fibril formation. However, the secondary structure and the chemical environments of the components observed in the DD- and CP-MAS spectra did not change throughout this process, and no additional peaks were observed (Figure 2A). These findings in ^{13}C NMR experiments imply that it is sufficient to consider the two-step reaction for the fibrillation kinetics of peptides.

Then what is the direct force to cause the molecular interaction among the monomers, to form a nucleus (at the first step) or to make an interaction of a monomer with a nucleus (at the second step)? Generally, it has been claimed that the hydrophobic and the electrostatic interaction might be necessary for the fibril formation since the “core region” which is essential to form a fibril, contains (a) cluster(s) of those amino acid residues. In the case of hCT, there exists only one negatively charged residue (Asp^{15}) in it, together with three positively charged group/side chains (NH_3^+, Lys^{18}, and His^{20}). And the results used D15N-hCT demonstrated that the negative charge at Asp^{15} does not increase the rate of fibrillation [22,23]. Instead larger positive net charges around Lys^{18} and His^{20} could cause decrease of the reaction rates, because the side chains of them locate on the same side of the β-strand which might destabilize the structure and disturb elongation of the fibrils [23]. On the other hand, a hCT fragment DFNKF (15–19) which is the shortest one to form a fibril in hCT [32] and is determined to be important for *in vivo* bioactivity too [33], gave 300 times smaller k_2 values at pH 7.5 compared with those of hCT at pH 7.5 (Table 1) [22]. Further, the loss of aromatic rings in the central region was observed to cause the delay in the second step of the fibrillation (Kamihira *et al.*, manuscript in preparation). These results could be a clue to the elucidation of the molecular association to lead to fibril formation.

Conclusion

It was clearly demonstrated that the use of solid-state NMR spectroscopy is very efficient to determine the local conformational changes during the amyloid fibril formation of hCT. Especially the analysis of the signal intensities enabled to examine the kinetic property of hCT fibrillation as a two-step autocatalytic reaction. Further determination using this method could clarify the mechanism of amyloid fibril formations more in detail.

Polymorphism of Alzheimer's Aβ Amyloid Fibrils

Oleg N. Antzutkin

Division of Chemistry, Luleå University of Technology, S-971 87 Luleå, Sweden

Abstract

An overview of the strategy and experimental solid-state NMR, STEM, and AFM methods useful for obtaining structural constraints on Alzheimer's amyloid-β peptide fibrils is presented. Polymorphism of amyloid fibrils and the relevance to neurotoxicity is discussed.

Abbreviations: STEM, scanning transmission electron microscopy; AFM, atomic force microscopy.

Alzheimer's disease (AD) is a form of senile dementia, which affects ca. 40 million senior citizens worldwide [1]. AD is one of the most expensive diseases because an intense daycare of patients is needed over many years. For example, direct and indirect costs of AD and other forms of dementia in Sweden alone (ca. 160,000 patients, a half of them with AD) amount to more than 5400 million euro in 2004 [2]. To this day, a microscopic diagnosis of AD is made on the invariable presence of the two primary criteria: (i) the presence of extracellular senile amyloid plaques surrounded by dead or severely damaged nerve cells in certain regions of the cerebral cortex, such as the hippocampus, amygdala, and other regions of the brain important for memory, learning, and judgment and (ii) dense bundles of abnormal fibers, neurofibrillar tangles, formed by another normally occurring neuronal protein, tau-protein, in the cytoplasm of certain degenerating neurons [3]. In addition, the pathology of AD was found to involve marked decreases in acetylcholine, the chemical used by nerve cells to transmit signals.

In 1984 Glenner and Wong [4,5] and later Masters *et al.* [6] found that amyloid isolated from blood vessels in the meninges and from Alzheimer's amyloid plaques consist of ca. 90% of amyloid-β-peptides (Aβ), 39–43 amino acid residue peptides with the principal components Aβ$_{(1-40)}$ and Aβ$_{(1-42)}$: DAEFRHDSGY$_{10}$ EVHHQKLVFF$_{20}$AEDVGSNKGA$_{30}$IIGLMVGGVV$_{40}$IA [4–8]. Transmission electron microscopy of amyloid plaques revealed numerous unbranched Aβ amyloid fibrils with diameter 6–12 nm, surrounded by the amorphous aggregates, diffuse amyloid.

Despite an imperfect correlation between amyloid deposits and dementia [9–11], recent reports from various research groups all tend to implicate Aβ, rather than tau-protein, as triggering a long cascade of biochemical reactions finally leading to neurodegeneration [12–14]. Early onsets of AD have been connected to the following genetic factors: (i) mutations in proteins Presenilin I and Presenilin II (putatively assigned to γ-secretases [12]) which lead to elevated plasma concentrations of Aβ$_{(1-42)}$, a more hydrophobic and neurotoxic form of human Aβ; (ii) point mutations in human Aβ$_{(1-40)}$ (and Aβ$_{(1-42)}$), Aβ$_{(1-40)}$(A21G) "Flemish" [15], Aβ$_{(1-40)}$(E22Q) "Dutch" [16], Aβ$_{(1-40)}$(E22K) "Italian" [17], Aβ$_{(1-40)}$(E22G) "Arctic" [18], and Aβ$_{(1-40)}$(D23N) "Iowa" [19]. Remarkably, these mutants aggregate faster and at lower critical concentrations compared with the wild type Aβ$_{(1-40)}$ [20]. Also, it has been found that the "Arctic" mutant found in Northern Swedish families with an early onset of AD (54–61 years), Aβ$_{(1-40)}$(E22G), forms a larger relative amount of smaller aggregates and proto-fibrils [18] as well as the peptide shows a high degree of polymorphism of amyloid fibrils grown in TRIS buffer solution at pH 7.4 (two non-coiled and three coiled types of fibrils) [21,22].

The sequence of Aβ includes the first 28 residues (mainly hydrophilic) of the extracellular domain and 11–15 residues (mainly hydrophobic) of the transmembrane region of a 695-residue amyloid precursor protein (APP), whose function is not fully understood [7]. It is believed that putatively incorrect processing [23] or abnormal post-translational modifications of APP [24] give rise to the extracellular neurotoxic Aβ. Moreover, it has been observed *in vitro* that significant levels of peptide aggregation into a structural fibrillar form are always associated with significant Aβ-induced neurotoxicity [25–27]. The exact mechanism of the Aβ neurotoxicity is still unknown, though recent reports suggest that Aβ$_{(1-40)}$ and Aβ$_{(1-42)}$ amyloid fibrils with distinct different morphologies and different supramolecular structures show remarkably different toxicity *in vitro* for cell cultures of hippocampal neurons obtained from rat embryos [28,29]. Even small but putatively structured Aβ oligomers have been found toxic for nerve cell cultures both *in vitro* [13] and *in vivo* [14]. These make structural studies on Alzheimer's amyloid fibers and oligomers significant neuropathologically.

It has been reported in a fair number of studies that both synthetic Aβ and its fragments [30–46], as well as isolated Alzheimer's senile plaque proteins [47,48],

spontaneously assemble into the typical 60–120 Å amyloid fibers that exibit a β-pleated sheet conformation and other properties consistent with native AD Aβ-peptides. Morphology and macroscopic features of the amyloid fibrils (shape, left or right handed twist, pitch, maximum and minimum heights) can be readily studied by AFM (see Figures 1A and B) or/and TEM (not shown). AFM is advantageous over TEM, because AFM allows very fine measurements of height and, therefore, all dimensions of coiled amyloid fibrils can be precisely elucidated (see Figure 1C and D). The latter is crucial in distinguishing of different types of fibril morphology, which may correlate with different neurotoxicity as discussed above. Polymorphism of Alzheimer's Aβ$_{(1-40)}$ (two types of amyloid fibrils [28]) and Aβ$_{(1-40)}$E22G ("Arctic" mutant, five different types of fibrils [21,22]) has been recently investigated in detail.

Structural features of amyloid fibrils can be further investigated by scanning transmission electron microscopy (STEM) [28,49,50] (mass-per-length measurements, Figure 1E) using the methods developed in the earlier works [51–54]. By STEM mass-per-length of different polymorphs of amyloid fibrils can be measured by recording intensity of the dark-field STEM image across an amyloid fibril, correcting it on image background and further normalizing to intensity of the signal across a calibrant, tobacco mosaic virus (TMV) with mass-per-length 131 kDa/nm known from single crystal X-ray diffraction data. Additional information that Alzheimer's amyloid fibrils adopt a cross-β-sheet structure with multiple folded or stacked β-sheet laminae, comes from X-ray diffraction data on oriented amyloid fibrils [32]. A cross-β-sheet structure is characterized by two typical reflections, which correspond to ca. 4.9 Å spacing (i.e. intermolecular hydrogen bonding) perpendicular to ∼10 Å spacing (interlaminae spacing filled with side groups of amino acid residues forming structures stabilized by van der Waals and electrostatic interactions). Therefore, mass-per-length statistics of amyloid fibrils can be readily recalculated into a number of β-sheet laminae folded and packed into fibrils, provided that molecular weight of peptide molecules is known (for example, MW(Aβ$_{(1-40)}$) ≈4329 a.u.). Fibrils with different morphology may be composed of different number of laminae: two, three or four, depending on the peptide sequence and on the preparation procedure (acidic or neutral pH, type of buffer, incubation with or without agitation [21,28,49]. For example, Alzheimer's amyloid fibrils of Aβ$_{(1-40)}$(R5G, Y10F, H13R), called as "rat" or "rodent" sequence, prepared at pH 7.25 in non-buffered solution and without additional agitation, consist of three folded laminae (see statistics in Figure 1E). Human Aβ$_{(1-40)}$ fibrils prepared in vertical dialysis tubes in an unstirred bath of phosphate buffer solution at pH 7.45 also consist of three laminae. In contrast, a gentle circular agitation of 0.1–1.0 mM Aβ$_{(1-40)}$ solutions (buffered or non-buffered, pH 7.4, room temperature, 1–10 weeks of incubation) in polypropylene tubes gives rise to fibrils with either two or four β-sheet laminae and with remarkably lower neurotoxicity compared with the quiescent three-laminated fibrils [28]. Interestingly, Aβ$_{(1-42)}$, which is more amyloidogenic peptide, and a shorter peptide, Aβ$_{(10-35)}$, usually used as a convenient model system [55–58], also form amyloid fibrils with either two or four β-sheet laminae when prepared in non-buffered solutions at either pH 3.8 or 7.4 with additional agitation [49].

However, mass-per-length STEM measurements combined with X-ray diffraction data on oriented amyloid fibrils provide only information about a number of β-sheet laminae packed and propagating along the long axis of fibrils. Pertinent questions about more detailed supramolecular structure of fibrils and their properties are: (i) Which fragments of peptide molecules form parallel or antiparallel β-sheets? (ii) Are any fragments of molecules, which do not adopt a β-sheet secondary structure? (i.e. forming α-helices, turns or random coils) (iii)What are precise structural parameters of these non-β-sheet structural fragments? (iv) Do certain side groups of amino acid residues form salt bridges? (v) Which side groups are packed together forming hydrophobic clusters? (vi) How a single β-sheet lamina is folded, "upwards" or "downwards", exposing side groups of different amino acid residues to the surrounding solution? (vii) What are these amino acid residues, which side groups form outer surfaces of amyloid fibrils and which may, therefore, induce neurotoxicity or can be accessed by "attacking" inhibitors or proteases of amyloid fibrils *in vivo*? (viii) How two (or three, or four) different β-sheet laminae are folded and packed together giving rise to a "ready" amyloid fibril? (ix) Where are binding sites either for metal ions that can stabilize certain structures of Aβ oligomers and fibrils (Cu^{2+}, Zn^{2+}, Fe^{3+}, and Al^{3+} found in Alzheimer's amyloid plaques) or for highly soluble metal–ligand complexes that can easily penetrate brain-blood-barrier (for example, alumninum citrates, $[Al_3(OH)(H_{-1}Cit)_3]^{4-}$ or $[Al_3(OH)_4(H_{-1}Cit)_3]^{7-}$)? (x) How different known pathologic point mutations in the peptide sequence affect the supramolecular structure, polymorphism, aggregation kinetics, and neurotoxicity of amyloid fibrils? (xi) Is the structure of aggregation intermediates (small oligomers, spherical bodies or protofilaments, which are also believed to be neurotoxic [13,14]) similar to structural fragments of amyloid fibrils or structural transitions do occur in the course of the aggregation cascade? (xii) How the assembly of amyloid fibrils proceeds, either by single molecules or by small oligomeric domains?

Solid-state NMR spectroscopy combined with either selective or uniform ^{13}C, ^{15}N isotopic labeling of Alzheimer's β-amyloid peptides were found as useful methods for answering on some of aforementioned questions about supramolecular structure of amyloid fibrils

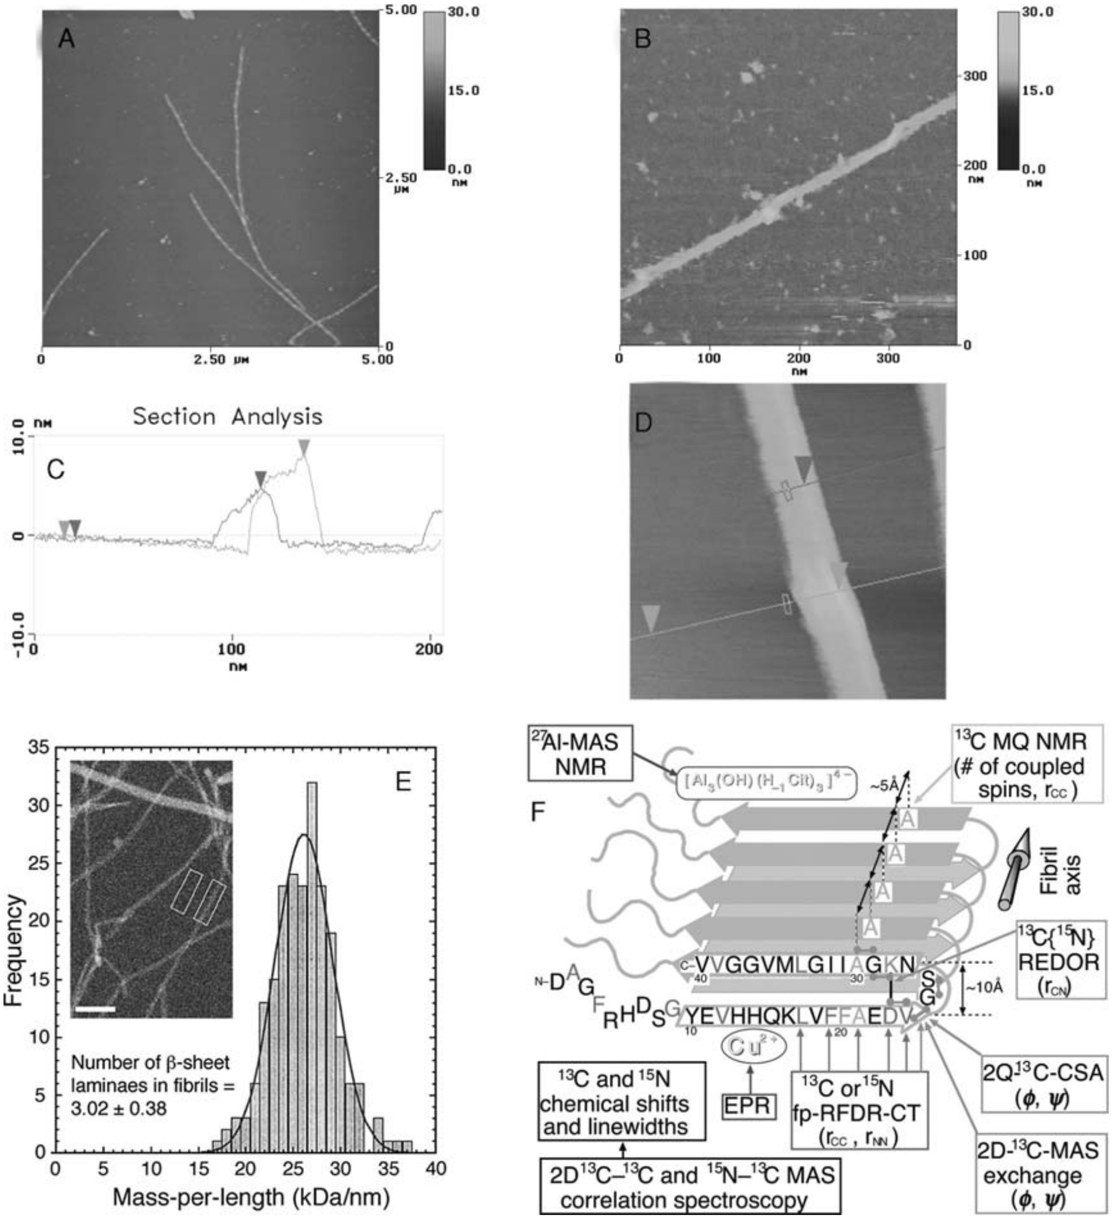

Fig. 1. (A–D) Tapping mode AFM images of A$\beta_{(1-40)}$ preparations on mica. A$\beta_{(1-40)}$ was incubated at 50 µM in TRIS buffer (10 mM TRIS, 0.5 mM EDTA, 10 mM KCl and 0.01wt% NaN_3, pH 7.4 adjusted with NaOH) in plastic tubes without additional agitation for 8 days. Images were obtained by M. Hellberg and N. Norlin (MSc thesis, Luleå University of Technology, 2003). Heights (C) can be readily measured across the fibril (D). (E) Mass-per-length of A$\beta_{(1-40)}$(R5G, Y10F, H13R), "rat"-sequence fibrils (incubated at pH 7.25 for 4 months without additional agitation) as determined by STEM. Fibrils appear as narrow structures of uniform intensity. Images were recorded at a dose of approximately 10^3 e/nm^2 and a pixel size of 1 nm. White boxes show typical regions from which the integrated signal in a 100 nm segment of fibril and background film were measured; the TMV was used as a calibrant (seen as wide fibrillar structures). Scale bar is 50 nm. Mass-per-length values of 215 individual fibril segments pooled into

(*Continued overleaf*)

(see Figure 1F) [21,59–61]. Recently, useful structural constraints on Alzheimer's amyloid fibrils were obtained from solid-state NMR and new structural models for A$\beta_{(10-35)}$ and A$\beta_{(1-40)}$ fibril polymorphs with either two or four β-sheet laminae have been developed [49,62]. The model for A$\beta_{(1-40)}$ fibrils was based on: (i) a few tens of distance and torsion angle constraints on singly and doubly ^{13}C-labeled Aβ-peptides aggregated in fibrils, obtained from specific novel solid-state NMR experiments, ^{13}C-MQ-NMR [63,64], CT-fp-RFDR [65,66], 2D-exchange-MAS [67–69], 2Q-CSA [69,70] (see Figure 1F); (ii) from about 180 ^{13}C and ^{15}N chemical shifts and line widths of resonance lines obtained from 2D correlation MAS NMR experiments on four A$\beta_{(1-40)}$ fibril samples with a small number (five, six, or seven) of selectively chosen and uniformly ^{13}C/^{15}N-labeled amino acid residues [28,62]; and (iii) from mass-per-length data for fibrils obtained from STEM [28,49].

For molecular structure determination local structural features of molecules can be elucidated by measuring either interspin distances or torsion angles in selectively ^{13}C- or ^{13}C/^{15}N- labeled parts of the peptide sequence. α-helix, β-sheet secondary structures can be estimated from chemical shifts and chemical shift anisotropies. Interspin distances can be measured using both homonuclear and heteronuclear dipole–dipole recoupling sequences, such as constant-time finite-pulse RFDR (fp-RFDR-CT) and REDOR, respectively, and using other analogous methods. Peptide torsion angles, ϕ and ψ can be measured, for example, by correlating ^{13}C chemical shift tensors of carbonyl carbons in $^{13}C_2$-labeled peptides (two consecutive amino acid residues) by means of either spin-diffusion (2D-^{13}C MAS exchange in Figure 1F) or by excitation of double-quantum coherences (2Q-^{13}C-CSA, see Figure 1F) or in combination with fp-RFDR-CT, which sets constraint on the interspin distance, r_{CC}, and, therefore, on the peptide angle ϕ. Structural domains of aggregated peptides and the geometry of spin clusters can be tested by "spin-counting" techniques, such as ^{13}C multiple-quantum NMR spectroscopy [63,71,72]. These methods are particularly useful for testing supramolecular organization of singly ^{13}C-labeled Aβ-peptides that form either parallel or antiparallel β-sheet secondary structures. For an in-register parallel β-sheet organization ^{13}C spins form an infinite "in-register" cluster of spins with interspin distance of ~5 Å that are coupled by the homonuclear dipole–dipole interaction of ca. 70 Hz (see pink labels in Figure 1F). In this particular situation a number of coherent spin states can be excited by a specific pulse sequence, and the highest order of the excited multiple-quantum coherence would be roughly the "count" of the number of coupled spins in the cluster.

The aforementioned solid-state NMR methods were used in obtaining structural constraints and developing structural models for Alzheimer's amyloid fibrils. The most important results are given below:

(i) Y_{10}EVHHQKLVFFAEDV$_{24}$ and A_{30}IIGLMVG-GVV$_{40}$ segments of A$\beta_{(1-40)}$ (fibrils prepared at pH 7.4) form *parallel* in-register β-sheets [64,66];

(ii) V_{24}GSNKGA$_{30}$ fragment of A$\beta_{(1-40)}$ forms a "loop" in fibrils since (ϕ, ψ) angles deviate considerably from those in β-sheet structures [62,69]. However, this is not a true β-hairpin structure, since hydrogen bonding between these amino acid residues is *intermolecular* rather than *intramolecular*. Therefore, a "loop" is a "fold" of the A$\beta_{(1-40)}$ laminate [62].

(iii) The D_1AEFRHDSG$_9$ segment is predominantly in a random coil conformation as was concluded from both ^{13}C chemical shifts and line widths of resonance lines in two-dimensional ^{13}C-^{13}C and ^{15}N-^{13}C MAS

Fig. 1. (*Continued*)
a histogram which was fitted with a single Gaussian curve to give an average mass-per-length of 26.15 kDa/nm with an s.d. of 3.29 kDa/nm. Images and the histogram were obtained from RD Leapman. (F) Putative model for a single A$\beta_{(1-40)}$ folded laminate with selective amino acid isotope labeling scheme shown in color (each label corresponds to a separate sample prepared for solid state NMR measurements): singly ^{13}C labeled carbonyl (*red F4, V12, L17, F20, V24, L34 and V39*) or methyl (*pink A2, A21 and A30*) sites in amino acid residues for ^{13}C fp-RFDR-CT (measurements of r_{cc} interspin intermolecular distances) or ^{13}C MQ NMR for elucidation of either a parallel or an antiparallel β-sheet supramolecular structures; ^{15}N labeled sites (*blue*) for frequency selective ^{13}C{^{15}N}-REDOR measurements of salt bridges (*black link D23-K28*) between the negatively charged side chain carboxylate carbon of Asp23 and the positively charged side chain amino nitrogen of Lys28 (uniformly ^{13}C and ^{15}N labeled amino acid residues); doubly ^{13}C labeled samples at carbonyl carbons of two consecutive amino acid residues (*orange links D23-V24, V24-G25, G25-S26, K28-G29 and G29-A30*) for ϕ and ψ peptide angle measurements using a combination of methods, 2Q-^{13}C-CSA, 2D-^{13}C-MAS exchange and ^{13}C fp-RFDR-CT NMR. ^{13}C and ^{15}N chemical shifts, line widths and sequential assignment were extracted from 2D ^{13}C-^{13}C and ^{15}N-^{13}C MAS NMR correlation spectra on A$\beta_{(1-40)}$ fibril samples with a few (five, six or seven) ^{15}N, ^{13} C uniformly labeled amino acid residues scattered across the peptide sequence. Binding of Cu^{+2} ions or Al-citrate complexes to A$\beta_{(1-40)}$ fibrils was tested by either Electron Paramagnetic Resonance or by ^{27}Al MAS NMR (after incubation, samples were dialyzed in 1 kDa cut-off dialysis tubes to remove unbound ions or complexes). (See also Plate 1 on page XVII in the Color Plate Section.)

correlation spectra of uniformly labeled amino acid residues scattered across the peptide sequence [62].

(iv) Two short fragments of Aβ, Ac-$A\beta_{(16-22)}$-NH_2 (Ac-K_{16}LVFFAE_{22}-NH_2) and $A\beta_{(11-25)}$ also form amyloid fibrils at pH 7.4. However, $A\beta_{(16-22)}$ or $A\beta_{(11-25)}$ molecules are organized in in-register *anti-parallel* β-sheets which are stabilized by electrostatic interactions (for example, Lys16 and Glu22) as well as by hydrophobic interactions between side-groups of amino acid residues in the central region of the peptide, LVFFA [68,73].

(v) Peptide molecules in $A\beta_{(1-42)}$-fibrils form *parallel* in-register β-sheets as concluded from ^{13}C fp-RFDR-CT and $^{13}C\{^{15}N\}$-REDOR measurements on a single sample of $A\beta_{(1-42)}$ ^{13}C-labeled in Ala21 ($^{13}CH_3$) and Leu34(^{13}CO) positions and ^{15}N-labeled in Val40 [49].

(vi) $A\beta_{(10-35)}$ (NH_2-Y_{10}EVHHQKLVFFAEDVGS-NKGAIIGLM_{35}-NH_2) fibrils also form a *parallel* in-register β-sheet structure as has been earlier suggested by Meredith, Lynn, and Botto on the basis of 2Q-DRAWS solid-state NMR measurements [55–58]. Our fp-RFDR-CT, REDOR, and ^{13}C-MQ NMR data have confirmed this conclusion [49]. However, we suggest that the $A\beta_{(10-35)}$ laminates are folded between V24 and A30 amino acid residues (similar to $A\beta_{(1-40)}$ fibrils) [49] instead of an extended β-sheet structure originally proposed by Lynn, Meredith, and co-workers [74]. The folded structure does not contradict with 2Q-DRAWS and other solid-state NMR measurements since molecules build two parallel in-register β-sheets, while it also fits well with fibril dimensions estimated from TEM and to STEM mass-per-length measurements consistent with only two or four laminates in fibrils prepared at pH 3.8 and 7.4, respectively [49].

It is important to note that the central, mostly hydrophobic, region of Alzheimer's amyloid peptides is of particular importance for the formation and stability of amyloid fibrils [75]. Therefore, it can be appreciated that all point mutations found so far in $A\beta_{(1-40)}$ which are associated with an early-onset of dementia are either at amino acid residues next to the central hydrophobic region of the peptide, LVFFA or those replacing negatively charged Glu22 or Asp23 residues on neutral (E22Q, D23N), hydrophobic (E22G), or positively charged (E22K) residues. All these mutations would change the net charge of the peptide, changing its solubility at neutral pH, make the "folding" region of the peptide molecule more flexible (as in the "Arctic" mutation, E22G) or enlarge the central hydrophobic region of the peptide, which will additionally stabilize β-sheet secondary structure in amyloid fibrils.

Figure 1F also shows that another NMR active isotope, such as ^{27}Al ($I = 5/2$, 100% natural abundance) can be useful in studies of binding of various biologically relevant soluble aluminum complexes (for example, aluminum citrate species, which may pass the brain-blood-barrier [76]) to Aβ-oligomers and fibrils. It is well known in biochemistry and medicine that aluminum ions are highly toxic. A link between aluminum and AD has been extensively discussed since beginning of the 1980s when high concentrations of aluminum were detected for the first time in Alzheimer's neurofibrillary tangles and later also in amyloid plaquies [77,78]. However, exact mechanism, binding sites for aluminum ions and Al complexes on Aβ-peptides and other important features of Al–Aβ-interaction are still unknown. For example, different Al-citrate complexes at low concentrations can either accelerate or retard the aggregation kinetics of $A\beta_{(1-40)}$ and also stabilize certain polymorphs of Aβ fibrils [79].

Binding of Cu(II) ions to $A\beta_{(1-28)}$, $A\beta_{(1-40),}$ and $A\beta_{(1-42)}$ molecules [80,81] has been studied by another magnetic resonance method, electron spin resonance (ESR). Due to its high sensitivity, ESR is a very useful method in studies of metal-ion binding to Aβ. The effects of metal ions on $A\beta_{(1-40)}$ aggregation are currently widely discussed after the observation of co-localization of high concentrations of Al(III), Zn(II), Cu(II), and Fe(III) at the center of the core of Alzheimer's amyloid plaques [82]. These metal ions accelerate Aβ aggregation kinetics, may stabilize amyloid fibrils and also increase neurotoxic effects of Aβ peptides [83,84]. It has been also suggested by Bush and co-workers that Cu(II) and Zn(II) may induce Aβ to form allosterically ordered oligomers that can penetrate lipid membranes [80]: Cu(II) ion initially coordinates His6, His13, His14, and Tyr10 in one Aβ molecule (see Figure 1F) but subsequently can coordinate two peptide molecules stabilizing a dimer and facilitating further aggregation of Aβ. Coordination of Cu(II) with His13 and His14 in two neighboring $A\beta_{(1-40)}$ molecules would facilitate propagation and stabilization of amyloid fibrils with in-register parallel β-sheet arrangement as found in all known polymorphs of $A\beta_{(1-40)}$ fibrils by recent solid state NMR measurements discussed above. Thus, studies of complexation of metal ions with Aβ are important in the search for the causes of and potential treatments for AD.

In order to answer the questions formulated in this article more efforts must be directed towards determining the structure of different polymorphs of Aβ-fibrils and oligomers, the effects of point mutations, metal ions, and metal complexes on the aggregation kinetics of Aβ-peptides, the search for potential inhibitors [85] and finally neurotoxicity tests on nerve cells cultures. Solid-state NMR has been already proven as a powerful tool in structural studies on other amyloidogenic peptides [86,87].

Chemical Shifts and Spin-Couplings

^{13}C, ^{15}N, ^{1}H, ^{2}H, and ^{17}O NMR Chemical Shift NMR for Hydrogen Bonds

Shigeki Kuroki
Department of Chemistry and Materials Science, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152-8552, Japan

Introduction

Hydrogen bonding plays an important role in forming higher-order structures of peptides, polypeptides and proteins. Accordingly, the nature of the hydrogen bond has been widely studied by various spectroscopic methods. High-resolution NMR spectroscopy has been used as one of the most powerful methods for obtaining useful information on the details of the hydrogen-bonded structure.

NMR chemical shifts are one of the most important parameters for providing information about molecular structure. Since the electronic structure around the carbonyl-carbon and oxygen, amide-nitrogen and hydrogen atoms in peptides and polypeptides is greatly affected by the nature of the hydrogen bond, the NMR chemical shifts for these atoms are sensitive to the spatial arrangement of the nuclei comprising the hydrogen bond. Also the electritic gradient (*eq*), which determined by the NMR spectrum of quadrupdan nucleus, is greatly affected by the electronic structure around the hydrogen bond.

Here, recent studies on the hydrogen-bonded structures of peptides and polypeptides in the solid state are presented through the observation of ^{13}C, ^{15}N, ^{1}H, ^{2}H, and ^{17}O NMR chemical shifts and theoretical calculations of nuclear shielding with a view to find a deeper understanding of the nature and inference of hydrogen bonds.

Hydrogen-bonded Structure and ^{13}C Chemical Shift [1–4]

Hydrogen-Bond Length and the ^{13}C Isotropic Chemical Shift (δ_{iso}) of the Carbonyl-Carbon in Several Amino Acids

At first, the relationship between the isotropic ^{13}C chemical shifts of carbonyl-carbons and the hydrogen-bonded structure is discussed. Figure 1 shows the plot of the observed isotropic ^{13}C chemical shifts (δ_{iso}) for the carbonyl-carbon in Gly, L-Ala, L-Val, D,L-Leu, and L-Asp residues in peptides against the $\mathrm{N}\cdots\mathrm{O}$ hydrogen-bond length($R_{\mathrm{N}\ldots\mathrm{O}}$). It is found that a decrease in $R_{\mathrm{N}\ldots\mathrm{O}}$ leads to a higher frequency shift, and there exists approximately a linear relationship between the ^{13}C chemical shift and $R_{\mathrm{N}\ldots\mathrm{O}}$. It is noted that not only in oligopeptides (dimer or trimer) but also in polypeptides, the carbonyl-carbon chemical shifts give a similar hydrogen-bond length dependence. This suggests that the ^{13}C chemical shifts of the carbonyl-carbon taking the hydrogen-bond, which is formed between the amide >C=O and amide >N–H, are predominantly determined by the hydrogen-bond length. The slope of this linear relationship is quite characteristic of individual amino acid residues.

Hydrogen-Bond Length and the Principal Values(δ_{11}, δ_{22} and δ_{33}) of the Carbonyl-Carbon

It is expected that the principal values of the ^{13}C chemical shift tensors (δ_{11}, δ_{22} and δ_{33}, from higher to lower frequency) are, in principle, more sensitive as parameters for obtaining detailed information on hydrogen-bonding to be related with electronic structure, than will the isotropic ^{13}C chemical shift ($\delta_{\mathrm{iso}} = (\delta_{11} + \delta_{22} + \delta_{33})/3$). It is well known that δ_{11} is in the amide sp^2 plane and lies along the direction normal to the C=O bond, the δ_{22} component lies almost along the amide C=O bond, and the δ_{33} component is aligned perpendicular to the amide sp^2 plane.

From the plots of the observed principal values of the ^{13}C chemical shift tensors such as δ_{11}, δ_{22} and δ_{33} for Gly, L-Ala, L-Val, D, L-Leu, and L-Asp residues in peptides against the $\mathrm{N}\cdots\mathrm{O}$ hydrogen-bond length ($R_{\mathrm{N}\ldots\mathrm{O}}$), it is found that the experimental δ_{22} values are the most sensitive to $R_{\mathrm{N}\ldots\mathrm{O}}$, and the δ_{22} values move linearly to high frequency with a decrease of $R_{\mathrm{N}\ldots\mathrm{O}}$. The δ_{22} component lies almost along the amide C=O bond, so the δ_{22} values are the most sensitive to a changing in $R_{\mathrm{N}\ldots\mathrm{O}}$. The slope and intercept of the variation of the plot ofδ_{22} against $R_{\mathrm{N}\ldots\mathrm{O}}$ varies depending on the amino acid residues. The δ_{11} and δ_{33} values are insensitive to a change in $R_{\mathrm{N}\ldots\mathrm{O}}$, but it seems that the δ_{11} and δ_{33} values move slightly to low and to high frequencies with a decrease in $R_{\mathrm{N}\ldots\mathrm{O}}$, respectively. Therefore, it can be said that the large high-frequency shift in δ_{iso}, with a decrease in $R_{\mathrm{N}\ldots\mathrm{O}}$, is predominantly governed by a decrease in δ_{22}. To understand the relationship between the ^{13}C chemical shifts and hydrogen-bond length, some theoretical MO calculations on the

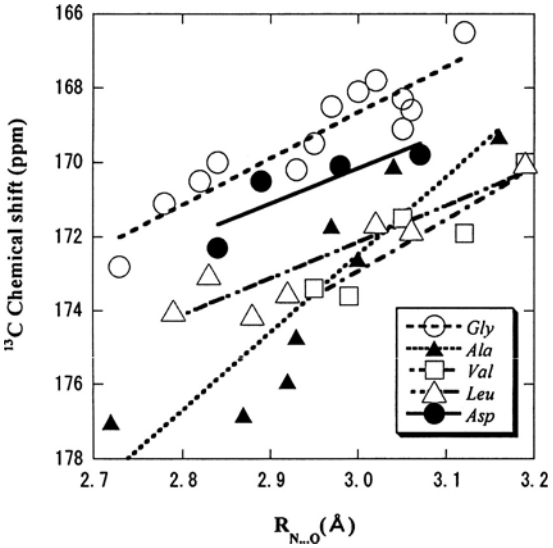

Fig. 1. Plots of the observed isotropic ^{13}C chemical shifts (δ_{iso}) for the carbonyl-carbon in Gly, L-Ala, L-Val, D, L-Leu, and L-Asp residues in peptides against the N *cdots* O hydrogen-bond length($R_{N...O}$).

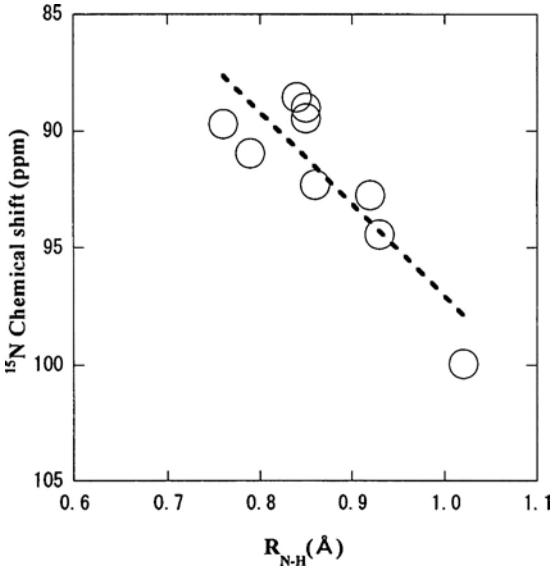

Fig. 2. Plot of the observed ^{15}N chemical shifts of the glycine residue in X-Gly-Gly against the N–H bond length (R_{N-H}) associated with a hydrogen bond.

^{13}C shielding tensors of model peptides have been carried out. From the calculations, it is found that δ_{22} is the most sensitive to a change of $R_{N...O}$ and moves linearly to high-frequency with a decrease in $R_{N...O}$. Correspondingly, δ_{11} increases with a decrease in $R_{N...O}$, whereas δ_{33} is insensitive to changes in $R_{N...O}$. The results of the theoretical calculations agree well with the experimental results. Such an agreement indicates that the ^{13}C chemical shift changes originate predominately from the change of the electronic state of the amino carbonyl groups caused by the hydrogen-bond length variation. Further, it can be said that the amino acid residue dependence of the calculated tensor components is similar to the experimental one.

Hydrogen-bonded Structure and ^{15}N NMR Chemical Shift

High-resolution ^{15}N NMR spectroscopy has been increasingly applied to the investigation of peptides, polypeptides and proteins in the solid state[5,6]. It is expected that a similar hydrogen-bond length dependence of the ^{13}C-carbonyl-carbon chemical shifts will aply to the amide nitrogen ^{15}N chemical shifts. But, there is no clear relationship between the observed ^{15}N chemical shifts of the Gly NH of peptides against the N$\cdots$O hydrogen-bond length ($R_{N...O}$).

The plot of the observed ^{15}N chemical shifts of the glycine residue in X-Gly-Gly against the N–H bond length (R_{N-H}) associated with a hydrogen bond is shown as in Figure 2. It is found that there is a clear relationship between these parameters and the decrease of R_{N-H} leads to a linear increase in shielding. Amide ^{15}N chemical shifts are closely related to the length of the N–H bond but are not related to $R_{N...O}$ distance. This implies that the ^{15}N chemical shift value gives useful information about the length of N–H bonds. It seems that the hydrogen bond angle ($\angle$N–H$\cdots$O) is also related to the ^{15}N chemical shift.

Theoretical calculations of ^{15}N chemical shift shows that a decrease of R_{N-H} leads to an increase of the calculated ^{15}N isotropic shielding which agrees with the experimental results. Therefore, such a relationship suggests that the isotropic ^{15}N chemical shift value can be used in the estimation of R_{N-H}. Combined with the carbonyl ^{13}C chemical shifts we can get very useful information about the hydrogen-bonded structure.

Hydrogen-bonded Structure and ^{1}H NMR Chemical Shift

The chemical shift of a ^{1}H nucleus has been widely applied to many works on the hydrogen bonding studies of peptides and proteins in the solution state.[7,8] However, in the solution state, the ^{1}H chemical shifts of peptides with rotational isomers are often the averaged values for all isomers because of rapid inversion by rotation about bonds and further are strongly influenced by solvent, pH, etc. Therefore, it is not easy to separate only the hydrogen-bonding effect on the ^{1}H chemical shift. In the solid state, chemical shifts provide information on fixed conformations and of hydrogen-bonded structures. But, in the solid state there are few studies on the high-resolution ^{1}H NMR of amide protons in peptides and polypeptides. One of the main reasons is the very large dipolar interaction of ^{1}H nuclei, which leads to a large broadening of the spectral line.

The problem is how to eliminate these dipolar interactions. The most popular method is combined rotational and multi-pulse spectroscopy (CRAMPS) with magic angle spinning (MAS).[9] One of the typical homo-nuclear dipolar decoupling sequence to be used in the CRAMPS experiments is br24. Although the conventional CRAMPS experiments have been made with a relatively low spinning rate of ∼3 kHz, this MAS rate is not always enough for the removal of dipolar couplings between protons and other nuclei. This is true for the amide proton of peptides and polypeptides bonded directly to the ^{14}N nucleus considered under here.

It is possible to eliminate this dipolar interaction between the amide ^{1}H bonded directly to the ^{14}N nucleus by high speed MAS such as 30 kHz and the observation at a high frequency such as 800 MHz. This procedure permits one to obtain, very high-resolution, ^{1}H spectra of peptides and polypeptides.

Figure 3 shows the observed amide proton chemical shifts plotted against the hydrogen-bond length between the amide nitrogen and oxygen atoms ($R_{N...O}$). It is shown that the ^{1}H chemical shift values move to high frequency with a decrease in $R_{N...O}$. This means that the observation of the amide proton ^{1}H chemical shift value leads to the determination of $R_{N...O}$. From neutron diffraction and *ab initio* MO studies it is shown that the reduction of $R_{N...O}$ leads to a decrease in the hydrogen-bond length ($R_{H...O}$) between the amide proton and the carbonyl oxygen. Thus, it can be said that the ^{1}H chemical shift values move to high frequency with a decrease in $R_{H...O}$.

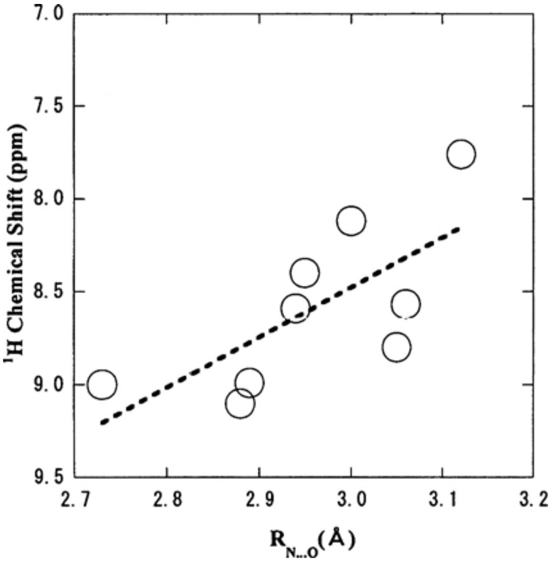

Fig. 3. Plot of the observed amide ^{1}H chemical shifts against the N · · · O hydrogen-bond length($R_{N...O}$).

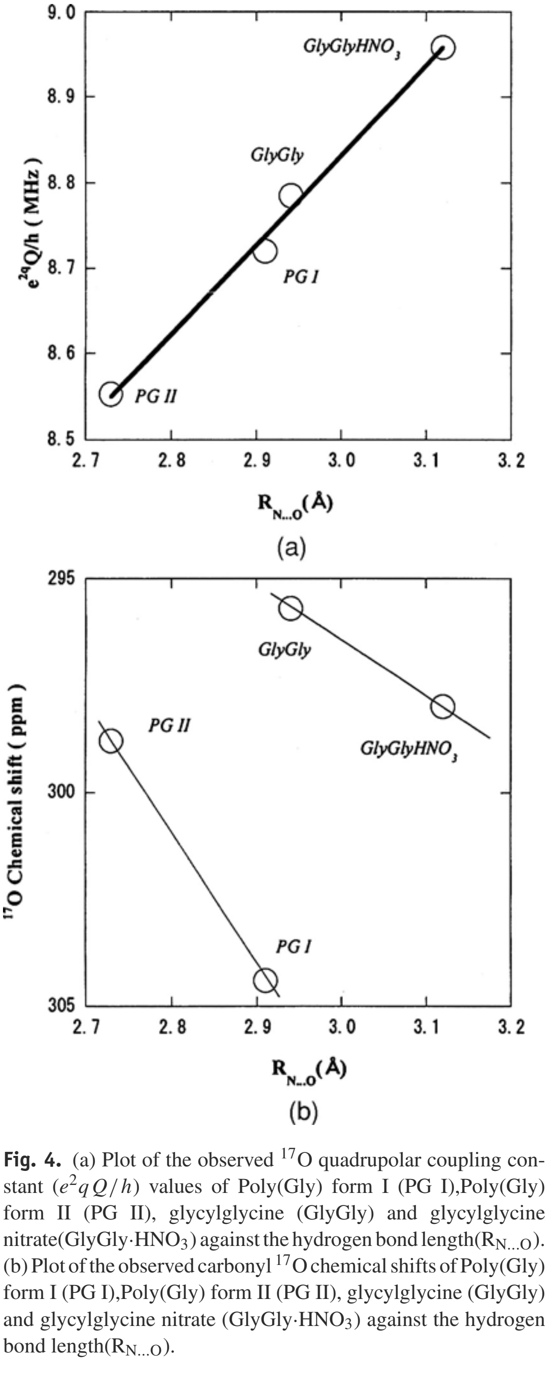
Hydrogen-bonded Structure and ^{17}O NMR Quadrupolar Coupling Constant and Chemical Shift[10−13]

The oxygen atom is also one of the most important one forming hydrogen-bonded structures in peptides and polypeptides. Nevertheless, solid-state ^{17}O NMR studies of peptides and polypeptides have not been carried out due to the very weak sensitivity of the solid-state ^{17}O NMR measurements which arises from the fact that the ^{17}O nucleus has a very low natural abundance of 0.037 %, and that the ^{17}O nuclear spin quantum number (I) is 5/2, thus the nucleus is quadrupolar, and the ^{17}O signal is broadened by nuclear quadrupolar effects in the solid. Solid-state ^{17}O NMR spectra of Poly(Gly) form I (PG I),Poly(Gly) form II (PG II), glycylglycine (GlyGly) and glycylglycine nitrate(GlyGly·HNO_3) are discussed with a view to understand the relationship between the hydrogen-bonded structure and the ^{17}O NMR parameters.

Figure 4(a) shows a plot of the observed quadrupolar coupling constant (e^2qQ/h) values against the hydrogen bond length ($R_{N...O}$). The e^2qQ/h values decrease linearly with a decrease of $R_{N...O}$ between the amide nitrogen and oxygen atoms. This change comes from a change of the q values which are the largest component of the electric gradient tensor. This experimental result shows that the decrease in the hydrogen bond length leads to a decrease in the electric field gradient. The q value seems to be very sensitive to the hydrogen-bonding length change. The results of theoretical MO calculations agree well with these experimental results.

Figure 4(b) shows the plot of the observed isotropic ^{17}O chemical shift (δ_{iso}) values against the hydrogen bond length ($R_{N...O}$). The isotropic ^{17}O chemical shift (δ_{iso}) values in both peptides and polypeptides move to low frequencies with a decrease in the hydrogen bond length ($R_{N...O}$). The difference of the chemical shifts between peptides and polypeptides comes from the geometrical location of the amide group and the carbonyl group which forms hydrogen-bonding. From the plots of the observed principal values (δ_{11}, δ_{22} and δ_{33}, from higher to lower



(a)

(b)

Fig. 4. (a) Plot of the observed ^{17}O quadrupolar coupling constant (e^2qQ/h) values of Poly(Gly) form I (PG I),Poly(Gly) form II (PG II), glycylglycine (GlyGly) and glycylglycine nitrate(GlyGly·HNO_3) against the hydrogen bond length($R_{N...O}$). (b) Plot of the observed carbonyl ^{17}O chemical shifts of Poly(Gly) form I (PG I),Poly(Gly) form II (PG II), glycylglycine (GlyGly) and glycylglycine nitrate (GlyGly·HNO_3) against the hydrogen bond length($R_{N...O}$).

frequency) of the ^{17}O chemical shifts against the hydrogen bond length ($R_{N...O}$), every principal value in both the peptides and polypeptides moves to low-frequency with a decrease in the hydrogen bond length ($R_{N...O}$). The hydrogen bond length dependence of the calculated isotropic chemical shielding (δ_{iso}) of the Gly carbonyl oxygen in the model molecule system shows that the ^{17}O chemical shift moves largely to low-frequency with an increase in $R_{N...O}$. This explains qualitatively the experimental trend as mentioned above.

Hydrogen-bonded Structure and ^{2}H Quadrupolar Coupling Constant[13]

The ^{2}H nucleus of an amide group in which ^{1}H is substituted by ^{2}H is one of the most important nuclei involved in a hydrogen-bonded structure in peptides and polypeptides.

In Figure 5, the plots of the observed e^2qQ/h values for ^{2}H against the hydrogen bond length ($R_{N...O}$) are shown. The e^2qQ/h value decreases with a decrease in $R_{N...O}$. The experimental result shows that the reduction of the hydrogen-bond length leads to a linear decrease in electritic field gradient (eq). The eq value is very sensitive to change in the hydrogen bond length. This experimental finding is consistent with the experimental results

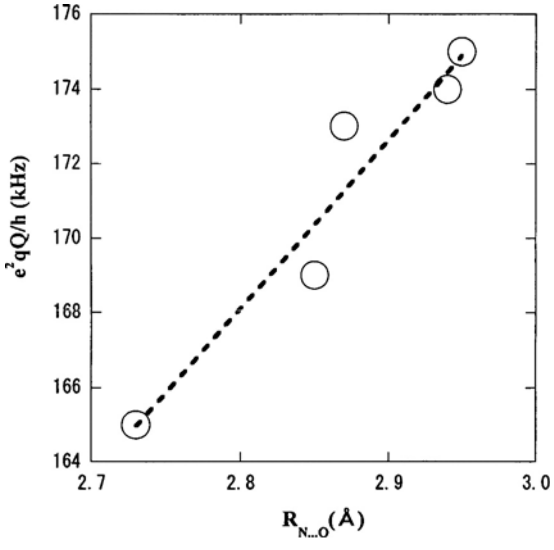


Fig. 5. Plots of the observed ^{2}H quadrupolar coupling constant e^2qQ/h values against the hydrogen bond length ($R_{N...O}$).

of the hydrogen-bonded amide ^{17}O nucleus of peptides and polypeptides and of other deuterium containing compounds. From this relationship, it is apparent that useful information about the hydrogen-bond length in peptides and polypeptides can be obtained by observation of the e^2qQ/h value.

Conclusion

As discussed, it is concluded that solid state ^{13}C, ^{15}N, ^{1}H, ^{2}H, and ^{17}O NMR spectroscopy combined with theoretical MO calculations is a very useful methodology for elucidating the hydrogen-bonded structures of peptides and polypeptides in the solid state.

NMR Chemical Shift Map

Isao Ando[1] and Tetsuo Asakura[2]
[1]Department of Chemistry and Materials Science, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152-0033, Japan; and
[2] Department of Biotechnology, Tokyo University of Agriculture and Technology, Koganei, Tokyo 184-8588, Japan

Most recently, the concept of an NMR chemical shift map has been used to characterize the conformation of synthetic polypeptides and the conformation of any specified amino acid residues of proteins. Here, we are concerned with the chemical shift map as established by a theoretical approach and experimental approach. The amino acid residues except for the proline amino acid residue have the freedom of internal rotation about the two consecutive bonds, NH–C_αHR and C_αHR–CO bonds, where R is the side chain. These torsional angles are defined by Φ and Ψ, respectively. It is very convenient to represent the chemical shift of the amino acid residue as a function of the torsional angles (Φ, Ψ), because the conformation-dependent chemical shift can be obtained and then the conformation can be determined through the chemical shift value. This is the so-called "chemical shift contour map" or "chemical shift map." This has similar significance to the Ramachandran map for the conformational energy of amino acid residues.

First, we are concerned with the theoretical approach for establishing the concept of an NMR chemical shift map. In the crystalline state polymer chains assume a fixed conformation. In this case, the structural information obtained from the chemical shift corresponds to the fixed conformation [1]. The calculation of ^{13}C chemical shifts for dipeptide fragments (N-acetyl-N′-methyl-L-alanine amide) [Ac-L-Ala-NHMe] of poly (L-alanine) and the L-alanine residue containing proteins has been attempted using the finite perturbation theory (FPT) method for chemical shift within the semi-empirical MO framework [2] in order to understand and predict the ^{13}C chemical shift behavior of polypeptides associated with the secondary structures such as the α-helix form, the β-sheet form, etc., and the determination of secondary structure through the observation of the ^{13}C chemical shift [1]. The observed ^{13}C chemical shifts of the C_β carbon of the L-Ala residue in various peptides and polypeptides vary significantly depending on the conformation, which may be the right-handed α-helix form, β-sheet form, or another form. Such sizeable displacements of the ^{13}C chemical shifts can be characterized by variations in the electronic structures of the local conformation as defined by the torsion angles (Φ, Ψ). The chemical shift maps for the C_β and C_α carbons have been made on the basis of the calculated data. From these maps, we can estimate semi-quantitatively the ^{13}C shielding for any specified conformation. This is a very useful representation of the chemical shift behavior resulting from changing the dihedral angles as in a Ramachandran energy map. It has been demonstrated from comparisons of the experimental data and the predicted values given by this chemical shift map that the map successfully predicts the ^{13}C chemical shifts of L-alanine residues in polypeptides and proteins [1–5].

More sophisticated *ab initio* calculations for the NMR chemical shifts have become available for medium-size molecules as a consequence of the remarkable advances in performance of workstations, personal computers, and supercomputers [3–5]. This leads to a quantitative discussion of the chemical shift behavior. From such a situation, the ^{13}C chemical shift map was made by *ab initio* MO calculations with the 4-31G basis set using the GIAO-CHF (gauge-independent atomic-orbital coupled Hartree–Fock) method on N-acetyl-N′-methyl-L-alanine amide as shown in Figure 1 [3], which is the same model molecule as used in the case of the above FPT calculations. All the geometrical parameters are energy-optimized. The isotropic ^{13}C chemical shift map of the C_β carbon as a function of the torsion angles was calculated as shown in Figure 1, where the positive sign indicates an increase in shielding and the calculated ^{13}C shielding of methane is 207.2 ppm and the observed ^{13}C chemical shift is −2.1 ppm relative to TMS. The overall trend of this map is similar to that obtained by the FPT method. The calculated isotropic shielding constant (σ) for the C_β carbon is 186.4 ppm for the torsion angles (Φ, Ψ), corresponding to the anti-parallel β (β_A)-sheet form, 189.4 ppm for the right-handed α(α_R)-helix form, 189.6 ppm for the left-handed α(α_L)-helix form as shown in Figure 1 (In Table 1 the calculated shieldings are converted to chemical shifts relative to TMS. Thus, the chemical shift values for the β_A-sheet form, the α_R-helix form, and the α_L-helix form become 18.74, 15.72, and 15.4 ppm, respectively.). On the other hand, the observed isotropic chemical shifts (δ) are 21.0 ppm for the β_A-sheet form, 15.5 ppm for the α_R-helix form, and 15.9 ppm for the α_L-helix form (Table 2). Such an experimental chemical shift behavior is well explained

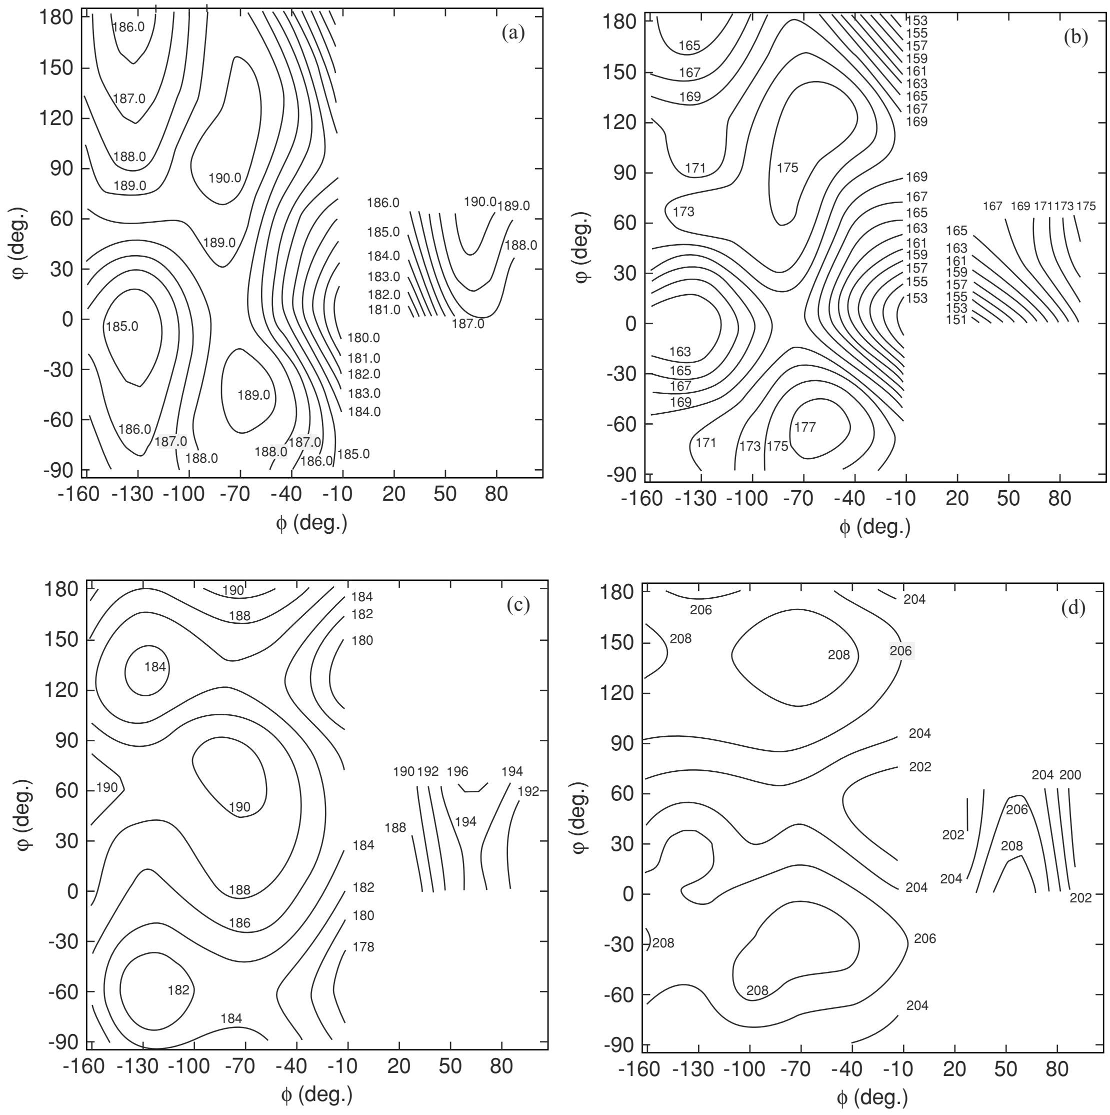

Fig. 1. The calculated ^{13}C chemical shift map of the C$_\beta$ and carbons of N-acetyl-N′-methyl-L-alanine amide by using the GIAO-CHF method with 4-31G *ab initio* MO basis sets. The 4-31G optimized geometries for the peptide were employed. (a) isotropic; (b) σ_{11}; (c) σ_{22} and (d) σ_{33} for the C$_\beta$ carbon(in ppm), and (e) isotropic; (f) σ_{11}; (g) σ_{22} and (h) σ_{33} for the C$_\alpha$ carbon(in ppm).

by the calculated behavior. It is found that the change of the torsion angle dominates the isotropic chemical shift behavior of the L-alanine residue C$_\beta$ carbon.

The principal values of the chemical shift tensor give information about the three dimensional electronic state of a molecule. However, in order to understand the behavior of the principal values, one should obtain information about the orientation of the principal axis system of the chemical shift tensor with respect to the molecular fixed frame. The orientations of the principal axis systems of the chemical shift tensors of the L-alanine C$_\beta$-carbons in some peptides can be theoretically determined [4], whose L-alanine moieties have different main chain torsion angles, $(\Phi, \Psi) = (-57.4°, -47.5°)$ [α_R-helix form],

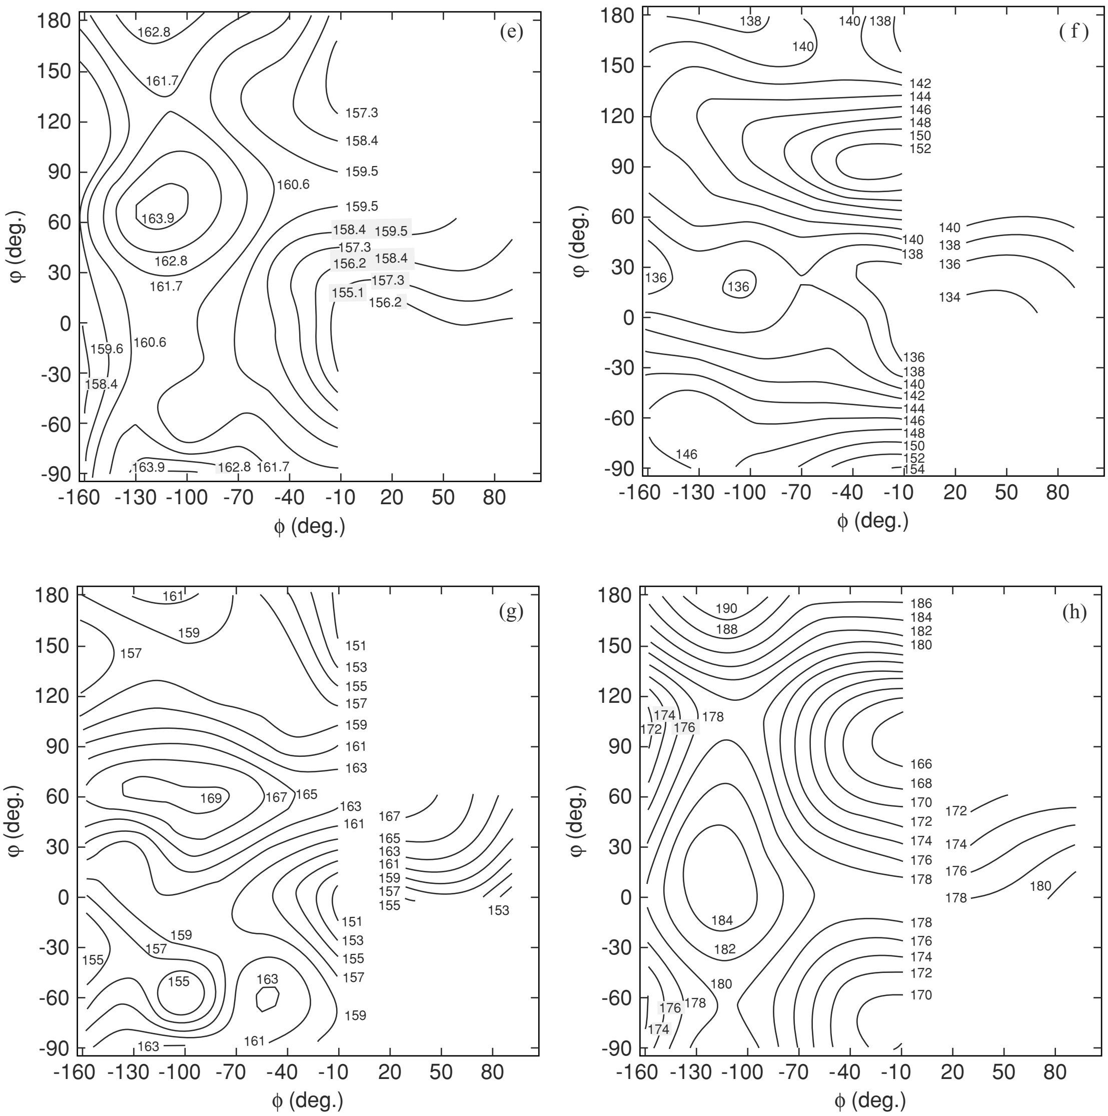

Fig. 1. (*Continued*)

(−138.8°, 134.7°) [β_A-sheet form], (−66.3°, −24.1°) [$3_{10}{}^{R}$-helix form], and (−84.3°, 159.0°) [3_1-helix form]. The σ_{33} component nearly lies along the $C_\alpha - C_\beta$ bond for all the peptides considered here, and also the σ_{11} is nearly perpendicular to the plane defined by the C_β, the C_α, and the N atoms in the L-alanine residue; on the other hand, σ_{22} is parallel to the plane. These results agree with the experimentally determined direction of σ_{33} of the C_β carbon in L-Ala amino acid by Naito *et al.* [7]. The σ_{11} component for the dihedral angles corresponding to the β_A-sheet form is 37.06 ppm. This shows a high frequency shift of about 9 ppm with respect to that for the α_R-helix form. This result means that the σ_{11} dominates the high frequency shift on the isotropic chemical shift of the C_β carbon for the β_A-sheet form. Since the σ_{11} value does not orient along a specified chemical bond, it is not easy to comprehend intuitively the chemical shift tensor behavior of the C_β carbon. However, it is obvious that the

through-space interaction between the C_β methyl group and its surroundings might be important for understanding the σ_{11} behavior.

For all the torsion angles employed in the calculations, the σ_{33} component of the chemical shift tensor of the L-alanine C_α-carbons always lies along the C_α–C′ bond. However, for the α_R-helix, the 3_{10}^{R}-helix, and the 3_1-helix forms, the σ_{11} component lies in a slightly deviated direction from the C_α–C_β bond: and for the β_A-sheet form, the σ_{11} component is along this direction. The tensor component which is nearly along the C_α–C_β bond is 47.53 ppm for the β_A-sheet form, 61.93 ppm for the α_R-helix form, 64.74 ppm for the 3_{10}^{R}-helix form, and 65.79 ppm for the 3_1-helix form. The change of the dihedral angles causes the large deviation of the chemical shift tensor component which is along the C_α–C_β bond. Moreover, since σ_{33} depends on changes from one torsion angle to another, it is obvious that there exists the explicit torsion angle dependence on σ_{33}. It is thought that if the carbonyl group in the L-Ala residue forms a hydrogen bond, σ_{33} will be probably affected [6].

Next, we are concerned about the preparation of isotropic NMR chemical shift maps for the C_α and C_β carbons in proteins from an empirical database [8]. It seems to be important to assemble a larger database of ^{13}C shifts in proteins of known structure, to enable us to study the effect of protein conformation and sequence on C_α and C_β chemical shifts experimentally. The database which contains 3,796 $^{13}C_\alpha$ and 2,794 $^{13}C_\beta$ chemical shifts from 40 different proteins are used for the preparation of the chemical shift maps. All the proteins have high-resolution crystal structures, and NMR studies have indicated that the

*With the α^R-helix conformation.
†With the β_A-helix conformation.

solution conformation of the protein is essentially identical to that in the crystal. There is no systematic effect of temperature, reference compound, or pH on the reported shifts, but there appear to be differences in the reported shifts arising from referencing differences of up to 4.2 ppm. The major factor affecting chemical shifts is the backbone geometry, which causes differences of *ca.* 4 ppm between typical α-helix and β-sheet geometries for C_α, and of *ca.* 2 ppm for C_β. The side chain dihedral angle χ_1 has an effect of up to 0.5 ppm on the C_α shift, particularly for amino acids with branched side chains at C_β. Hydrogen bonding to main chain atoms has an effect of up to 0.9 ppm, which depends on the main chain conformation. The sequence of the protein and ring-current shifts from aromatic rings has an insignificant effect (except for residues following proline). There are significant differences between different amino acid types in the backbone geometry dependence; the amino acids can be grouped together into five different groups with different (Φ, Ψ) shielding surfaces. The overall fit of individual residues to a single non-residue-specific surface, incorporating the effects of hydrogen bonding and χ_1 angle, is 0.96 ppm for both C_α and C_β.

As examples, the chemical shift maps prepared for the C_α and C_β carbons of Ala residues are shown in Figure 2a and b, respectively, as functions of the torsion angles (Φ, Ψ) [9]. Here only the regions $(-180^\circ < \Phi < 0^\circ, -180^\circ < \Psi < 180^\circ)$ are shown. Data are only shown for areas with enough data points to give reliable chemical shift predictions, in which the density function is greater than 1. There is a clear conformation dependence in the chemical shifts, for example, the chemical shift in the

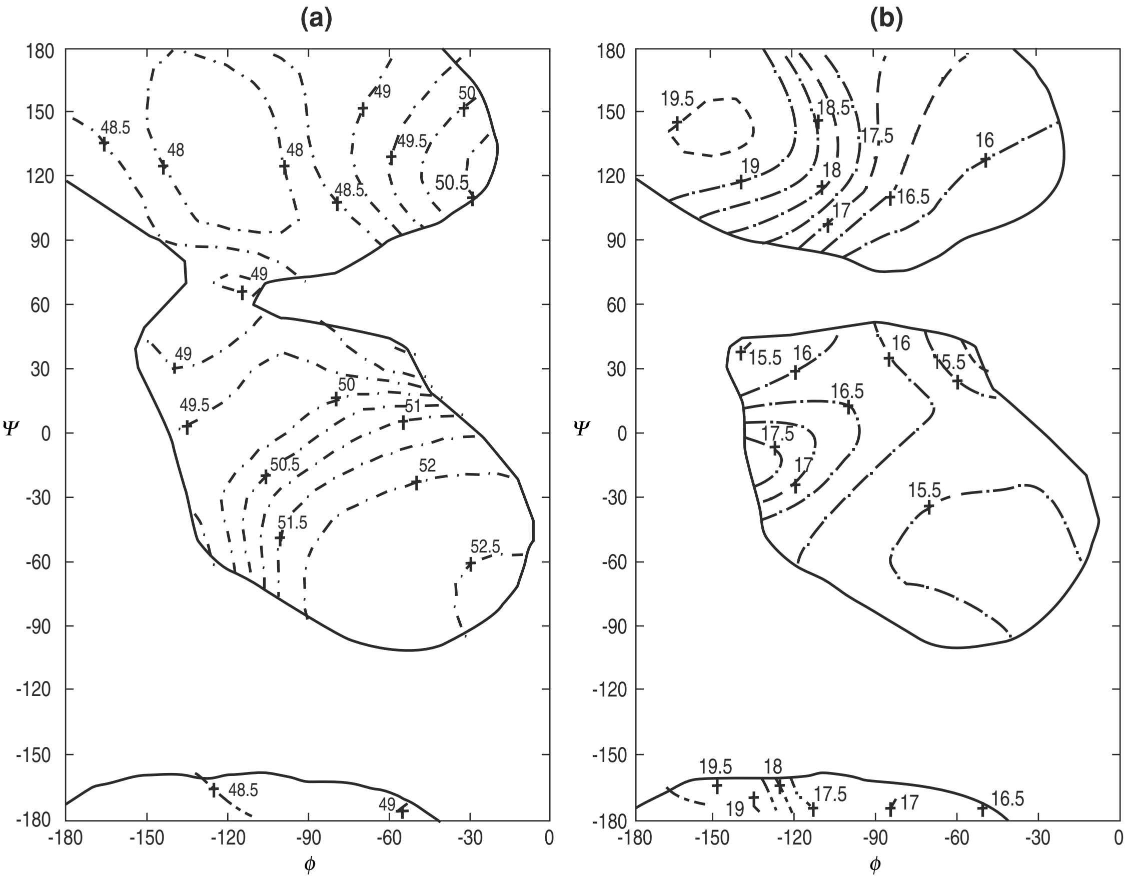

Fig. 2. Contour plots of the conformation-dependent chemical shifts (in ppm) of C_α(a) and C_β(b) carbons of Ala residues in 40 proteins. Chemical shift values in the region $(-180^\circ < \Phi < 0^\circ, -180^\circ < \Psi < 180^\circ)$ are shown, where the density function is more than 1. Random coil chemical shifts are 50.0 ppm for Ala C_α carbon and 16.6 ppm for Ala C_β carbon.

α-helix region is predicted at lower frequency for C_α than the chemical shift in the β-sheet region, but at higher frequency for the C_β. These chemical shift maps in turn will help to guide efforts in protein structure refinement using ^{13}C chemical shifts.

Introduction

Nuclear shielding offers microscopic information about the stereochemical and crystal structures of polymers which in turn are important factors in understanding physical properties. Details of electronic structure can also be deduced from nuclear shielding data, and this is also important in controlling physical properties [1]. In order to obtain the information about the electronic structure of polymers from nuclear shielding, it is necessary to use a theoretical approach in addition to an experimental one.

In general, there are two possibilities to obtain such information by theoretical methods. One is to use a fragment of a polymer such as a dimer, trimer, etc. for theoretical calculations. Such an approach is useful because the nuclear shielding is sometimes governed by the local electronic structure. However, there is doubt whether the electronic structure obtained from the model compound appropriately reproduces that of the polymer chain. Another approach is to employ directly an infinite polymer chain with periodic structure. This leads to the application of the tight-binding (TB) molecular orbital approximation, which was developed in the field of solid-state physics [2]. Its advantages are that it treats the polymer directly and that relatively long-range interactions such as hydrogen bonding in the α-helix form of the polypeptide may be included.

In using the model compound approach, the electronic structure of large chains can be visualized by drawing the orbital energies associated with chains of increasing length. On the other hand, for an infinite polymer chain, the energy levels are built up as a continuous band structure. As rotation about the bond is strongly restricted in solid polymers, the periodicity of a polymer chain is retained. From the point of view of calculating nuclear shielding, use of the TB model for the calculation of the electronic structure of polymers has been successful. Herein we described the basic ideas for deducing the electronic structure and the nuclear shielding of solid polymers by the TB approximation.

Theoretical Aspects of Electronic State and Nuclear Shielding in Solid Polymers

Polymers can be characterized by a possible periodicity in their conformational structure and a large number of electrons. In this system, the potential energy that an electron experiences is periodic. Periodic systems have the advantage of translational symmetry when compared with aperiodic systems. It is possible to exploit this symmetry in order to reduce to reasonable proportions the formidable task of computing the electronic states of an extended system. The TB molecular orbital model is employed to describe the electronic structure of linear periodic polymers within the framework of a "linear combination of atomic orbitals" approximation for electronic eigenfunctions. By means of Bloch's theory [3], the eigenfunction $\Phi_n(k)$ for an electron at position r, belonging to the nth crystal orbital is given by

$$\Phi_n(k) = N^{-(1/2)} \sum_{j=-(N-1)/2}^{(N-1)/2} \sum_{\nu=1}^{s} e^{ijkb} C_{\nu n}(k) \phi_\nu(r - jb) \qquad (1)$$

where k is the wave number, ν is an orbital index for the jth cell, s is the total number of atomic orbitals in a given cell, N is the total number of cells considered, and b is the unit vector of translational symmetry. In equation (1), $\phi_\nu(r - jb)$ represents the ν atomic orbital in the jth cell and $C_{\nu n}$ (k) its expansion coefficient in the linear combination of atomic orbitals. The limits of k, within a given Brillouin zone, are $-\pi/2$ and $\pi/2$. Using Equation (1), the total energy E of the polymer can be expressed as

$$E(k) = \sum_{n}^{\mathrm{occ}} \left\langle \Psi_n(k) \left| \hat{H} \right| \Psi_n(k) \right\rangle \qquad (2)$$

where $\Psi_n(k)$ is the Slater determinant composed of $\Phi_n(k)$. $\hat{H}$ is the Hamiltonian, consisting of terms representing the kinetic energy, the potential energy of the electronic field

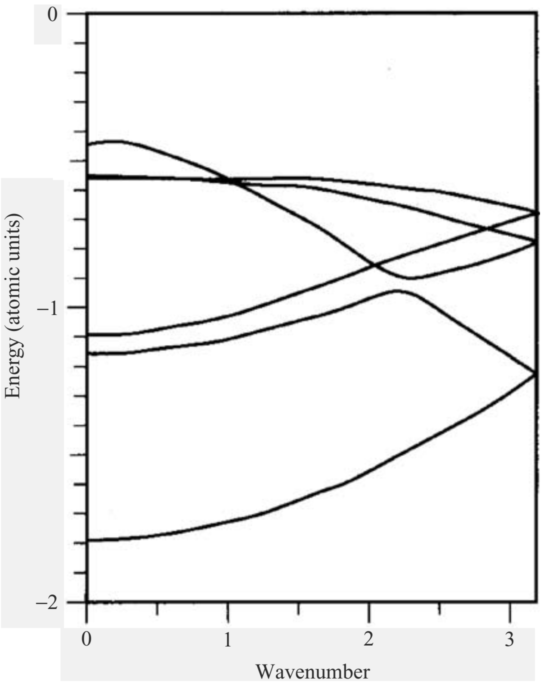

Fig. 1. Electronic band structure of polyethylene with trans zigzag conformation calculated using CNDO/2 TB MO.

of the polymer, and the electron repulsion energy. The advantage of Equation (1) is that calculation of the electronic structure of an infinite polymer can be reduced to the calculation for a unit cell (monomer unit) interacting with all other unit cells, using the periodicity of the polymer.

By solving the Fock matrix, the expansion coefficients in Equation (1) can be obtained. These expansion coefficients and energies are dependent on k, which leads to a band structure for a polymer chain. Figure 1 shows the calculated band structure of polyethylene with a trans zigzag conformation.

As only six valence electrons in a monomer unit cell are included in the calculation, the corresponding six valence bands can be seen in Figure 1. Calculations with model compounds give discrete energy levels. In a series of homogeneous molecules, the number of energy levels increases with the molecular size, and correspondingly the separation between these energy levels decreases. For an infinite polymer chains, the energy level is the continuous band structure as shown in Figure 1. The electronic structure of solid polymers is characterized by this band structure, with a dependence of energy level on k.

The nuclear shielding for the various nuclei in a given macromolecule can be calculated from the obtained electronic band structure, $C_{\nu n}(k)$ and $E_n(k)$. In general, a nuclear shielding can be written as [1]

$$\sigma = \sigma^{\mathrm{d}} + \sigma^{\mathrm{p}} + \sigma' \tag{3}$$

where σ^{d} and σ^{p} are the diamagnetic and paramagnetic contributions, respectively, σ' is the contribution from neighboring atoms. For a carbon atom, σ' is much smaller than 1 ppm and can be considered to be negligible. Thus, σ can be estimated by the sum of σ^{d} and σ^{p}. Based on the TB MO theory, $\sigma^{\mathrm{d}}$and σ^{p} are obtained by a sum-over-states (SOS) method as follows [4–6]:

$$\sigma^{\mathrm{d}}_{\mathrm{A}}(k) = \frac{\mu_0 e^2}{6\pi m_{\mathrm{e}}^2} \sum_{\nu}^{\mathrm{A}} \sum_{\nu'}^{\mathrm{A}} P_{\nu\nu'}(k) \left\langle \phi_\nu(r) \left| r^{-1} \right| \phi'_\nu(r) \right\rangle \tag{4}$$

$$\begin{aligned}\sigma^{\mathrm{p}}_{\mathrm{A},\alpha\beta}(k) = {} & \frac{-\mu_0 h^2 e^2}{4\pi m_{\mathrm{e}}^2} \sum_{m}^{\mathrm{occ}} \sum_{n}^{\mathrm{unocc}} \sum_{j}^{\mathrm{A}} \langle r^{-3} \rangle_{2\mathrm{p}} \left({}^1E_m^n - {}^1E_0 \right)^{-1} \\ & \times \sum_{j}^{\mathrm{B}} \sum_{l}^{\mathrm{B}} [X(j, m, n, \beta, \gamma) X(l, n, m, \gamma, \alpha) \\ & - Y(j, m, n, \beta, \gamma) Y(l, n, m, \gamma, \alpha) \\ & + X(j, m, n, \gamma, \alpha) X(l, n, m, \beta, \gamma) \\ & - Y(j, m, n, \gamma, \alpha) Y(l, n, m, \beta, \gamma)]\end{aligned} \tag{5}$$

Here e is the charge and m_{e} the mass of the electron, μ_0 is the permeability of free space,

$$P_{\nu\nu'}(k) = \sum_{m}^{\mathrm{occ}} C^*_{\nu m}(k) C_{\nu' m}(k) \tag{6}$$

where m refers to the number of occupied crystal orbitals and n to those that are unoccupied, E_0 is the electronic energy of the ground state and E_m^n is the energy of the state created by promoting an electron from orbital m to orbital n. j and l are atomic orbitals on centers A and B, respectively, and

$$\begin{aligned} X(j, m, n, \beta, \gamma) = {} & C^{\mathrm{R}\beta}_{jm} C^{\mathrm{I}\gamma}_{jn} + C^{\mathrm{R}\beta}_{jn} C^{\mathrm{I}\gamma}_{jm} \\ & - C^{\mathrm{R}\gamma}_{jn} C^{\mathrm{I}\beta}_{jm} - C^{\mathrm{R}\gamma}_{jm} C^{\mathrm{I}\beta}_{jn} \end{aligned} \tag{7}$$

$$\begin{aligned} Y(j, m, n, \beta, \gamma) = {} & C^{\mathrm{R}\beta}_{jm} C^{\mathrm{R}\gamma}_{jn} - C^{\mathrm{R}\gamma}_{jm} C^{\mathrm{R}\beta}_{jn} \\ & + C^{\mathrm{I}\beta}_{jm} C^{\mathrm{I}\gamma}_{jn} - C^{\mathrm{I}\gamma}_{jm} C^{\mathrm{I}\beta}_{jn} \end{aligned} \tag{8}$$

where α, β, and γ refer to the x, y, and z components of the shielding tensor in cyclic order and R and I indicate the real and imaginary parts of the coefficients

$C_{vn}(k)$. As shown by Equations (4) and (5), the nuclear shielding is calculated as a function of k. In order to be able to compare the calculated and experimental values of the nuclear shielding, it is necessary to average the calculated data over k, within the first Brillouin zone, as given by

$$\sigma = \int_{-(\pi/b)}^{\pi/b} \sigma(k) D(k) dk \tag{9}$$

where $D(k)$ is the density of state, namely the number of states per unit amount of energy. Thus, the nuclear shielding can be obtained through the electronic band structure of a polymer, especially a solid polymer.

The quantities calculated using Equations (4) and (5) are the nuclear shielding, σ, and so the negative sign means deshielding. On the other hand, a negative sign of the observed chemical shift, δ, means an increase in shielding. Hereinafter, calculated and observed data are expressed as the nuclear shielding and chemical shift, respectively. The absolute value of the calculated shielding should be compared directly with the observed chemical shift.

Furthermore, the formalism for calculating the NMR shieldings of infinite polymer chains with a three-dimensional (3D) periodicity in the crystalline state by *ab initio* TB MO theory has been developed [7]. For the calculations on a 3D system, the program code CRYSTALS88 [8,9] which is available for a crystal orbital calculation of 3D systems was used for calculating the electronic states and a program for calculating the shielding constant[4,5,10,11] using the SOS method was added to CRYSTAL88.

Interpretation of Nuclear Shielding by the TB Method

^{13}C shielding reflects the magnetic environment of the atom considered, and this depends on the conformation, configuration, and crystal structure in the case of polymers. In order to understand ^{13}C shielding, examples illustrating the applications of TB MO methods to some polymers will be described.

Conformation

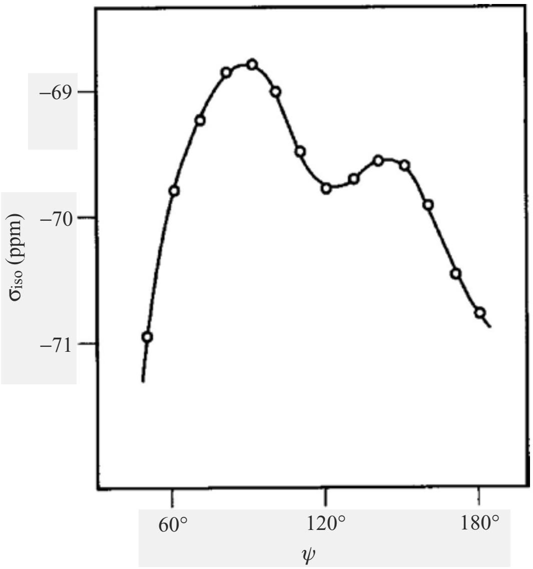

Fig. 2. Dependence of the calculated ^{13}C NMR shielding of polyoxymethylene on dihedral angle ψ.

It is known from an X-ray diffraction study that a polyoxymethylene chain in the crystalline region takes an all-gauche conformation with a 9/5 helix [12]. However, in the non-crystalline region the structure is not yet determined exactly, because of the complicated conformation of the chain. It has been reported that the observed ^{13}C chemical shifts of polyoxymethylene in the crystalline and non-crystalline regions appear at 88.5 and 89.5 ppm, respectively [13]. Figure 2 shows the dependence of the calculated isotropic ^{13}C shielding on the dihedral angles (ψ) within the framework of the CNDO/2 TB MO method.

The isotropic ^{13}C shielding increases as ψ is increased from 50° to 90°, and the shielding decreases through a minimum value as ψ is increased from 90° to 180°. The values of 60° and 180°, for ψ correspond to the all-gauche and all-trans conformations, respectively. The calculated isotropic ^{13}C shielding of the all-gauche conformation appears at lower frequency by about 1 ppm than that of the all-trans conformation. Dividing the difference of ^{13}C shielding between the all-gauche and all-trans conformations, for the diamagnetic term, the difference between the all-gauche and all-trans conformations is 0.1 ppm, and for the paramagnetic term the corresponding difference is 0.9 ppm. Thus, the contribution to the relative ^{13}C shielding is due mainly to a change in the paramagnetic term. The diamagnetic term is determined only by the ground state, whereas the paramagnetic term involves interactions between the ground and excited states, as seen from Equations(4) and (5). Thus, the observed chemical shift difference between the crystalline and non-crystalline regions comes from a variable interaction due to a conformational change. Therefore, it can be argued that the calculated value confirms well the experimental finding that the ^{13}C shielding for the crystalline region is greater by about 1 ppm than that for the non-crystalline region.

Calculated results of $\Delta\sigma (= \sigma_{yy} - \sigma_{zz}$; spectrum breadth) for the all-gauche and all-trans conformations are 37.7 and 1.8 ppm, respectively. $\Delta\sigma$ for the all-gauche conformation is much larger than that for the all-trans conformation. On the other hand, the experimental values of $\Delta\delta$ for the crystalline and non-crystalline regions are about 35 and 7–10 ppm, respectively [13]. The calculated and experimental values agree relatively well with each other. The fact that the calculated value of $\Delta\sigma$ for the all-trans conformation is rather small suggests that the electronic environment around the carbon nucleus considered here is relatively symmetric. The small value of $\Delta\delta$ may be due mainly to the high symmetry of the electronic environment in addition to the averaging of the ^{13}C shielding anisotropy by molecular motion. Further, we are concerned with the behavior of δ_{22}, whose value is obtained from the apex of the tent-like powder pattern. In the experimental data, δ_{22} for the crystalline region appears at about 5 ppm to low frequency when compared with that for the non-crystalline region. However, the calculated value of σ_{xx} for the all-gauche conformation appears at lower frequency by about 2.5 ppm when compared with that for the all-trans conformation. Thus the calculation explains the experimental observation reasonably, despite the rough assumption of an all-trans conformation for the non-crystalline region.

Table 1 shows the calculated and observed ^{13}C shieldings of a polyglycine chain with forms I and II [14]. The observed carbonyl ^{13}C signal for form I is shielded by about 4 ppm compared with that for form II. The calculated ^{13}C shielding for form I is larger by about 11 ppm than that for form II, which matches the experimental finding. There is no significant difference between the methylene ^{13}C chemical shifts for forms I and II within experimental error. At this stage, it cannot be determined whether the methylene shielding for form I or that for form II is the larger. The calculated shielding of ^{13}C for form I is smaller by about 3 ppm than that for II, so the calculation predicts the existence of a shielding difference (about 3 ppm) between forms I and II. It appears that the calculated shieldings are somewhat exaggerated compared with the observed values. Nevertheless, the observed trend that the ^{13}C chemical shift difference for the methylene carbon is very small when compared with that for the carbonyl carbon is reproduced qualitatively by the calculation.

†The negative sign means deshielding.

Configuration

Polyacetylene (PA) is the simplest conjugated polyene and has two configurations (cis and trans). It is reported that the ^{13}C shielding of *cis*-PA appears at a lower frequency by about 10 ppm than that of *trans*-PA [15]. Calculations of the ^{13}C shielding of PAs are carried out based on the use of CNDO/2 TB MO and INDO/S TB MO methods. The differences in the isotropic ^{13}C shielding between the *cis*- and *trans*-PAs, calculated by the CNDO/2 and INDO/S TB MO methods, are about 2.0 and 3.5 ppm, respectively [16], i.e. the results differ by a factor of about 2. As the observed difference is about 10 ppm, both types of calculation somewhat underestimate the real value in this case.

Figure 3 shows the observed [17] and calculated components of the ^{13}C shielding tensors of *cis*- and *trans*-PAs. As is seen, the absolute values of Φ_{zz} and Φ_{xx} calculated using the INDO/S TB MO method are smaller by about 40 ppm than those obtained by the CNDO/2 TB MO method. The value of σ_{yy} calculated by the INDO/S TB MO method is larger by about 10 ppm than that obtained using CNDO/2 TB MO procedure. Consequently, the separation between the values of σ_{xx} and σ_{yy} calculated using the INDO/S TB MO is much larger than that obtained by CNDO/2 TB MO's. Further, it is shown that in going from the calculation using CNDO/2 method to that using INDO/S the values of σ_{zz} and σ_{xx} are changed considerably. The most remarkable difference is in the estimation of the π–π overlap integral. The values of σ_{zz} and σ_{xx} are affected by the distribution of π electrons.

The electronic band structures of a PA consist of five valence bands within the framework of the semiempirical methods. The highest occupied band has π symmetry. Comparing the electronic band structures calculated by CNDO/2 TB MO with that of INDO/S TB MO, the energies of the three high-energy bands increase, in particular that of the highest occupied band. As can be seen from Equation (3), σ^{p} contains a term proportional to the inverse of the excitation energy. The increase in the energies of the three high-energy bands is one of the factors leading to the deshielding of σ_{zz} and σ_{xx}, which implies a lower excitation energy. In fact, the band gaps (the energy difference between the highest occupied and the lowest

unoccupied bands) for *trans*-PA, calculated using the CNDO/2 and INDO/S TB MO methods, are about 8.0 and 4.2 eV, respectively. The observed band gap for *trans*-PA is about 1.9 eV. Thus, the description of the contributions of these high energy bands to σ_{xx} and σ_{zz} is remarkably improved in going from the CNDO/2 to the INDO/S TB MO procedure.

It is clear from Figure 3 that the reason why the calculated difference in isotropic shielding of ^{13}C between the *cis*- and *trans*-PAs is underestimated is that the difference in σ_{yy} cannot be reasonably reproduced. In order to reproduce more reasonably the observed difference in σ_{yy} between the *cis*- and *trans*-PAs, it may be necessary to use MOs that can properly describe band structures that have σ symmetry.

Polypyrrole is one of a series of heterocyclic polymers that has attracted much attention because of its characteristic electric and electronic properties. Fundamental structural formulae have been proposed for undoped and doped polypyrroles, where the aromatic form

Table 2: Calculated ^{15}N shieldings and band gaps for aromatic and quinoid polypyrrole models using INDO/S TB MO

Structure	Calculated shielding σ_{iso}(ppm)	Band gap (eV)
Aromatic	−223.50	5.12
Quinoid	−232.21	2.86

corresponds to the undoped state and the quinoid form to the doped state. From analysis of the high-resolution solid-state ^{15}N NMR, it is known that the ^{15}N chemical shift for the quinoid form appears to high frequency of that for the aromatic form. In order to obtain information about the ^{15}N chemical shift, and electronic band structures of an infinite polypyrrole chain with aromatic or quinoid forms, calculations were carried out using the INDO/S TB MO's [18].

As listed in Table 2, the calculated shielding of ^{15}N for the quinoid form appears to high frequency compared with that for the aromatic form. The calculated results agree with the observed ones, suggesting that the electronic band structure has been properly estimated. From the calculated electronic band structure, the band gaps for the aromatic and quinoid forms are 5.1 and 2.9 eV, respectively. This result implies that the electrical conductivity of the quinoid form is larger than that of the aromatic form. Therefore, it can be expected that if the amount of the quinoid form is increased, polypyrrole with a higher electric conductivity can be obtained.

Crystal Structure

The crystal structure in the solid state, which describes how molecules condense, is an important factor when discussing physical properties. The effect of crystal structure on the nuclear shielding in principle, can be separated from the effect of conformation and configuration within the limitation of a given quantum chemical method.

Experimentally, it is reported that the ^{13}C chemical shifts of the CH_2 carbon for the n-paraffins, cyclic paraffins, and polyethylene with a trans zigzag conformation in the orthorhombic and triclinic forms are about 33 and 34 ppm, respectively [19,20]. As the conformation is the same in each case, the difference of about 1 ppm may be due to a local change in intermolecular interactions resulting from the change of the orthorhombic to the triclinic form. Paraffins can be considered as models for the crystallographic form of polyethylene. The result of X-ray diffraction studies suggests that the trans zigzag plane of any specified chain in the orthorhombic and triclinic forms is, respectively, perpendicular and parallel to those of the neighboring chains. The ^{13}C chemical shift of polyethylene with a monoclinic form appears at higher frequency by 1.4 ppm compared with that of polyethylene with the orthorhombic form. The orientation of the trans zigzag plane in the monoclinic form is very close to that in the triclinic form [21]. Thus, the solid-state ^{13}C NMR chemical shift depends on the orientation of the C–C–C plane in trans zigzag chains.

Since the chains lie periodically in the solid state, calculations of the chemical shifts should be employed that take account of the 3D structure, including interactions between chains. In order to take into account interchain interaction, a "seven-polyethylene-chains model" has been used to compute the ^{13}C shielding [10]. Figure 4 shows models for polyethylenes with an orthorhombic form and a monoclinic form. The setting angle ψ for the orthorhombic polyethylene is not clearly determined. Figure 5 shows the ψ dependence of difference in shielding of the ^{13}C between orthorhombic and monoclinic polyethylenes ($\sigma_{\text{orth}} - \sigma_{\text{mono}}$) calculated using the INDO/S TB MO method.

As can be seen, the calculated difference in the shielding of the ^{13}C between these forms is positive in the case of $\psi = 25°–42°$, and negative in the case of $\psi = 20°–25°$ and $\psi = 42°–55°$. The largest difference occurs at $\psi = 35°$. From these results, the angle of $\psi = 25°–42°$ is good for the setting angle of orthorhombic polyethylene, and can reasonably reproduce the observed data. This result shows that the difference in chemical shift between the orthorhombic and monoclinic forms is caused by the difference in interchain interactions through the electronic band structure.

In order to elucidate the intermolecular interaction effect on the NMR chemical shift of PA crystal, the 3D *ab initio* TB MO calculations were carried out [22]. Before going to the 3D PA crystal, it is significant to employ a single PA chain, because the intermolecular interaction effect on the electronic structure and NMR chemical shift behavior is clear. In Table 3, the total energy per monomer unit and NMR chemical shielding for a single *cis*- and *trans*-PA chain are shown as calculated by using the *ab initio* TB MO method within the framework of the STO-3G minimal basis set. It is shown that, the total energy per monomer unit for *trans*-PA is lower by 0.0069 a.u. than that for *cis*-PA. This means that the trans-form is more stable than the cis-form. The tendency of the calculated results qualitatively explains the experimental results that, undoped trans-PA is thermally more stable than *cis*-PA. Experimentally, the ^{13}C chemical shift for the cis-form appears at a lower frequency by 10 ppm than that of the trans-form [17]. On the other hand, the calculation shows that the ^{13}C chemical shift of

the cis-form appears at a slightly lower frequency by 0.1 ppm than that of the trans-form. Comparing with the experimental results, the chemical shift difference between the cis- and trans-forms, is very small. This means that, the single chain model is insufficient to reasonably explain the experimental results. Therefore, it can be said that the interchain interactions should be taken into account by the 3D polymer crystal. The electronic structures and NMR chemical shieldings of the 3D infinite *cis*- and *trans*-PA chains with orthorhombic crystallographic form were calculated using the *ab initio* TB MO method within the framework of the STO-3G minimal basis set. The total energies per monomer unit and chemical shieldings, along with the experimental chemical shift values are listed in Table 3. The total energy per monomer unit for the trans-form is lower by 0.0024 a.u. than that for the cis-form. The trans-form is thus more stable than the cis-form. This explains reasonably the experimental thermal stability of the trans-form in the PA crystal over the cis-form.

As seen from Table 3, the ^{13}C chemical shift for the cis-form in a the PA crystal appears at a lower frequency by 1.0 ppm than that for the trans-form, calculated using the experimental lattice parameters (Case A). The calculated results approach the experimental ones more closely, compared to the single chain model. This shows that the intermolecular interaction plays an important role towards the ^{13}C chemical shift behavior. What is the ^{13}C chemical shift behavior if the intermolecular interaction is increased in the 3D PA crystal model? When the lattice

Table 3: Total energies, band gaps, and NMR chemical shieldings for a single chain of *cis*- and *trans*-polyacetylenes and for a 3D crystal of *cis*- and *trans*-polyacetylenes as calculated by *ab initio* TB MO method within the framework of STO-3G minimal basis set

	A single chain		Three-dimensional crystal			
				^{13}C chemical shielding[‡] (ppm)		
Polyacetylene form	Total energy[†] (a.u.)	^{13}C chemical shielding[‡] (ppm)	Total energy[†] (a.u.)	Case A[§]	Case B[§]	Experimental ^{13}C chemical shift[*] δ (ppm)
Cis-form	−75.9368	−121.6	−75.9430	−117.7	−114.7	127.3

		Δ[¶] = 0.1		Δ[¶] = 1.0	4.5	

[*] Relative to TMS. The positive sign means deshielding. This is opposite to the calculation.

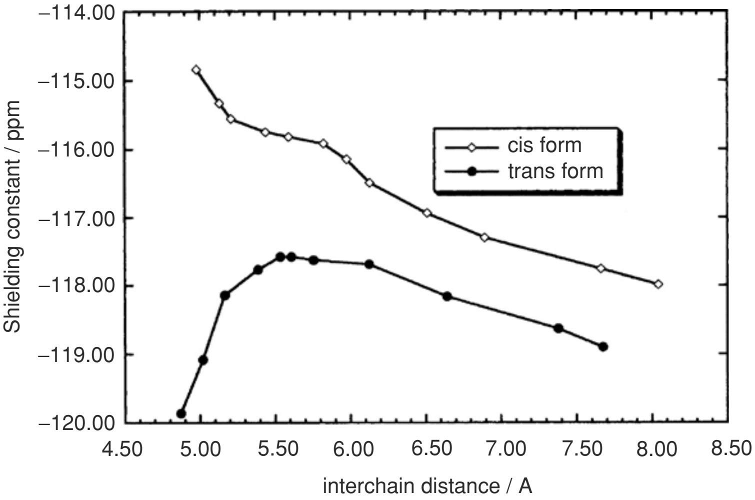
[†] Per monomer unit.

[‡] The calculated ^{13}C chemical shielding indicates that the negative sign means deshielding.

[§] *Case A*: by using experimental lattice parameters and *Case B*: using reduced interchain distance (reduce lattice parameter $b = 5.0$ A. This means that the reduced interchain distance leads to increase intermolecular interaction).

[¶] Chemical shift difference between cis- and trans-forms.

Fig. 6. The plots of the ^{13}C chemical shieldings for a 3D crystal of *cis*- and *trans*-PAs, as calculated by the *ab initio* TB MO method within the framework of STO-3G minimal basis set against the length of the lattice parameter *a*.



parameter *a* is reduced to 5 A(this means an increase in the intermolecular interaction) (Case B), the ^{13}C chemical shift difference between the cis- and trans-forms becomes 4.5 ppm. This approaches the experimental results more closely.

Therefore, in order to clarify the interchain distance effect of the ^{13}C chemical shift for the cis- and trans-forms, their ^{13}C chemical shieldings were calculated, with a change in the length of the lattice parameter *a* using the *ab initio* TB MO method, within the framework of the STO-3G minimal basis set. The calculated chemical shieldings are plotted against the length of the lattice parameter *a* as shown in Figure 6. It is seen that the ^{13}C chemical shift for the cis-form moves slowly to low frequency, as the length of the lattice parameter *a* decreases from 8 to 5 A, that is, the intermolecular interaction increases. On the other hand, for the trans-form, the ^{13}C chemical shift, moves slowly to low frequency, as the length of the lattice parameter *a* decreases from 7.7 to 5.6 A, and moves largely to high frequency as the length of the lattice parameter *a* decreases from 5.6 to 4.9 A. With a decrease in the length of the lattice parameter *a* below 5.5 A, the chemical shift difference becomes large and quantitatively approaches the experimental result. As predicted from Figure 6, the calculated chemical shift difference becomes 10 ppm (the experimental value) when the length of the lattice parameter *a* is about 4.7 A. The calculation with a shorter length of the lattice parameter *a* agrees with the experimental result. This may come from the approximations implied with the low level MO minimal basis set such as STO-3G, which is used in the calculation. If a higher level minimal basis set is used, the situation may be modified. Nevertheless, it can be said that the present calculation explains well the experiment, and the chemical shift is very sensitive to intermolecular interactions. This means that the ^{13}C chemical shift is a very sensitive measure for use in investigating intermolecular interactions in a polymer crystal.

Modeling NMR Chemical Shifts

Julio C. Facelli
Center for High Performance Computing, University of Utah, Salt Lake City, UT 84112-0190, USA

Abstract

This article presents a discussion of the origin of the chemical shieldings, which is followed by a discussion on how they are calculated using state-of-the-art electronic structure methods. Several examples of quantum chemical calculations of chemical shieldings in common nuclei are presented to provide the reader with a general overview of the reliability of these calculations. The shortcomings of the current methods are finally discussed.

Introduction

Perhaps the most important discovery after the successful detection of the NMR signal has been the observation that the nuclear spin resonance frequencies depend on the chemical or electronic environment of the nuclei [1,2], or as Norman Ramsey states in his landmark papers [3,4] of 1950: "In measurements of nuclear magnetic moments, a correction must be made for the magnetic field arising from the motions of the molecular electrons which are induced by the externally applied field." Ramsey realized that corrections using only Lamb's diamagnetic theory were inadequate for molecules because there are additional shielding contributions arising from the second-order paramagnetism. To address this problem, he developed the necessary theoretical framework to explain and eventually to calculate the "chemical effect," that would become the chemical shift commonly used in our days for structural elucidation. The calculation of chemical shieldings has been a challenge to theoreticians and computational chemists for more than 50 years. Great impetus for this theoretical and modeling work has been provided by the extraordinary sensitivity of the chemical shielding to electronic and molecular structure and environment which can only be unraveled by computational modeling.

It should be noted that the chemical shieldings are tensor properties, i.e. the shift of the resonance frequency depends on the molecular orientation with respect to the external magnetic field, but the brevity of this article precludes any discussion of the tensor properties of the chemical shieldings [5]. In this chapter, as customary in the literature, we will refer to the isotropic component of the chemical shielding tensor as the chemical shielding.

There is considerable confusion in the literature about the use of the terms "chemical shift" and "chemical shielding." The chemical shielding is the tensor that describes the relative change in the local magnetic field at the nucleus position relative to the external magnetic field. This change in the local magnetic field, which is originated in the interaction of the electron cloud with the external magnetic field, can produce shielding or de-shielding of the nucleus. In the first case, the local magnetic field is increased with respect to the external field, while in the second case the local field is decreased. In general, shielding effects are associated with diamagnetic effects from spherical charge distributions, while de-shielding effects are associated with the nonspherical charge distribution originating from *p* or higher angular momentum electrons. When experiments are performed at a constant magnetic field, as it is normally done in modern NMR spectrometers, a shielding effect results on a shift of the resonance to a higher frequency, while a de-shielding effect will result in a lower resonance frequency. In practice, NMR experiments do not measure the chemical shielding directly, instead the common practice is to measure the chemical shifts as the change of resonance frequency of a nucleus relative to a given standard. Moreover, for historic reasons it is customary to reverse the frequency scale, i.e. nuclei more shielded than the standard are considered to have lower chemical shifts and those less shielded larger ones. The formal relation between the chemical shift and chemical shielding tensors is given by

$$\boldsymbol{\delta} = \mathbf{1}\sigma_{\text{iso}} - \boldsymbol{\sigma}. \tag{1}$$

where $\boldsymbol{\delta}$ is the chemical shift tensor, $\boldsymbol{\sigma}$ is the chemical shielding tensor, $\mathbf{1}$ is the unit matrix and σ_{iso} is the isotropic value or trace of the chemical shielding of the standard reference used in the NMR experiments. The determination of the value of σ_{iso}, usually known as absolute chemical shift, is quite difficult. It involves the estimation of the paramagnetic contribution to the chemical shielding in the center of mass of the molecule using its relationship with the spin rotational constant and the calculation of the corresponding diamagnetic part using quantum mechanical methods. The procedure for selecting primary and secondary reference compounds has been extensively discussed by Mason [6].

Graham A. Webb (ed.), Modern Magnetic Resonance, 53–62.

The material presented in this chapter is restricted to the chemical shifts and shielding calculations in diamagnetic molecules. When the molecular electronic ground state is not a singlet, i.e. there are unpaired electrons present in the sample, additional mechanisms contributing to the chemical shielding are present [7].

Theory of the Chemical Shieldings

The theory and modeling of the chemical shifts have been described in numerous publications [8–36]. To obtain exact expressions for the calculation of chemical shieldings using the non-relativistic Born–Oppenheimer approximation [37], it is necessary to include the vector potential representing the external magnetic field and the dipolar field from the magnetic moment of the nucleus into the electronic Hamiltonian. In the gauge of Coulomb, the final expressions for the diamagnetic and paramagnetic contributions are given by

$$\sigma^{d}_{\alpha\beta}(\mathrm{O}) = \frac{1}{2c^2}\left\langle \psi_0 \left| \left(r_k r_{Nk} \delta_{\alpha\beta} - r_{k_\alpha} r_{Nk_\beta} \right) r_{Nk}^{-3} \right| \psi_0 \right\rangle, \tag{2}$$

$$\begin{aligned} \sigma^{p}_{\alpha\beta}(\mathrm{O}) = \frac{-1}{2c^2} \sum_n \frac{1}{E_n - E_0} \left\langle \psi_0 \left| L_{k_\alpha} \right| \psi_n \right\rangle \\ \times \left\langle \psi_n \left| L_{Nk_\beta} r_{Nk}^{-3} \right| \psi_0 \right\rangle + C.C. \end{aligned} \tag{3}$$

Following the derivation in reference [11], we have indicated explicitly that Eqs. [2] and [3] are valid when the origin of the vector potential is at the position O. The sum in Eq. [3] is over all the exited states of the molecule. It is important to understand the behavior of the diamagnetic, Eq. [2], and paramagnetic, Eq. [3], terms under a translation of the origin of coordinates. Both terms exhibit an explicit dependence on the origin of coordinates used in the calculations, but as demonstrated elsewhere for exact and variational wave functions in a complete space, these dependences cancel each other making the total chemical shielding independent of the origin of coordinates. Unfortunately, this is not true for a finite expansion of the wave function. Serious complications arise in chemical shielding calculations as a consequence of the imperfect cancelation of origin-dependent terms in the diamagnetic and paramagnetic components.

Several methods have been proposed to mitigate the gauge problem and to make the results formally gauge invariant for incomplete basis sets and hopefully to produce better results when using moderate size basis sets. The most common approach is to use London or Gauge Invariant (or including) Atomic Orbitals or GIAOs in the atomic expansion of the molecular orbitals [17,20,21]. Other popular methods are individual gauge for localized orbitals (IGLO) [30,31,38], localized orbitals local origin (LORG) [39,40], individual gauges for atoms in molecules (IGAIM) [41], and continuous gauge transformation (CSGT) [42]. While the methods mentioned above take different approaches to mitigate the gauge problem, all of them are exact and converge to the same chemical shielding values in the limit of very large basis [33]. Of course, the converged values are identical to those obtained with the common origin method when the same extended basis is used in the calculations. But what is more important for practical applications is that these methods produce better results when using somehow modest basis sets.

Modeling Chemical Shieldings

The calculation of the diamagnetic part, Eq. [2], presents no serious complications and can be evaluated for any kind of wave function or electronic density. This calculation requires only the computation of one electron integrals of the type 1/r, $1/r^3$, and xy/r^3, which are readily available for almost any approximation used to calculate the electron density in most quantum chemical codes. The more complex paramagnetic term, Eq. [3], requires, in principle, the knowledge of all the exited electronic states of the molecule, in which case direct evaluation of Eq. [3] would be immediate. Unfortunately, this is not the case and a great deal of effort is necessary to obtain reliable values of the paramagnetic contribution. It is always important, if possible, to calculate the paramagnetic contribution with the same accuracy as the diamagnetic contribution to achieve the greatest possible gauge invariance of the numerical results. Unfortunately, this may increase the computational complexity beyond practical limits, therefore making the evaluation of the paramagnetic contribution the limiting factor in the calculations of chemical shieldings.

Today, there are two major approaches to the calculation of the paramagnetic component of the shielding, which are based on the two predominant types of electronic structure methods in use. Those based in the Hartree–Fock theory and its systematic improvements using perturbation methods to include the electronic correlation [37], which we will label "traditional *ab initio* methods" and those based on the Density Functional Theory (DFT) [43]. The reader is referred to the recent reviews by Gauss and Stanton [44] and by Wilson [45] for up-to-date comprehensive reviews of these two complementary methodologies. The first approach is preferred because it provides a systematic path to improve the calculated results, but this systematic improvement arrives with a considerable increase in the computational cost of the calculations. Therefore, in practice these highly precise calculations of chemical shieldings using traditional *ab initio* methods are restricted to small molecules of relative minor interest to practitioner chemists. In the fourth column of Table 1, we present a compilation of the best

Table 1: Comparison of the calculated chemical shieldings using the KT1, KT2, and KT3 exchange-correlation functionals with those from other electronic structure methods. The calculations were performed using the experimental geometries of the compounds. Data from references [46–49] in ppm, referenced to the bare nucleus (i.e. absolute shieldings).

calculations available using traditional *ab initio* methods for a representative set of small molecules with shieldings spanning over 1500 ppm. The agreement between theory and experiment is quite impressive; the observed standard deviation of 11.3 ppm corresponds to a relative error of 0.7%. Also, it is remarkable that the slope of the correlation is almost exactly one, indicating that for this level of calculation there is no need for any *ad hoc* scaling of the calculated results. For medium size and large molecules, the computational limitations of the traditional *ab initio* methods make those based on DFT, with their relatively low computational cost and increasingly improved performance, highly competitive. As a result, DFT methods have become the dominant approach for modeling chemical shieldings for medium-to-large molecules. While DFT does not provide a systematic way to improve the results, recently introduced exchange-correlation functionals designed to reproduce chemical shifts (KT1, KT2, and KT3) [46–49] are able to provide results that are quite comparable to those from the best electronic structure calculations. An example of these results is given in Table 1 and Figure 1, where the KT*n* results are compared with the

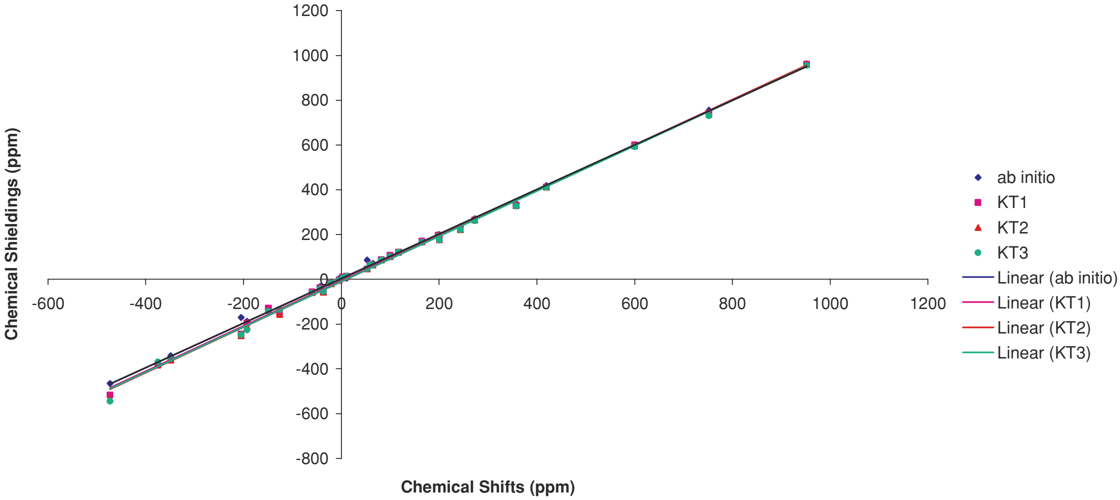

Fig. 1. Comparison of the linear correlation between calculated and experimental chemical shieldings for DFT calculations using the KT1, KT2, and KT3 exchange-correlation functional with those from the best traditional *ab inito* electron correlated calculations. All calculations were performed using the experimental structures of the molecules. Data from references [46–49].

best traditional *ab inito* (electron correlated calculations), Hartree–Fock and DFT calculations using the LDA (local density approximation) [43] and the hybrid B3LYP [50] exchange-correlation functional. In this set of small molecules, the performance of the KT*n* functionals is quite impressive. While not achieving the level of the best *ab inito,* electron correlated calculation, the KT*n* results show relative errors of only 1.1–0.9% compared with 2% for B3LYP, 2.4% for LDA, and 3.5% for the Hartree–Fock calculations. It should be noted that the scaling of the KT*n* results is only a 1% correction in the slope of the correlation, while this correction is 5% for B3LYP, 9% for LDA, and 4% for Hartree–Fock.

While the results presented above demonstrate that the KT*n* exchange-correlation functionals outperform most other DFT methods in this set of small molecules, there have not been calculations, using these functionals, reported for larger molecules. In the following, we provide a general overview of the quality of results that can be obtained routinely when using the popular B3LYP [50], MPW1PW91 [51], and OLYP [52] exchange-correlation functionals for shielding calculations in medium size organic molecules from the G2 and G3 standard sets [53,54]. The calculations were done with the popular Gaussian system for molecular modeling [55], using the GIAO [56], CSGT [42], and IGAIM [41] approaches to enforce the gauge invariance and the Dunning's d95** basis sets [57]. In all cases, the calculations were performed using the optimized (mp2(full)/6-31g*) geometries that are available for the molecules in the G2 and G3 data sets (http://chemistry.anl.gov/compmat/comptherm.htm). From the molecules selected for the shielding calculations, we have included for the analysis presented here 244 ^{1}H chemical shieldings, 133 ^{13}C chemical shieldings, 18 ^{15}N chemical shieldings, and 26 ^{17}O chemical shieldings.

Figures 2–5 and Tables 2–5 depict the correlation between the calculated and their corresponding experimental chemical shifts. In the tables the slope, intercept, and standard deviation of the linear fits are given. Deviations of the values of the slopes from the ideal value of –1 (except for ^{15}N where it is one) provide an estimate of the systematic errors in the calculations that are usually attributed to the deficiencies in the way that the electron correlation is taken into account. In general, the values of the intercept are less informative because it is widely accepted that there are large uncertainties in determining absolute shieldings of reference compounds. Finally, for practical applications it is important to use the standard deviation to estimate the relative accuracy of the calculations, which gives an indication on how successful the method is in discriminating the resonances of nuclei with similar chemical environments.

The methods considered here are able to predict the ^{1}H chemical shifts with relative accuracies of 2–3%. The slopes, that vary from 10% (GIAO) to 20% (IGAIM and CSGT), are independent of the exchange-correlation functional used. For ^{13}C the results also are quite satisfactory, providing relative accuracies of 1.4–1.9% and slopes different than -1 by less than 6%. A more

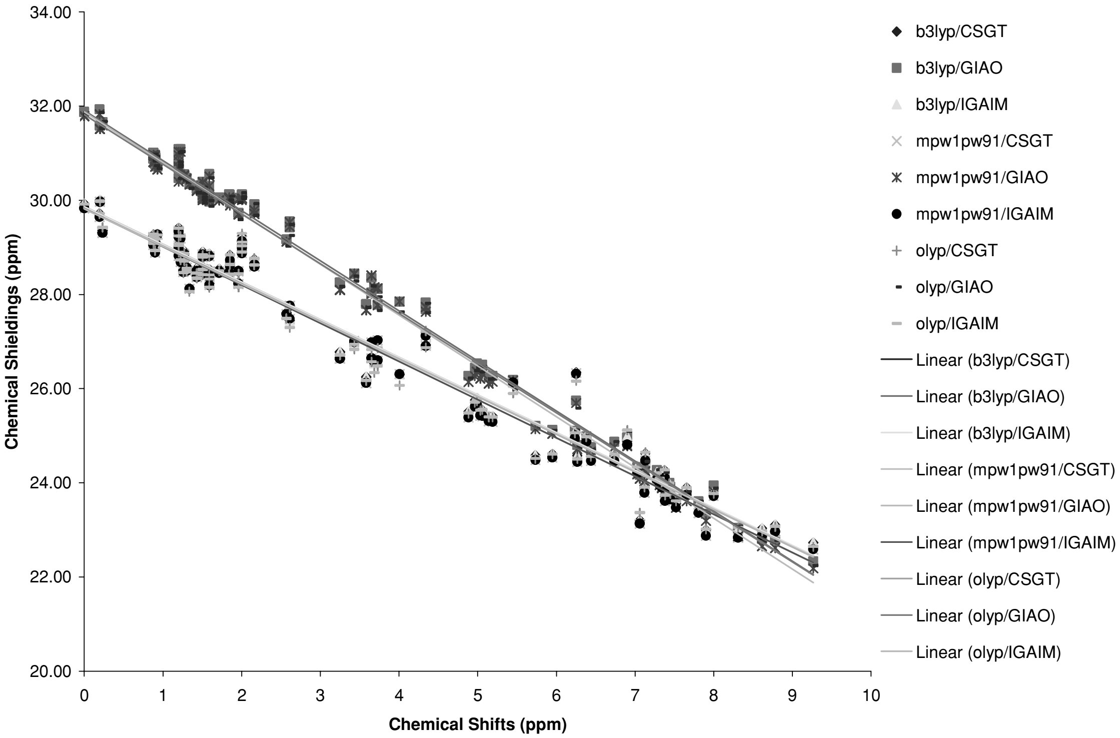

Fig. 2. Calculated ^{1}H chemical shift using different exchange-correlation functionals with the GIAO, CSGT, and IGAIM approaches for selected molecules in the G2 and G3 set of molecules. (See also Plate 2 on page XVIII in the Color Plate Section.)

clear indication of deficiencies of these methods becomes apparent for ^{15}N and ^{17}O chemical shieldings, where the standard deviations reach ~10% and ~14%, respectively. Also significantly larger deviations in the slopes are observed for these nuclei, up to 20% for ^{15}N and up to 8% for ^{17}O. However, in these cases the agreement can be also reduced by well known medium effects on these experimental chemical shifts [6], that are not taken into account in the calculations. The results presented here to illustrate the agreement between calculated and experimental isotropic chemical shifts represent a best case scenario because it has been recently documented that fortuitous cancelation of errors in the individual tensor components of the calculated chemical shieldings can lead to artificially high agreement in the isotropic chemical shifts [58].

In spite of the success of the chemical shielding calculations demonstrated above, there are several limitations in the current methods that should be considered. These limitations can be broadly divided as those inherent to the approximations used in the calculations and those due to the lack of knowledge of the molecular or crystalline structure.

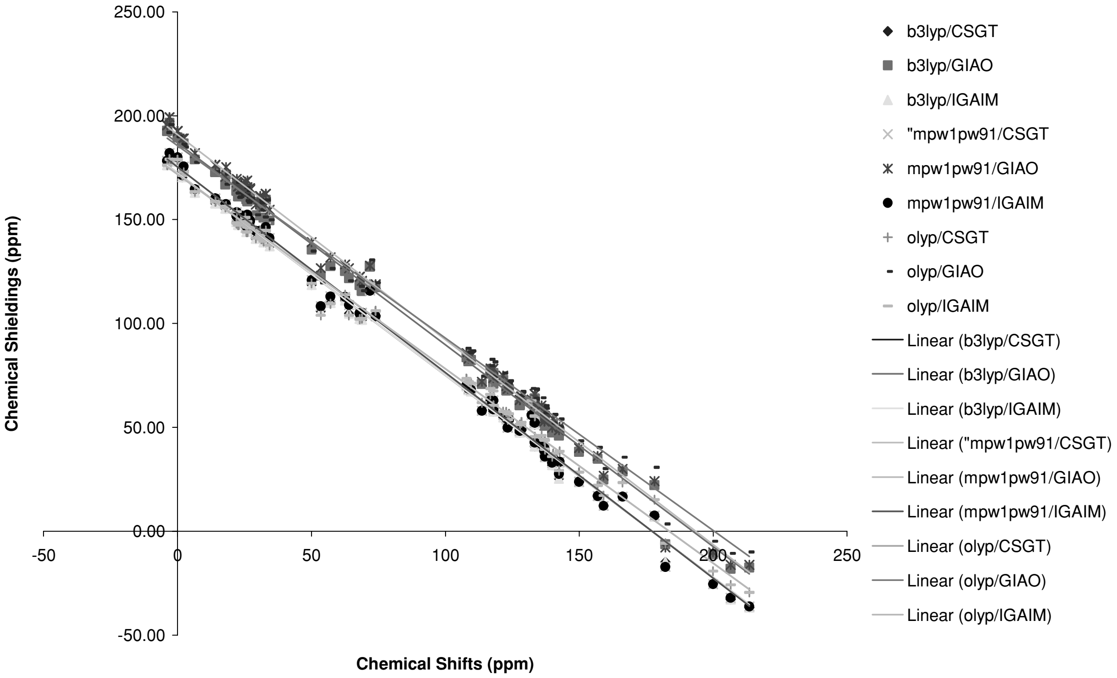

Fig. 3. Calculated ^{13}C chemical shift using different exchange-correlation functionals with the GIAO, CSGT, and IGAIM approaches for selected molecules in the G2 and G3 set of molecules. (See also Plate 3 on page XVIII in the Color Plate Section.)

In the first category, the greatest deficiency of the current methods is the neglect of relativistic corrections. This is of minor consequence when dealing with molecules including first or second row atoms but becomes a significant problem when the molecule includes atoms beyond the third row of the periodic table. There is a great deal of literature dealing with relativistic effects on chemical shielding calculations but there are no well-established methods that can be used routinely. Moreover, the most common approximations to take into account these effects have not been implemented in the most popular software used for chemical shielding calculations. The calculation of chemical shieldings in molecules containing heavy atoms remains mostly the realm of very specialized research groups [59], a situation that may change with the recent implementation of shielding calculations using the ZORA [60,61] approach in the ADF (http://www.scm.com/) package.

The second methodological challenge in the calculation of NMR chemical shielding is associated with the uncertainties in the molecular or crystalline geometry and the effects that the lattice may have on the NMR chemical shieldings. The first problem is a consequence of the great sensitivity of the chemical shieldings to the molecular geometry, a fact that has been known for some time [62,63]. This sensitivity has been instrumental in using

NMR chemical shift information to elucidate structural problems [64], but at the same time it can lead to unacceptable large errors in the calculated chemical shieldings due to the uncertainties in the position of hydrogen atoms determined by common structural methods such as X-ray. It has become a common practice to optimize the position of the hydrogen atoms, determined by X-ray structures before performing shielding calculations. Unfortunately, the practice of using optimized or partially optimized structures to calculate NMR chemical shieldings leads to significant questions about possible cancelation of errors between the method used to optimize the geometry and the one used to calculate the NMR chemical shieldings. It is conceivable that good agreement could be achieved due to the use of a optimized geometry that underestimates the interatomic bond distances, in conjunction with a method to calculate NMR chemical shieldings that also underestimates the shieldings or vice versa. Note that almost always the derivative of the chemical shielding with respect to the interatomic bond distances is negative, $\frac{\delta\sigma}{\delta r} \leq 0$ [65].

This situation has been recently discussed in the case of the calculations of the ^{15}N chemical shifts of $^{15}NO_2$ in aminonitropyridines, aminonitropyrimidines, and their *N*-oxides [66]. Comprehensive studies, including intermolecular effects (see below) and vibrational corrections are needed to fully understand the interplay between geometry optimization and chemical shielding calculations.

The inclusion of intermolecular effects in the calculation of chemical shieldings has attracted a great deal of attention over the years [8,16,34,67–69] but no "off the shelf" methods are available to take into account these effects in solid or in liquid phase. Unfortunately, in many cases the intermolecular interactions cannot be neglected without losing the quantitative agreement between experimental and calculated results. In these situations, it is necessary to exercise care and complement the standard methods available to calculate chemical shieldings with appropriate ways to take into account the intermolecular effects.

Ab Initio Calculation of NMR Shielding Constants

Peter B. Karadakov
Department of Chemistry, University of York, Heslington, York YO10 5DD, UK

Introduction

The *ab initio* calculation of NMR shielding constants is one of the "hot" areas in contemporary theoretical chemistry. The reasons for this follow from the extremely high popularity of NMR as an experimental approach and from the fact that, while in many other areas the existing quantum chemical methodology and codes promise much but frequently deliver less than what is required by the practicing chemist, the *ab initio* theoretical NMR results even at this stage reproduce many experimental measurements to a high degree of accuracy.

The aim of the present text is to provide a concise account of the quantum chemical methods for calculating NMR shielding constants, placing the emphasis on the approaches that already are, or are very likely to become available to the research community through implementations in widely available *ab initio* program packages. Although this choice will inevitably lead to certain omissions, it should be emphasized that there is no shortage of detailed review articles covering a wide range of topics within the area. Central place amongst these is taken by the very comprehensive account of the *ab initio* methods for the calculation of NMR shielding and indirect spin–spin coupling constants presented by Helgaker *et al.*[1] Various aspects of the theory and its applications have been discussed by Gauss,[2,3] Jameson,[4] de Dios,[5] Fukui,[6] Bühl *et al.*[7] The *Encyclopedia of NMR*[8] contains a wealth of information on pre-1996 work.

In the next section, we have given a brief overview of the theoretical background. This is followed, in the third section, by an overview of the *ab initio* program packages capable of evaluating NMR shielding tensors. The concluding section discusses the methods suitable for the calculation of NMR shielding tensors in large molecules.

Overview of the Theoretical Background

The electronic Hamiltonian which describes a molecule in the presence of a uniform magnetic field **B** and the field of fixed nuclear magnetic moments $\{\mathbf{m}_J\}$ at positions R_J can be written as[9] (in atomic units)

$$\begin{aligned}\hat{H}(\mathbf{B},\{\mathbf{m}_J\}) &= \sum_j \hat{h}_j(\mathbf{B},\{\mathbf{m}_J\}) + \frac{1}{2}\sum_{j\neq k} r_{jk}^{-1} \\ &= \hat{H}_1(\mathbf{B},\{\mathbf{m}_J\}) + \hat{H}_2, \qquad (1)\end{aligned}$$

where all differences from the standard non-relativistic time-independent many electron Hamiltonian are confined to the modified one-electron operator

$$\begin{aligned}\hat{h}_j(\mathbf{B},\{\mathbf{m}_J\}) &= \frac{1}{2}\left[-i\nabla_j + c^{-1}\mathbf{A}(\mathbf{r}_j-\mathbf{R})\right]^2 \\ &\quad -\sum_J Z_J r_{jJ}^{-1}. \qquad (2)\end{aligned}$$

In these expressions c is the velocity of light, Z_J stands for the charge of nucleus J, and r_{jJ} and r_{jk} are the distances between electron j and nucleus J, and between electrons j and k, respectively. The vector potential at electron j

$$\mathbf{A}(\mathbf{r}_j-\mathbf{R}) = \frac{1}{2}\mathbf{B}\times(\mathbf{r}_j-\mathbf{R}) + \sum_J(\mathbf{m}_J\times\mathbf{R}_{jJ})\,r_{jJ}^{-3}, \qquad (3)$$

depends on the gauge origin **R** which can be chosen arbitrarily. Physical intuition suggests that the energy spectrum of $\hat{H}(\mathbf{B},\{\mathbf{m}_J\})$, as well as all other electronic properties of the molecule should be independent of the choice of **R**. A rigorous proof of the gauge invariance of properties calculated with the exact eigenfunctions of $\hat{H}(\mathbf{B},\{\mathbf{m}_J\})$ has been provided by Hameka.[10] As shown by Epstein,[11] variational methods employing approximate wavefunctions made of orbitals, such as the Hartree–Fock (HF) approach and multiconfigurational self-consistent field (MCSCF) theory, also produce gauge-invariant results, if the orbitals are expanded in a complete basis. By implication, the same is assumed for results obtained using complete-basis-set non-variational approximate wavefunctions, for example, second-order and fourth-order Møller–Plesset (MP2 and MP4) constructions and coupled–cluster (CC) theory.

Graham A. Webb (ed.), Modern Magnetic Resonance, 63–70.
© 2008 *Springer.*

Calculations with finite basis sets based on the Hamiltonian (1) produce results which, as a rule, are gauge-dependent. One way to minimize the associated errors is to use larger basis sets which is computationally inefficient, especially for larger molecules. Another possibility is to employ techniques that introduce local gauge origins to define the vector potential of the external magnetic field.

Two approaches of this type have become particularly popular: the first of these uses London's gauge-including atomic orbitals (GIAOs), while the second one, individual gauge for localized orbitals (IGLOs) associates an individual gauge origin with each of the localized molecular orbitals (MOs) in a molecular system. Both approaches exist in HF, as well as in post-HF implementations, based on multi-configuration self-consistent field (MCSCF) wavefunctions (MC-IGLO[12] and MCSCF-GIAO[13]), second- and higher-order MP perturbation theory expansions (MP2-GIAO,[14,15] MP3-GIAO[16] and MP4-GIAO[17]), CC constructions (CCSD-GIAO[18] and CCSD(T)-GIAO[19]). Density functional theory (DFT) incarnations of the IGLO and GIAO ideas are also available (DFT-IGLO[20,21] and DFT-GIAO[22]).

In the GIAO scheme, which was first applied to NMR shielding calculations by Ditchfield,[23] the MOs for a molecule in a magnetic field are constructed from basis functions that depend on the field explicitly

$$\chi_p(\mathbf{B}) = \exp\left\{-\frac{i}{2c}[\mathbf{B}\times(\mathbf{R}_p-\mathbf{R})]\cdot\mathbf{r}\right\}\chi_p(\mathbf{0}), \qquad (4)$$

where $\chi_p(\mathbf{0})$ is the usual field-independent AO associated with the atomic centre at $\mathbf{R}_p$. Each GIAO has its own local gauge origin placed at its centre. The GIAO approach became very popular after Wolinski *et al.* developed a highly efficient HF-level implementation[24] incorporating computational techniques similar to those used in the calculation of analytical gradients. In a GIAO calculation, in addition to the two-electron integrals over the original basis functions $\chi_p(\mathbf{0})$, one needs to evaluate two-electron integrals over an extended basis involving the original basis functions $\chi_p(\mathbf{0})$ and their products with x, y and z. Integrals of this type are calculated by the analytic gradients routines present in most standard *ab initio* packages. This has much facilitated the provision of HF and post-HF GIAO-based approaches within large *ab initio* codes: the HF-GIAO implementation in TEXAS90[24] (based on Pulay's TEXAS[25]) was soon followed by similar developments in GAUSSIAN94 (the current version of the GAUSSIAN suite is GAUSSIAN03, see Ref. 26), ACES II[27] and TURBOMOLE.[28]

The IGLO approach[29] takes an alternative route and assumes that the local gauge origins are associated with localized MOs, rather than AOs. The wavefunction in the presence of a magnetic field is constructed in terms of field-dependent MOs defined similar to Equation (4),

$$\phi_j(\mathbf{B}) = \exp\left\{-\frac{i}{2c}[\mathbf{B}\times(\mathbf{R}_j-\mathbf{R})]\cdot\mathbf{r}\right\}\phi_j(\mathbf{0}), \qquad (5)$$

where $\phi_j(\mathbf{0})$ is a localized occupied MO in the zero-field wavefunction and $\mathbf{R}_j$ is usually chosen as the corresponding orbital centroid,

$$\mathbf{R}_j = \langle\phi_j(\mathbf{0})|\mathbf{r}|\phi_j(\mathbf{0})\rangle. \qquad (6)$$

From a computational viewpoint, the main difference between the GIAO and IGLO methods is that IGLO avoids calculating the additional two-electron integrals required by GIAO by means of a completeness insertion. This approximation is well-justified when using MOs, but would not work for AOs (that is, in the GIAO case). As a result, an IGLO calculation can be much cheaper computationally than a corresponding GIAO calculation, especially for large molecules. Despite this advantage, the IGLO scheme is currently less popular than its GIAO counterpart which is related to the lower availability of IGLO-based codes and the absence of MPn-IGLO (especially MP2-IGLO) approaches.

The elements of the NMR chemical shielding tensor of a nucleus J can be expressed as the second partial derivative of the molecular energy in the presence of an external magnetic field $\mathbf{B}$ with respect to the components of the nuclear magnetic moment $\mathbf{m}_J$ and $\mathbf{B}$ (in the following expression $\alpha, \beta \in \{x, y, z\}$):

$$\sigma_{J,\alpha\beta} = \left.\frac{\partial^2 E}{\partial m_{J,\alpha}\,\partial \boldsymbol{B}_\beta}\right|_{\mathbf{B}=\mathbf{0},\forall\mathbf{m}_J=0}. \qquad (7)$$

σ_J is a second-rank tensor, which can be written as the sum of three tensors of ranks zero, one and two, respectively,[30]

$$\boldsymbol{\sigma}_J = \sigma_{J,\,\mathrm{iso}}\begin{pmatrix}1&0&0\\0&1&0\\0&0&1\end{pmatrix} + \begin{pmatrix}0&\sigma^{\mathrm{A}}_{J,xy}&\sigma^{\mathrm{A}}_{J,xz}\\-\sigma^{\mathrm{A}}_{J,xy}&0&\sigma^{\mathrm{A}}_{J,yz}\\-\sigma^{\mathrm{A}}_{J,xz}&\sigma^{\mathrm{A}}_{J,yz}&0\end{pmatrix}$$
$$+\begin{pmatrix}d_{J,xx}&d_{J,xy}&d_{J,xz}\\d_{J,xy}&d_{J,yy}&d_{J,yz}\\d_{J,xz}&d_{J,yz}&d_{J,zz}\end{pmatrix} \qquad (8)$$

where $\sigma_{J,\mathrm{iso}}$ is the isotropic shielding

$$\sigma_{J,\mathrm{iso}} = \tfrac{1}{3}(\sigma_{J,xx}+\sigma_{J,yy}+\sigma_{J,zz}), \qquad (9)$$

$\sigma^{\mathrm{A}}_{J,\alpha\beta}$ stands for the antisymmetry parameter

$$\sigma^{\mathrm{A}}_{J,\alpha\beta} = \tfrac{1}{2}(\sigma_{J,\alpha\beta} - \sigma_{J,\beta\alpha}), \tag{10}$$

and the quantities $d_{J,\alpha\beta}$ are given by

$$d_{J,\alpha\beta} = \tfrac{1}{2}(\sigma_{J,\alpha\beta} + \sigma_{J,\beta\alpha} - 2\sigma_{J,\mathrm{iso}}). \tag{11}$$

As a rule, shielding tensors are quoted in the principal axis system (PAS), in which the second-rank tensor with elements $d_{J,\alpha\beta}$ in Eq. (8) is diagonal (and so is the symmetrized shielding tensor $\boldsymbol{\sigma}^{\mathrm{S}}_J = \frac{1}{2}(\boldsymbol{\sigma}_J + \boldsymbol{\sigma}^{\mathrm{T}}_J)$, where $\boldsymbol{\sigma}^{\mathrm{T}}_J$ is the transpose of $\boldsymbol{\sigma}_J$). It is usual to assume that the PAS shielding tensor is diagonal, which amounts to discarding the first-rank tensor involving the antisymmetry parameters in Eq. (8),

$$\boldsymbol{\sigma}^{\mathrm{PAS}}_J = \sigma_{J,\mathrm{iso}} \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix} + \begin{pmatrix} d^{\mathrm{PAS}}_{J,xx} & 0 & 0 \\ 0 & d^{\mathrm{PAS}}_{J,yy} & 0 \\ 0 & 0 & d^{\mathrm{PAS}}_{J,zz} \end{pmatrix}. \tag{12}$$

The shielding anisotropy, $\triangle\sigma_J$, and asymmetry, η_J, are defined as

$$\triangle\sigma_J = \sigma^{\mathrm{PAS}}_{J,11} - \tfrac{1}{2}(\sigma^{\mathrm{PAS}}_{J,22} + \sigma^{\mathrm{PAS}}_{J,33}) \tag{13}$$

and

$$\eta_J = \left(\sigma^{\mathrm{PAS}}_{J,22} - \sigma^{\mathrm{PAS}}_{J,11}\right) \Big/ \left(\sigma^{\mathrm{PAS}}_{J,33} - \sigma^{\mathrm{PAS}}_{J,11}\right) \tag{14}$$

where it is assumed that $\sigma^{\mathrm{PAS}}_{J,33} \geq \sigma^{\mathrm{PAS}}_{J,22} \geq \sigma^{\mathrm{PAS}}_{J,11}$. Other quantities that can be used to characterize the shielding tensor are the span, Ω_J, and the skew, κ_j,[31]

$$\Omega_J = \sigma^{\mathrm{PAS}}_{J,33} - \sigma^{\mathrm{PAS}}_{J,11} \tag{15}$$

and

$$\kappa_J = 3\left(\sigma_{J,\mathrm{iso}} - \sigma^{\mathrm{PAS}}_{J,22}\right) \Big/ \left(\sigma^{\mathrm{PAS}}_{J,33} - \sigma^{\mathrm{PAS}}_{J,11}\right). \tag{16}$$

Theoretical values for NMR chemical shifts can be obtained through the expression

$$\begin{aligned} \delta_J &= (\sigma_{J,\mathrm{iso,ref}} - \sigma_{J,\mathrm{iso}})/(1 - \sigma_{J,\mathrm{iso,ref}}) \\ &\approx \sigma_{J,\mathrm{iso,ref}} - \sigma_{J,\mathrm{iso}} \quad \text{when } |\sigma_{J,\mathrm{iso,ref}}| \ll 1, \end{aligned} \tag{17}$$

where $\sigma_{J,\mathrm{iso,ref}}$ is the (absolute) isotropic shielding of nucleus J in a reference molecule.

The energy expectation value of the Hamiltonian (1) for an arbitrary wavefunction constructed from MOs expanded in a GIAO basis can be represented in terms of the elements of the one- and two-electron density matrices in the GIAO basis, P_{pq} $(\mathbf{B})$ and $\Pi_{pq,rs}$ $(\mathbf{B})$, in analogy to a well-known expression for the $\mathbf{B} = \mathbf{0}$ case,[32] as

$$\begin{aligned} E(\mathbf{B}, \{\mathbf{m}_J\}) = &\sum_{p,q} P_{pq}(\mathbf{B}) \langle \chi_q(\mathbf{B}) | \hat{h}(\mathbf{B}, \{\mathbf{m}_J\}) | \chi_p(\mathbf{B}) \rangle \\ &+ \frac{1}{2} \sum_{p,q,r,s} \Pi_{pq,rs}(\mathbf{B}) \langle \chi_r(\mathbf{B}) \chi_s(\mathbf{B}) \\ &\times | r_{12}^{-1} | \chi_p(\mathbf{B}) \chi_q(\mathbf{B}) \rangle. \end{aligned} \tag{18}$$

In view of the fact that the terms dependent on the nuclear magnetic moments are just those involving the matrix elements of $\hat{h}(\mathbf{B}, \{\mathbf{m}_J\})$, it is convenient to start the derivation of the expression for the elements of the shielding tensor (7) based on Equation (18) with the derivative (see Ref. 17)

$$\frac{\partial E}{\partial m_{J,\alpha}} = \sum_{p,q} P_{pq}(\mathbf{B}) \frac{\partial h_{qp}(\mathbf{B}, \{\mathbf{m}_J\})}{\partial m_{J,\alpha}} \tag{19}$$

where $h_{qp}(\mathbf{B}, \{\mathbf{m}_J\}) = \langle \chi_q(\mathbf{B}) | \hat{h}(\mathbf{B}, \mathbf{m}_1, \mathbf{m}_2, \ldots) | \chi_p(\mathbf{B}) \rangle$. A second derivation differentiation, with respect to the elements of $\mathbf{B}$, yields

$$\begin{aligned} \sigma_{J,\alpha\beta} = &\sum_{p,q} P_{pq}(\mathbf{0}) \left. \frac{\partial^2 h_{qp}(\mathbf{B}, \{\mathbf{m}_J\})}{\partial m_{J,\alpha} \partial B_\beta} \right|_{\mathbf{B}=\mathbf{0}, \forall \mathbf{m}_J=0} \\ &+ \sum_{p,q} \left. \frac{\partial P_{pq}(\mathbf{B})}{\partial B_\beta} \right|_{\mathbf{B}=\mathbf{0}} \left. \frac{\partial h_{qp}(\mathbf{B}, \{\mathbf{m}_J\})}{\partial m_{J,\alpha}} \right|_{\mathbf{B}=\mathbf{0}, \forall \mathbf{m}_J=0}. \end{aligned} \tag{20}$$

This equation provides a convenient starting point for the calculation of NMR shielding tensors by means of GIAO approaches utilizing different wavefunction constructions (see e.g., Refs. 17, 33). Detailed expressions for the derivatives of the matrix elements of the one-electron operator $\hat{h}(\mathbf{B}, \{m_J\})$ have been reported by Gauss.[33] The derivatives of the one-electron density matrix with respect to the magnetic field are evaluated using linear response theory which, in the case of a HF wavefunction, is well-known as the coupled-perturbed HF (CPHF) approach.

An alternative expression for the elements of the NMR shielding tensor can be obtained through direct differentiation of the expectation value of the Hamiltonian $\hat{H}(\mathbf{B}, \{\mathbf{m}_J\})$ [see Equation (2)] with respect to a field-dependent wavefunction $\Psi(\mathbf{B})$ as follows:

$$\begin{aligned}
&\frac{\partial}{\partial m_{J,\alpha}}\left\langle \Psi(\mathbf{B}) \middle| \hat{H}(\mathbf{B},\{\mathbf{m}_J\}) \middle| \Psi(\mathbf{B}) \right\rangle \\
&\qquad = \left\langle \Psi(\mathbf{B}) \middle| \frac{\partial \hat{H}_1(\mathbf{B},\{\mathbf{m}_J\})}{\partial m_{J,\alpha}} \middle| \Psi(\mathbf{B}) \right\rangle, \\
&\sigma_{J,\alpha\beta} = \left[\left\langle \Psi(\mathbf{B}) \middle| \frac{\partial^2 \hat{H}_1(\mathbf{B},\{\mathbf{m}_J\})}{\partial m_{J,\alpha}\partial B_\beta} \middle| \Psi(\mathbf{B}) \right\rangle \right. \\
&\qquad \left. \left. + 2\,\mathrm{Re}\left\langle \frac{\partial \Psi(\mathbf{B})}{\partial B_\beta} \middle| \frac{\partial \hat{H}_1(\mathbf{B},\{\mathbf{m}_J\})}{\partial m_{J,\alpha}} \middle| \Psi(\mathbf{B}) \right\rangle \right] \right|_{\mathbf{B}=\mathbf{0},\forall \mathbf{m}_J=0} .
\end{aligned} \tag{21}$$

When dealing with complicated wavefunction constructions, it may prove simpler and more straightforward to evaluate the first derivatives of the wavefunction with respect to the elements of the magnetic field, rather than the corresponding derivatives of the elements of the one-electron density matrix required by Equation (20).

Ab Initio Program Packages Capable of Calculating NMR Chemical Shielding Tensors

There are several general-purpose *ab initio* program packages which incorporate modules for calculating NMR chemical shielding tensors. Apart from these packages, most of which are commercial, there are other codes with similar or even better functionality, developed in different research groups, which are less readily available to the scientific community. The focus in this section will be on the first group of packages, as their features and functionality are much better documented.

The GAUSSIAN suite (see *http://www.gaussian.com*) is probably the most widely used general-purpose *ab initio* package. It has been capable of computing NMR chemical shielding tensors since the 1994 version, GAUSSIAN94, which introduced implementations of the GIAO, continuous set of gauge transformations (CSGT), individual gauges for atoms in molecules (IGAIM) and single origin approaches at the HF and DFT levels of theory. GAUSSIAN94 and later versions of the package can also calculate HF and DFT-level magnetic susceptibilities with the CSGT, IGAIM and single origin approaches. GAUSSIAN98 extended the NMR-related capabilities of the package through the addition of an MP2-GIAO module. In addition to this, the current version, GAUSSIAN03,[26] allows the calculation of indirect spin–spin coupling constants using HF and DFT wavefunctions, as well as the calculation of NMR properties in the presence of a solvent.

The DFT functionals in the GAUSSIAN suite do not include magnetic field dependent terms, which may be one of the reasons why the DFT-level NMR results are not systematically better than their HF-level counterparts. However, it should be pointed out that the results of Lee *et al.*[34] indicate that the use of a local exchange-correlation functional, which depends on both the electron density and the paramagnetic current density in the DFT-GIAO framework leads only to a slight deshielding effect. There is computational evidence (see Ref. 35) showing that extension of the basis set in DFT-GIAO calculations performed using GAUSSIAN can lead to poorer-quality NMR shielding constants. This suggests that although the DFT-GIAO approach is one attractive way of including correlation effects in shielding calculations on large molecules, the results should be treated with care.

The HF-GIAO and DFT-GIAO codes incorporated into the GAUSSIAN suite are reasonably fast and have relatively modest memory and disk space requirements, especially when use is made of the direct routines which recompute all integrals as required instead of storing them after the initial evaluation. The GAUSSIAN MP2-GIAO module is much slower, uses the conventional procedure of storing integrals to disk and, as a result, needs large amounts of temporary disk space. It can treat systems involving more than 255 basis functions (up to 361 on a 32-bit computer system), although the disk space requirements can become prohibitive: a calculation with a large locally dense basis set on hexafluorobenzene (90 electrons, 270 basis functions) produces a read–write file of over 52 Gb. This is well beyond the capabilities of 32-bit computer systems, which cannot handle files larger than 16 Gb.

The ACES II[27] package (see *http://www.qtp.ufl.edu/Aces2/*) can calculate NMR chemical shielding tensors at the HF-GIAO and MP2-GIAO levels of theory. The HF-GIAO and MP2-GIAO codes in this package were contributed by J. Gauss and realize the theory presented in Ref. 15. The memory requirements for an MP2-GIAO calculation in ACES II are about $2n^2N^2/h$ double (eight-byte) words, where n and N denote the numbers of occupied and virtual orbitals, respectively, and h stands for the order of the molecular point group. The MP2-GIAO code in ACES II uses the conventional procedure of storing integrals to disk, and the size of each of the three largest temporary files, associated with the perturbations corresponding to the elements of $\mathbf{B}$, is about $1.5M^4/(4h)$ double words, where M stands for the number of basis functions. The program can treat the perturbations caused by the three magnetic field components separately, which can lead to a substantial reduction in the disk space requirements at the expense of some loss of efficiency. The maximum number of basis functions in a MP2-GIAO calculation performed within ACES II is 255.

Turbomole[28] (see *http://www.ipc.uni-karlsruhe.de/tch/tch1/index.de.html*) is another *ab initio* package that can computes NMR chemical shieldings within the GIAO ansatz at the HF and MP2 levels of theory. The MPSHIFT module of Turbomole implements the direct MP2-GIAO approach developed by Kollwitz and Gauss[36], which allows calculations on large molecules using machines with limited amounts of memory and disk space. For example, the largest MP2-GIAO calculation reported by Kollwitz and Gauss,[36] on the anthracenium cation (94 electrons, 288 basis functions), was carried out on a workstation with just 128 Mb RAM and 2 Gb of scratch disk space. The most recent version of this code makes full use of molecular point group symmetry, including non-Abelian point groups,[37] and has been used in calculations on highly symmetric molecules involving more than 600 basis functions.[37]

DALTON[38] (see *http://www.kjemi.uio.no/software/dalton/dalton.html*) is an *ab initio* package that can calculate a very wide range of molecular properties at different levels of theory. Gauge origin independent nuclear shieldings and magnetizabilities can be obtained through the use of GIAOs, or through the continuous transformation of the origin of the current density (CTOCD) approach,[39] in its CTOCD-DZ form.[40] Dalton allows the use of GIAOs with HF and MCSCF wavefunctions, while the CTOCD-DZ technique can be combined with the second order polarization propagator approximation (SOPPA), and with SOPPA with CCSD amplitudes. Dalton can also calculate indirect spin–spin coupling constants using the triplet linear response function.

deMon (Density of Montréal)[41] (see *http://www.demon-software.com*) is a DFT package that incorporates the deMon-NMR code written by Malkin *et al.* deMon-NMR can calculate chemical shifts, coupling constants and electron pair resonance quantities. It implements the sum-over-states-density functional perturbation theory (SOS-DFPT) approach[21,42] in combination with the IGLO choice of gauge origins and in many cases produce more accurate results than the standard DFT-GIAO and DFT-IGLO methods, and the more common HF-GIAO and HF-IGLO approaches. The reasonable accuracy and lower computational costs of the SOS-DPFT-IGLO method makes it an attractive alternative to MP2-GIAO in shielding calculations on larger molecular systems (for example, biosystems or transition metal complexes), which require inclusion of correlation effects.

DGauss (see *http://www.cachesoftware.com/cache/dgauss/index.shtml*) is another DFT code for calculating NMR shielding constants, which is also largely based on theory developed by Malkin *et al.*[20,43] DGauss uses DFT in combination with the IGLO and LORG (localized orbital/local origin) techniques.

The Cambridge analytic derivatives package (CADPAC) (see *http://www-theor.ch.cam.ac.uk/software/cadpac.html*) incorporates HF-LORG and DFT-LORG modules for calculating NMR shielding constants.

The RPAC molecular properties package developed mainly by Bouman and Hansen[44] (e-mail address for enquiries concerning RPAC: *aaeh@rpac.ki.ku.dk*) is a post-SCF code that can work with the US version of GAMESS[45] or with GAUSSIAN. It calculates electronic excitation and response properties employing first-order (random-phase approximation/coupled HF) and second-order (SOPPA/second-order LORG (SOLO)) linear response theory. In addition to a number of other electronic ground state response properties, RPAC can calculate NMR shielding tensors with the inclusion of electron correlation effects in the case of the SOLO approach.

Ab Initio Calculation of NMR Chemical Shielding Tensors for Large Molecules

In recent years, the calculation of NMR chemical shielding constants of large molecules, using a variety of theoretical methods, has become largely a routine task. However, the computational cost scales with at least the fourth power of the number of basis functions and the calculations can quickly become prohibitively expensive in terms of the computational resources required, particularly when electron correlation is included. The demand on resources can be reduced by taking into account the fact that nuclear shielding is predominantly governed by local effects. This idea is behind the locally dense basis set (LDBS) technique suggested by Chesnut and Moore[46] in which the atoms of interest are described using larger basis sets, while a smaller basis set is employed for the rest of the molecule. All *ab initio* packages discussed in the previous section allow straightforward specification of different basis set for different atoms, which has made the use of LDBS constructions the most popular way of reducing the computational effort associated with NMR shielding tensor calculations. A now classic example of the advantage of LDBS involves the study of a cluster of 17 H_2O molecules,[47] in which the results obtained using a 6-311G(d,p) basis on the central H_2O molecule and its two-nearest hydrogen-bonded partners were found to be virtually identical to those obtained using the larger basis throughout, but were produced in just one-sixth of the time required for the larger calculation.

The treatment of very large molecular systems may require more drastic approximations. In one approach, advanced by de Dios *et al*, distant parts of the molecular system, solvent molecules, etc., are modeled by partial point charges, creating a classical electrostatic field. In spite of its simplicity, this idea has been demonstrated to work very well for the ^{13}C shielding tensors in crystals of L-tyrosine and L-threonine.[48] This idea was taken further by Cui and Karplus,[49] who suggested a general approach to chemical shielding calculations within the quantum mechanics/molecular mechanics (QM/MM) framework, in which the most important region of a molecule is described by a QM wavefunction, while its surroundings are described using MM. These authors showed that the MM atoms, which polarize the wavefunction of the QM region as point charges, make a two-fold contribution to the elements of the NMR shielding tensor in Equation (20): firstly, the charges on the MM atoms modify the one-electron density matrix P_{pq} ($\mathbf{0}$) and, secondly, these atoms influence the derivatives of the density matrix, $\partial P_{pq}(\mathbf{B})/\partial B_\beta|_{\mathbf{B}=\mathbf{0}}$. As a consequence, the correct treatment of the effects due to the charges on the MM atoms requires a modified variant of linear response theory. The results of Cui and Karplus show that their QM/MM approach, with an appropriate QM/MM partitioning, allows a good description of the environmental effects on the chemical shifts. The typical errors relative to full QM calculations within the same basis set were found to be about 1–2 ppm for distances between QM and MM atoms greater than 2.5 Å. At shorter distances, such as those corresponding to hydrogen bonds, the deviations from the full QM results become more significant as the QM/MM model does not account for the Pauli repulsion and the magnetic susceptibility of the environment. One way to correct for this is to extend the QM region so that it includes all atoms that interact directly with the atom of interest.

The fact that it is possible to perform higher level calculations on the nuclei of interest in a large molecule, as long as their local chemical environment is adequately described, without having to use the same level of theory for the whole system, is fully exploited in the ONIOM-NMR approach,[50] which is quickly gaining popularity (for example, see Refs. 51, 52).

The ONIOM approach involves splitting the system into two or more layers that can be described using different levels of theory and/or basis sets (for an in-depth discussion of the theory behind the ONIOM, our own n-layer integrated molecular orbital and molecular mechanics, approach see, e.g., Refs. 53, 54). A two-layer ONIOM-NMR construction requires the performance of three NMR calculations in order to obtain the shielding of each of the nuclei of interest. First, the shieldings for the whole system must be calculated at the selected lower level of theory, and then those for the molecular fragment surrounding the nucleus of interest have to be evaluated at both the selected higher and lower levels of theory. The expression for the elements of the NMR chemical shielding tensor for nucleus J in the two-layer ONIOM-NMR approach is given by

$$\begin{aligned}&\sigma_{J,\alpha\beta}[\text{ONIOM2(H-GIAO}:\text{L-GIAO)}]\\&\quad=\sigma_{J,\alpha\beta}(\text{H-GIAO, model})\\&\quad+\sigma_{J,\alpha\beta}(\text{L-GIAO, real})-\sigma_{J,\alpha\beta}(\text{L-GIAO, model}),\end{aligned}\tag{22}$$

where ‘H’ and ‘L’ represent the higher and lower levels of theory, respectively, both of which would normally

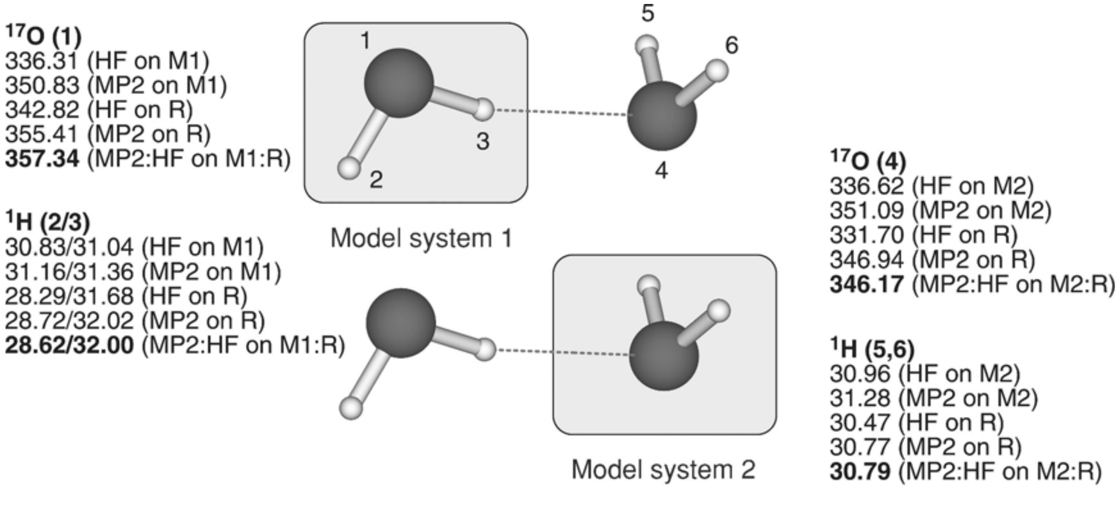

Fig. 1. Application of the ONIOM2(MP2-GIAO:HF-GIAO) approach to the water dimer (MP2//6-31G** geometry of C_s symmetry). Abbreviations in the shielding descriptions: HE = HF-GIAO/6-31G**, MP2 = MP2-GIAO/6-31G**, MP2:HF = ONIOM2(MP2-GIAO/6-31G**:HF-GIAO/6-31G**), Ml = model system 1 (left water molecule), M2 = model system 2 (right water molecule), R = real system (the whole dimer). All shieldings in ppm.

be GIAO-based approaches. The 'model' system corresponds to the inner layer formed by nucleus *J* and its local environment, and the 'real' system represents the entire molecule. One important advantage of the ONIOM-NMR approach is that the expression (21) can be evaluated using any *ab initio* package that implements the 'H-GIAO' and 'L-GIAO' methods, without any need for additional programing.

The choice of suitable molecular fragments is a very important aspect of the use of the ONIOM-NMR approach. In most cases, when calculating the shielding of a particular nucleus, inclusion of its nearest neighbours in the "model" system is sufficient to achieve an adequate description of its local environment. Usually, the definition of the "model" system requires breaking of chemical bonds, and within the ONIOM approach the resulting "free valencies" are saturated through the addition of terminal hydrogen atoms. The ONIOM-NMR approach works particularly well for hydrogen-bonded systems, as illustrated by Figure 1, which shows the results of its application to the water dimer.[50]

Due to the local nature of the NMR shielding tensor, local-correlation treatments (see *e.g.* ref. 55) should be a suitable way of reducing the computational effort associated with post-HF shielding calculations on large molecules. Gauss and Werner have developed a LMP2-GIAO scheme,[56] which has been shown to be comparable in accuracy to the standard MP2-GIAO approach. However, the limited data available at the moment does not allow an estimate of the potential computational savings associated with the use of this local-correlation treatment.

Introduction

The NMR chemical shift is available from practically every conventional NMR experiment. In contrast to X-ray diffraction it is mainly caused by the density distribution of the valence electrons, hence it contains genuine information about the valence structure of the molecular system. High-resolution solid-state investigations on crystalline systems revealed a considerable dependence of the chemical shift on the 3D arrangement of the atoms and on their packing within the unit cell [1]. In many cases, an asymmetric content of the unit cell could be deduced from NMR line splittings. The point group symmetry of the molecule under study is frequently reflected within the NMR spectra and especially within the chemical shift tensors [2]. It was demonstrated by Taulelle [3] that even the complete space group could be deduced from NMR results.

The success of diffraction methods originates from the direct dependence of the measured intensities on the coordinate of the scattering particles. NMR structure analysis is more complex, but the better we understand how chemical shifts change with the 3D arrangement of atoms, the more reliably we can construct molecular models from our experiments. In the case of chemical shifts, this connection is far from simple and requires quantum chemical computations. In some cases, the molecular packing could be directly deduced by calculating chemical shifts induced by intermolecular interactions [4]. These effects become dominant with increasing polarity of the lattice. In *ab initio* chemical shift calculations molecules are embedded into point charge lattices to simulate the crystallographic surrounding [5]. These computations are highly demanding and for many solid state problems prohibitive. The quest for simple empirical and semi-empirical approaches to structure analysis using chemical shifts has been recently reviewed by Sternberg *et al.* [6]. The ultimate goal will be to perform an accurate chemical shift calculation coupled to a 3D structure refinement. In many cases, *ab initio* CS calculations are used to supplement NMR investigations to extract aspects of the spatial arrangement, but for complete structure refinement a number of severe problems still have to be solved. Chemical shift calculations often require extended basis sets or correlation corrections that may easily lead to multiples of the original computational time. If refinements are to be performed in addition to the chemical shift calculation, their derivatives with respect to the molecular coordinates need to be evaluated. This is again much more demanding than the chemical shift calculations alone. We believe that the success story of liquid state NMR in protein structure elucidation is going to continue in the solid state once chemical shifts can be successfully exploited.

In many cases, the chemical shift will be only one parameter amongst many others that can yield constraints for structure calculation. In solution, we can measure Nuclear Overhauser Enhancements (NOEs), J-couplings, and residual dipolar couplings, and for these parameters there exist well-established relationships to aspects of the molecular structure. In solid-state investigations, we face the situation that up to now there is no general protocol for structure calculations from NMR data. Direct dipolar couplings are often used as distance constraints, provided that the interaction between two spins can be singled out. Likewise, anisotropic chemical shift information is highly useful to determine orientational constraints in macroscopically oriented samples such as membranes or fibers. For solid-state NMR protein structure analysis there exist a number of excellent reviews covering most aspects of chemical shift approaches [7–10].

To solve crystal structures by NMR or to at least augment diffraction studies, the following computational requirements have to be fulfilled: (i) the energy of a unit cell including the influence of the lattice has to be calculated, (ii) extremely fast methods are required for calculating chemical shifts, and (iii) the chemical shift derivatives with respect to the atomic coordinates need to be evaluated. The following paragraphs will give a short introduction into the appropriate methods, before several applications will be presented.

Computational Methods

Bond Polarization Theory for Chemical Shifts

In principle, chemical shielding calculations are performed by investigating the perturbation of a molecular wave function due to the presence of an external field B_Z

Graham A. Webb (ed.), Modern Magnetic Resonance, 71–78.
© 2008 *Springer.*

and magnetic moments caused by the nuclei. Within the context of the Hartree-Fock (HF) theory we have to solve perturbed HF equations. Even if more powerful computers will be available in the future and *ab initio* nuclear shielding calculations are sped up further [11], the calculations will still be very computationally demanding. In many cases, the HF level is not sufficient for reliable results. Correlated methods, such as coupled clusters, have to be applied. However, for MD calculations of crystal lattices these methods are far too time consuming. Therefore, we have to apply a highly efficient method that concentrates on the key points of quantum mechanical chemical shift calculations.

The first key point is that chemical shift is a local quantity, which depends mainly on the first sphere of chemical bonds around the nucleus under consideration. Therefore, bond orbitals are best suited for our task. Bond orbitals can be constructed from the geometry of the system, provided that their occupation numbers and polarity parameters are known.

Secondly, we account for polarization by invoking anti-bonds as excited configurations. Instead of parametrizing the Hamiltonian matrix like other semi-empirical methods the expectation value for the chemical shift is parametrized directly. The complete wave function is not needed, because we are only interested in the change of a local quantity and rather than its absolute value.

Finally, we arrive at an expression were two (in the tensorial case 6) linear empirical parameters per bond type have to be determined. Within the bond polarization theory BPT approach [12, 13] the chemical shift tensor is expressed by

$$\left\langle \Psi_0 | \hat{\delta}_{\alpha\beta} | \Psi_0 \right\rangle = \sum_{i}^{i \in A} \sum_{\alpha'\beta'} D^{i}_{\alpha\alpha'} D^{i}_{\beta\beta'} \left(n_i \delta_i^{\alpha'\beta'} + n_i^2 A_i^{\alpha'\beta'} \right. \\ \left. \times \left[\langle \chi_{\mathrm{A}}^{i} \,|\, \hat{V} \,|\, \chi_{\mathrm{A}}^{i} \rangle - \langle \chi_{\mathrm{B}}^{i} \,|\, \hat{V} \,|\, \chi_{\mathrm{B}}^{i} \rangle \right] \right). \quad (1)$$

The matrix elements $D_{\alpha\alpha'}$ describe the coordinate transformation from the bond orbital frame to the reference frame. The first sum runs over all bond contributions of atom A. The bond polarization matrix elements are given (in atomic units) by

$$\left\langle \chi_\lambda \,|\, \hat{V} \,|\, \chi_\lambda \right\rangle = \sum_{x}^{\text{charges}} \sum_{k} h_k^2 \int \phi_k^\lambda(r) \\ \times \frac{Q_x}{|R_x - r|} \phi_k^\lambda(r) \mathrm{d}r^3, \quad (2)$$

with the charges Q_x at position R_x, the Slater type orbitals [14] $\phi_k^\lambda(r)$, and the bond coefficients h_k. The first sum runs over all polarizing atomic charges. The bond tensor increments $\delta_i^{\alpha\beta}$ and polarization tensor parameters $A_i^{\alpha\beta}$ (in ppm/Hartree) are obtained by calibration procedures, [15]. A collection of crystal structures and single crystal chemical shift measurements has been used to establish a set of linear equations for the parameters [16][17], and in some cases we also included *ab initio* results.

The correlation coefficient obtained from the parameter calibration is $R = 0.994$ with a standard deviation of $\mathrm{SD} = 7.2$ ppm. Once the bond increments $\delta_i^{\alpha\beta}$ and polarization parameters$A_i^{\alpha\beta}$ are determined, only the matrix elements $\langle \chi_\lambda^i | \hat{V} | \chi_\lambda^i \rangle$ and the occupation numbers n_i (from valences [18]), have to be calculated. Introducing point charges in the expression for the potential $\hat{V}$ leads to compact analytic expressions for the integrals, hence calculations within the BPT approach are highly efficient. In Equation (1) there are two sums, which run over all bond contributions of the atom under consideration and over all polarizing charges of the potential $\hat{V}$. If the charge distribution is known, the computational cost for a chemical shift calculation is thus proportional to the number of atoms N.

BPT Calculation of Atomic Charges

As can be seen from Equation (2), accurate atomic charges, Q_x, are also prerequisite of BPT chemical shift calculations. The chemical shifts in this theory are proportional to bond polarization integrals that account for the change of the chemical shift caused by surrounding charge distributions. Since semi-empirical polarization parameters are introduced into the chemical shift calculations, the absolute values of the charges are not of concern. The polarization parameters $A_i^{\alpha\beta}$, on the other hand, will depend on the type of *ab initio* calculation and on the procedure for the population analysis. The atomic charges can be calculated within the BPT approach in a manner analogous to Equation (1) [19]:

$$Q_{\mathrm{A}} = \sum_{i}^{i \in A} \left(n_i q_i + n_i^2 A_i^q \left[\left\langle \chi_{\mathrm{A}}^i \left| \frac{Q_x}{|R_x - r|} \right| \chi_{\mathrm{A}}^i \right\rangle \right. \right. \\ \left. \left. - \left\langle \chi_{\mathrm{B}}^i \left| \frac{Q_x}{|R_x - r|} \right| \chi_{\mathrm{B}}^i \right\rangle \right] \right). \quad (3)$$

Overlap contributions are omitted when calculating the bond polarization integrals. By investigating the charge equations, it is obvious that the charge on atom A, Q_{A}, has to be estimated from all other charges Q_x. By taking the Q_x as factors out of the integrals, we end up with a system of linear equations for the Q_x and Q_{A} with the sum over $n_i q_i$ as inhomogeneities. The parameters q_i and A_i^q have been calibrated against atomic charges of a set of 175 structures consisting of H, C, N, O, F, Si, P, S, Cl, and Zn atoms [20]. The calculations were performed using the 6-31G(d, p) basis set, and the atomic charges are obtained by a natural population analysis (NPA) of the *ab initio* charge distributions. BPT and *ab initio* charges of small molecules correlate regularly with $R = 0.996$. For details of the parametrization and the formalism see Witter [20].

Molecular Force Fields and Chemical Shift Pseudo-Forces

For a complete solid-state NMR structure determination the most desirable approach would be to calculate the energy, the chemical shifts and their derivatives using *ab initio* methods. Even on fast computers this does not seem to be feasible for systems with much more than 10 heavy atoms. With the advent of DFT calculations the situation improved, but a breakthrough in chemical shift calculations was not achieved. One of the most promising developments is the combination of quantum mechanical *ab initio* methods with molecular mechanics calculations (QM/MM). Cui and Karplus [21] combined the empirical CHARMM force field [22] with HF and DFT calculations. In this framework, the chemical shielding calculations can be performed on the GIAO-DFT, -HF or -MP2 level in the QM part of the system under the influence of a larger MM surrounding. The electrostatic perturbations of all relevant matrix elements are treated by a point charge distribution from the MM part of the system, and their influence on the chemical shielding can be studied. Even with the limitations on the size of the QM part this method will be of great value, especially in the treatment of reaction centers in large molecules.

Traditional methods for the treatment of large molecular systems using NMR constraints are molecular mechanics force fields like DYANA [23]. It was demonstrated that such empirical force field reproduce the 3D structures rather well and can compete in this aspect with elaborate *ab initio* calculations. The limitations of molecular mechanics in system size are due to the calculation of the intermolecular energy terms, which scale with the second power of the number of atoms. Hundreds or even thousands of atoms are no real problem for molecular mechanics force field calculations. The most popular method for the search of global minima in NMR force field calculations is to run MD simulations at elevated temperatures, to surmount most conformational barriers and populate extended areas of the configurational space. A larger number of coordinate snapshots is then cooled down in the so-called simulated annealing procedure, or the energy minimum is determined by geometry optimization. The latter method has the advantage that we can weight every structure by its minimum energy. A combination of simulated annealing and geometry optimization is preferred in some investigations to avoid side minima.

The problem of all previous molecular mechanics force field methods is that electronic properties cannot be calculated without wave functions or electron distributions. Even atomic charges are mostly fixed parameters of the force field, and polarizations of the electron distribution are excluded. One possibility to overcome the limitations of the traditional molecular mechanics is the combination of the BPT with a force field. Within the COSMOS force field [24, 25] two-center bond orbitals are constructed for every bond defined in the force field. If the hybridization coefficients and the bond occupation numbers n_i are calculated from the geometry, only the bond polarities are left as free parameters. Within the framework of the BPT, bond polarities or atomic charges can be readily calculated. Therefore, this force field works with charges that depend in the same way on the 3D structure of the molecular systems as the *ab initio* charge values that were used in the parametrization. For σ-bonds the occupation numbers n_i are set to two, and for conjugated π-bonds the value is estimated from the bond distance[25].

Using the COSMOS force field it is possible to divide the molecular system into an MM part and a BPT-QM part, which considers only the polarizations caused by the point charges of the MM part. BPT calculations are very fast and scale with the number of atoms multiplied by the number of bonds. Nevertheless, the BPT atomic charge calculation is the most time consuming step in the force field cycle, hence cutoffs or smaller QM parts help to run efficient simulations. Since all polarizations can be included into the Coulomb energy, the COSMOS force field can be used to study interactions of highly charged systems as for instance ions and peptides [25].

To apply molecular mechanics calculations to crystal structures, the force field has to represent the influence of the crystal lattice in an adequate way. This is achieved by surrounding a central unit cell by one or two shells of translationally created images of itself. The number of shells depends on the electrostatic cutoff radius in relation to the size of the unit cell. In most molecular crystal structures some of the bonds span the borders of the unit cell, therefore, one also has to account for these periodic intramolecular contributions besides the intermolecular energy. To perform realistic crystal structure simulations, the force field has to maintain strict lattice periodicity throughout the calculations:

$$\vec{F}(\vec{r}) = \vec{F}(\vec{r} + i\vec{a} + j\vec{b} + k\vec{c}), \{i, j, k\} = 0, \pm1, \pm2. \tag{4}$$

For every part of a molecule that is not within the unit cell, a code is stored to update the positions of the atoms, forces, and charges from the central unit cell (analogous to

Equation 4). Therefore, all energies and forces are only-calculated only for the central unit cell, but under the influence of one or two shells of neighboring cells. Space group symmetry was not enforced, but the chemical shift constraints conserve the symmetry relations within the unit cell if two or more sites display the same chemical shift value.

Given the COSMOS force filed, NMR parameters are now introduced as constraints in the energy calculations. When searching for the most probable structure of a polyatomic molecule like a peptide, one has to find an energy minimum on a hypersurface possessing a vast multitude of minima. Every experimental constraint will limit the free configurational space and drive the system toward the genuine structure. Even with a large number of constraints we have to search for a global minimum on a multidimensional energy hypersurface. It is important to realize that the minimum structure will not be the most probable structure, because this will depend on Gibbs free energy, ΔG, containing not only the enthalpy but also the entropy. Broad shallow minima may thus be preferred because of the entropic term. Our NMR constraints, on the other hand, will contain an average over the most probable structures in solution or the solid state. Therefore, in most cases the experimental constraints will drive our molecular system energetically uphill.

BPT Pseudo-Forces

In order to obtain energetic corrections, the contribution of the bonds around nucleus A to the polarization energy has to be calculated [20]. The total energy can be approximated by

$$E = \sum_{\mathrm{A}} \sum_{i}^{i\in A} \left(2n_i E_0^i + n_i^2 \frac{\langle \chi_{\mathrm{A}}^i | \hat{V} | \chi_{\mathrm{A}}^i \rangle - \langle \chi_{\mathrm{B}}^i | \hat{V} | \chi_{\mathrm{B}}^i \rangle}{E_0 - E_{i*}} \right). \tag{5}$$

E_0^i are the energies of un-polarized bond contributions, E_0 is the total ground state energy of the molecular system, E_{i*} is the excited state energy for the polarized bond contribution i, and n_i is the occupation number. In a force field approach, we are only interested in relative energies and disregard the constant contributions, hence we introduce the molecular polarization energy E^{P} as well as the atomic polarization energy $E_{\mathrm{A}}^{\mathrm{P}}$

$$E^{\mathrm{P}} = \sum_{\mathrm{A}} \sum_{i}^{i\in A} n_i^2 \frac{\langle \chi_{\mathrm{A}}^i | \hat{V} | \chi_{\mathrm{A}}^i \rangle - \langle \chi_{\mathrm{B}}^i | \hat{V} | \chi_{\mathrm{B}}^i \rangle}{E_0 - E_{i*}} = \sum_{\mathrm{A}} E_{\mathrm{A}}^{\mathrm{P}} \tag{6}$$

The chemical shift can be expressed in terms of the atomic polarization energy [20]. By expanding it with respect to the chemical shift tensor $\delta_{\alpha\beta}^{\mathrm{theo}}$ around the experimental value $\delta_{\alpha\beta}^{\mathrm{exp}}$ and evaluating the gradient, the BPT pseudo-force can be deduced (for isotropic chemical shifts) as:

$$F_j = k^{\mathrm{CS}} (\delta^{theo} - \delta^{\mathrm{exp}}) \frac{\partial \delta^{theo}}{\partial x_j}. \tag{7}$$

The chemical shift derivatives can be calculated within the BTP approach mainly from the derivatives of the polarization energy integrals (see Equation 2). In this case, the force constant becomes

$$k^{CS} = \sum_{\mathrm{A}} \sum_{i}^{i\in A} \frac{2A_i^q}{n_i^2 (A_i^\delta)^2}. \tag{8}$$

The computational cost depends, to a first degree, on the charge calculation, which is proportional to the cube of the number of atoms, N^3. Calculations on systems of about 10^4 atoms are feasible within a day on current standard GHz machines.

Applications in Crystal Structure Refinement

Refinement of Proton Positions

The first application of the COSMOS–NMR force field to a crystallographic problem was the refinement of proton positions from ^{13}C chemical shifts [26]. Accurate proton positions are not so readily determined by X-ray diffraction, especially for large molecules, because protons have no core electrons. Even if there are good X-ray data available, the refinement of the proton sites using NMR chemical shifts will lead to better-defined structures, and can provide valuable insights into the formation of hydrogen bonds. In our first example of β-D-mannitol, both the high-resolution X-ray structure and the solid-state ^{13}C chemical shifts were known. The BPT calculations of the chemical shifts from the X-ray atomic positions gave a mean deviation from the experimental NMR data of 1.7 ppm, with a maximum difference of 2.7 ppm. A force field optimization of the protons, while keeping the positions of the heavy atoms unchanged, lead to a structure with an even larger mean deviation of 2.5 ppm for the calculated ^{13}C chemical shifts from their experimental values. Next, ^{13}C chemical shift pseudo-forces were switched on, to act only on the proton positions. Even though ^{13}C chemical shifts are used as target parameters, this does not mean that the pseudo-forces act only on the carbons. All atoms that contribute to the polarization of a carbon bond acquire pseudo-forces and can thus be influenced by the geometry optimization. The pseudo-forces were scaled in a range starting from 10^{-3} up to 10^3. Significant changes started

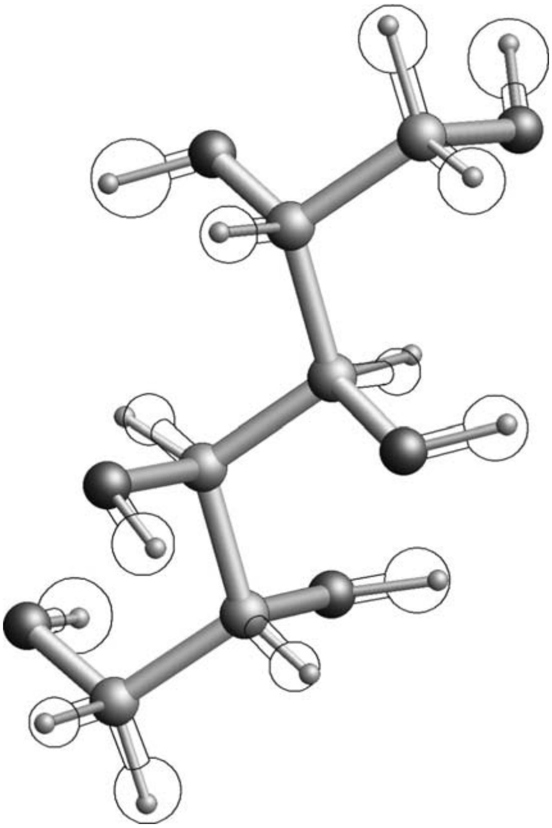

Fig. 1. Superposition of the X-ray structure of D-mannitol with its refinement from ^{13}C NMR chemical shifts. The 50% probability spheres of the protons from the X-ray investigation are shown for comparison.

to show up around 10^{-1}, and at for a scaling constant of 10^2 a lower limit of 0.02 ppm for the chemical shift difference is reached. Notably, the refined proton positions do not violate the limits of the X-ray diffraction, even if the pseudo-forces exceed all other force field energies. The average proton displacement parameter derived from the temperature factor is about 0.2 Å. The standard deviation of the NMR-refined structure with respect to the X-ray structure is only about 0.13 Å [26].

In Figure 1, the superposition of the X-ray and the porton-refined structure (scaling factor 1000) is shown. The spheres at the proton positions are the isotropic 50% probability ellipsoids. It is thus possible to refine crystal structures using chemical shifts as target functions, and thereby resolve structural features such as proton positions that are not well represented in diffraction investigations.

Structure of Cellulose Polymorphs from ^{13}C Chemical Shifts

The lack of crystalline order in polymers such as cellulose or silk fibers significantly reduces the number of interference spots in diffraction investigations, hence the patterns often cannot be analyzed unambiguously. In these cases, a crystal structure refinement using NMR chemical shifts will be of great value, because it does not require long-range crystalline order.

For cellulose three major polymorphs are known, namely natural occurring cellulose I_α and I_β, as well as regenerated cellulose II. When starting our investigations, good crystal structures had been published for cellulose II, while for the other polymorphs only preliminary models based on electron diffraction were available. Optimizations with ^{13}C chemical shift target functions succeeded to produce structures that fulfill the requirements of both the NMR and diffraction data [27]. It was thus demonstrated that some inner-chain hydrogen bonds induce geometry changes of the glycosidic linkage, which cause the C4 resonance to shift from an amorphous value of typically 75 ppm to the observed crystalline value of about 88 ppm. Since this chemical shift value is observed in all cellulose I and II polymorphs, it was concluded that their hydrogen bond patterns have to be similar. The chemical shift of the C4 carbon site can thus be taken as indicator of crystallinity for all three cellulose polymorphs [27].

Recently, native cellulose structures was re-investigated by Nishiyama *et al.* [28], using X-ray and neutron diffraction experiments. For the first time, data concerning the hydrogen bond network could be extracted, hence it was of interest to compare the diffraction results with newly refined NMR structures. 2D NMR investigations on ^{13}C-enriched bacterial cellulose made it possible to assign all six resonances of the glucose units, and moreover to obtain chemical shift anisotropy data [29]. Nishiyama *et al.* [28] had discussed two possible schemes of how the hydroxyl groups could form two alternative hydrogen bond networks. These two networks were proposed to coexist within the cellulose crystallites, and the authors presented occupation numbers for the alternative deuteron positions.

We used these two sets of data to derive two alternative structural models (A and B) with the COSMOS–NMR force field. There are furthermore two possibilities of assigning the two simultaneously observed sets of chemical shifts to the two glucose rings in the unit cell (designated with I and II), hence four sets of MD calculations had to be performed (see Table 1). To assess the stability of the hydrogen bond schemes and to clarify the glucose assignments, we ran 100 ps crystal dynamics simulations on each model, in which the coordinates and atomic charges were recalculated every 0.5 femtoseconds. The simulations

Table 1: Energy contributions and chemical shift differences of the original and chemical shift refined cellulose Iα structures

Structure and method	Hydrogen bond scheme	NMR assignment of glucose units	Van der Waals energy (kJ/mol)	Electrostatic energy (kJ/mol)	Pseudo-energy (kJ/mol)	Total energy (kJ/mol)	RMSD of CS values (ppm)
Neutron diffraction	A	I	40.4	−622.6	2970.4	161.8	5.4
		II			2991.0		5.4
CS optimized	A	I	67.0	−1369.1	71.0	−1111.6	0.83
		II	93.8	−1557.6	323.0	−1249.7	1.77
Neutron diffraction	B	I	71.1	65.2	3677.3	876.4	6.0
		II			3705.1		6.0
CS optimized	B	I	139.6	−1389.7	389.0	−1061.7	1.93
		II	77.9	−1624.8	702.8	−1294.6	2.61

were performed at 293 K to create structures near all minima that could be populated at room temperature. A total of 200 coordinate snapshots were sampled for geometry optimizations with ^{13}C isotropic chemical shifts as target functions. First, all structures were geometry optimized, and in a second step the chemical shift pseudo-forces were switched on.

The results of the optimization procedures are given in Table 1. The first remarkable observation is that for both hydrogen bond schemes, A and B, deep minima for the electrostatic and total energies are obtained, which makes a spontaneous conversion of the two forms at room temperature very unlikely. Since in most cases the chemical shift pseudo-forces drive the structures energetically uphill, we selected the most preferable structure according to the sum of the total and pseudo energies. The most favorable structural model thus corresponds to hydrogen bond scheme A and assignment I (A-I). This structure is moreover in 6th best position of all optimized MD conformations with respect to the total energy, and it has the lowest RMS deviation between the calculated and observed chemical shifts (see Table 1).

The drop in total energy in all cases where chemical shift pseudo-energies are applied, is a clear indication that the calculated chemical shifts are of high quality. After optimization we reach minima with small pseudo-energies and with chemical shift values that lie within the error range of the NMR experiment. The pseudo-energy of 71 kJ/mol is only about 5% of the electrostatic energy in the case of the A-I structure. To test the reliability of the chemical shift refined structured, a least-squares superposition of structure A-I onto the original neutron diffraction coordinates was performed. The RMSD of the two cellulose chain fragments is 0.51Å for all atoms, and this difference drops to 0.37 Å if only heavy atoms are considered (see Figure 2). Most atomic positions fall clearly within the error bounds of the fiber diffraction analysis.

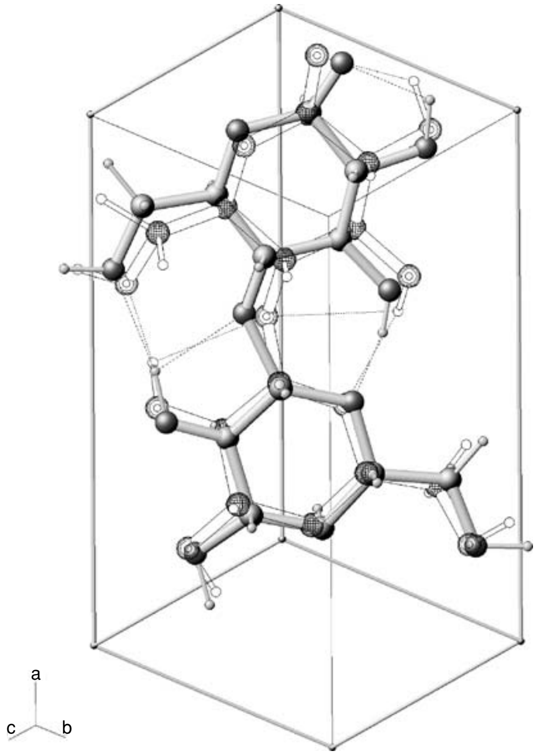

Fig. 2. Least-squares superposition of the cellulose I_α coordinates from neutron diffraction by Nishiyama *et al.* [28] (transparent model) together with the NMR-refined structure A-I (hydrogen bond scheme A and chemical shift assignment I, see Table 1) that was optimized according to chemical shift restraints. The RMSD for all atoms is 0.51 Å, and 0.37 Å for the carbon and oxygen atoms. (See also Plate 6 on page XX in the Color Plate Section.)

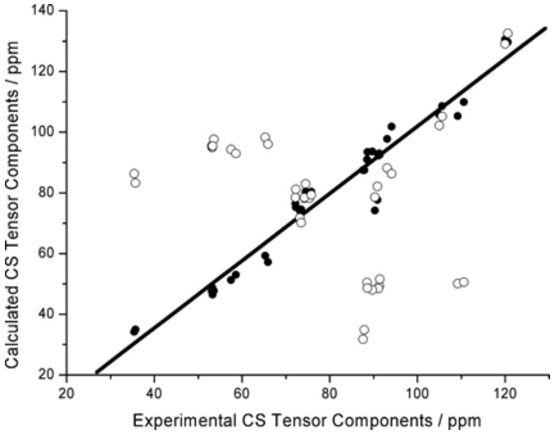

Fig. 3. Calculated principal ^{13}C chemical shift tensor components (δ_{11}, δ_{22}, δ_{33}) of cellulose I_α, plotted against the experimental values. The values after optimization with chemical shift-pseudo-forces are displayed as filled circles, while the result evaluated from the original (non-optimized) diffraction structure are open circles.

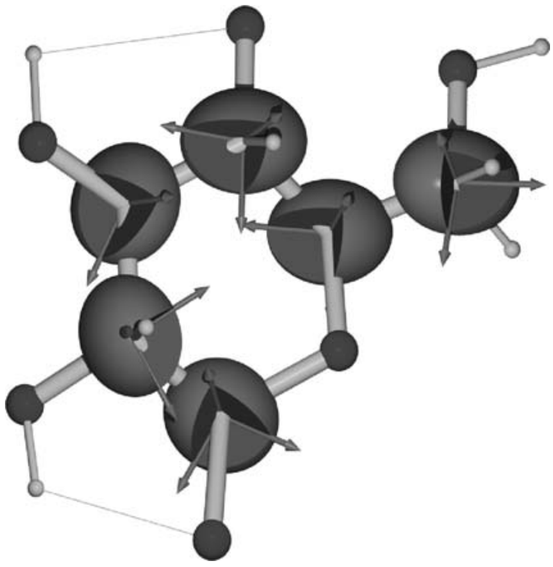

Fig. 4. Orientation of the ^{13}C chemical shift tensors in a glucose ring, calculated from a structure obtained by a geometry optimization with chemical shift boundary conditions. The δ_{33} principal axis components of the tensors (calculated by BPT) are nearly parallel with the C–O bond directions. In the case of carbon C1 with two neighboring oxygen atoms, the δ_{22} component lies on the bisector of the O–C–O angle. (See also Plate 7 on page XX in the Color Plate Section.)

Figure 3 shows an excellent correlation between the observed and calculated principal CS tensor components of all 12 carbons in the unit cell (filled circles). Notably, the chemical shift components derived from the original diffraction coordinates gave no correlation at all (open circles). This must be regarded as strong evidence for the validity of the new NMR-refined structure (see Figure 2). It has moreover been possible for the first time to derive the orientations of the individual chemical shift tensors in the molecular framework of the glucose rings, as illustrated in Figure 4.

Based on these chemical shift calculations, some characteristic rules for CS tensors in carbohydrates can be tested. As discussed by Koch *et al.* [30], for carbons carrying a hydroxyl group the principal component δ_{33} should be oriented along the C–O bond. As seen from Figure 4, the δ_{33} directions deviate only by a few degrees from the respective C–O bond directions. In the case of C1, which is bound to two oxygen atoms, the δ_{33} component lies within the O1–C1–O5 plane, and the δ_{22} direction is aligned with the bisector of the angle formed by the three atoms.

The Theory of Nuclear Spin–Spin Couplings

Hiroyuki Fukui
Kitami Institute of Technology, Kitami, Hokkaido, Japan

Introduction

One of the reasons for difficulties in explaining indirect nuclear spin–spin coupling constants is that this phenomenon has no analogs in classical physics. The main driving force for inducing nuclear spin–spin couplings in molecules is not electromagnetic interactions but the Pauli's exclusion principle, operating between electrons with the same spin. It was demonstrated that Fermi correlation, due to the Pauli's exclusion principle, can be considered to be the mechanism whereby distant atoms communicate with each other [1]. The indirect nuclear spin–spin coupling is described by the form of $J_{MN}\vec{I}_M \cdot \vec{I}_N$ in which $\vec{I}_M$ and $\vec{I}_N$ are the nondimensional nuclear spin vectors, and J_{MN} is called an isotropic nuclear spin–spin coupling constant [2,3]. J_{MN} has the units of hertz (2π rad/s) Unlike the direct interaction of magnetic dipoles, an energy of this sort of nuclear spin–spin coupling does not average out to zero when the molecules are rotating, so its effect still remains in the spectra of liquids. This fact indicates that the indirect nuclear spin–spin coupling comes from an indirect coupling mechanism via the electrons in the molecule. The indirect coupling mechanism between nuclear spins will be considered in the next section.

Origin of the Indirect Nuclear Spin–Spin Coupling Interaction

A full and successful theory of the indirect nuclear spin–spin coupling based on the complete Hamiltonian for electron–nuclear interactions was first outlined by Ramsey and Purcell [4] and developed in more detail in a later paper by Ramsey [5]. We will describe the origin of the indirect nuclear spin–spin coupling interaction below.

The electron–nuclear magnetic interactions come from the interactions between nuclear spins and electronic motions or electronic spins. The magnetic interactions in an electronic system are well described with the use of the relativistic Dirac equation [6,7]. Let us consider an electronic system consisting of one electron and two hypothetical nuclear spins which have the nuclear magnetogyric ratios, γ_M and γ_N, respectively, but do not possess nuclear charges. The time-independent Dirac equation for the electron is then given by

$$\begin{aligned}\Bigg\{\begin{bmatrix}0 & c\vec{\sigma}\\ c\vec{\sigma} & 0\end{bmatrix}\cdot\Big[&-i\hbar\vec{\nabla}+(\mu_0/4\pi)e\hbar\gamma_M r_M^{-3}\vec{I}_M\\ &\times\vec{r}_M+(\mu_0/4\pi)e\hbar\gamma_N r_N^{-3}\vec{I}_N\times\vec{r}_N\Big]\\ &+m_\mathrm{e}c^2\begin{bmatrix}0 & 0\\ 0 & -2\end{bmatrix}\Bigg\}\psi=E\psi,\end{aligned}\tag{1}$$

where $\vec{\sigma}$ is the 2×2 Pauli spin matrix vector. The three components of the $\vec{\sigma}$ vector are given by

$$\sigma_x=\begin{bmatrix}0 & 1\\ 1 & 0\end{bmatrix},\ \sigma_y=\begin{bmatrix}0 & -i\\ i & 0\end{bmatrix},\ \sigma_z=\begin{bmatrix}1 & 0\\ 0 & -1\end{bmatrix}.\tag{2}$$

$\vec{\sigma}$ is the double of the electronic spin vector $\vec{s}$, i.e. $\vec{\sigma} = 2\vec{s}\cdot$ μ_0 is the permeability of the vacuum, c is the velocity of light, and m_e and $-e$ are the rest mass and electronic charge of the electron, respectively. $\vec{r}_M$ and $\vec{r}_N$ are defined by $\vec{r}_M = \vec{r} - \vec{R}_M$ and $\vec{r}_N = \vec{r} - \vec{R}_N$, respectively, with the electronic position $\vec{r}$ and the nuclear positions, $\vec{R}_M$ and $\vec{R}_N$. The wave function ψ has four components, i.e. large two-component spinor ϕ_L (the first and second components of ψ) and small two-component spinor ϕ_S (the third and fourth components of ψ). Equation (1) is decomposed into the two component equations:

$$c\vec{\sigma}\cdot\vec{\pi}\phi_\mathrm{S}=E\phi_\mathrm{L}\tag{3}$$

and

$$c\vec{\sigma}\cdot\vec{\pi}\phi_\mathrm{L}-2m_\mathrm{e}c^2\phi_\mathrm{S}=E\phi_\mathrm{S},\tag{4}$$

where

$$\begin{aligned}\vec{\pi}&=-i\hbar\vec{\nabla}+(\mu_0/4\pi)e\hbar\gamma_M r_M^{-3}\vec{I}_M\times\vec{r}_M\\ &\quad+(\mu_0/4\pi)e\hbar\gamma_N r_N^{-3}\vec{I}_N\times\vec{r}_N.\end{aligned}\tag{5}$$

π is called the mechanical momentum of the electron.

In order to eliminate the small component ϕ_S, we solve Equation (4) for ϕ_S and obtain

$$\phi_\mathrm{S}=(2m_\mathrm{e}c^2+E)^{-1}c\vec{\sigma}\cdot\vec{\pi}\phi_\mathrm{L}.\tag{6}$$

Graham A. Webb (ed.), Modern Magnetic Resonance, 79–83.
© 2008 *Springer.*

We substitute Equation (6) into Equation.(3) and get

$$\left[\left(2m_{\mathrm{e}}c^2 + E\right)^{-1} c^2 \left(\vec{\sigma} \cdot \vec{\pi}\right)^2 - E\right]\phi_{\mathrm{L}} = 0. \tag{7}$$

Equation (7) gives us the energy of the system

$$E_{\pm} = -m_{\mathrm{e}}c^2 \pm \left[m_{\mathrm{e}}^2 c^4 + c^2(\vec{\sigma} \cdot \vec{\pi})^2\right]^{1/2}. \tag{8}$$

We are usually interested in the positive energy of the system. So we discard the negative energy E_- and keep the positive energy E_+ alone. We expand the positive energy E_+ in terms of a power series of the reciprocal velocity of light c^{-1}.

$$E_+ = (\vec{\sigma} \cdot \vec{\pi})^2/2m_{\mathrm{e}} - (\vec{\sigma} \cdot \vec{\pi})^4/8m_{\mathrm{e}}^3c^2 + O(c^{-4}) + \cdots. \tag{9}$$

The first term is the nonrelativistic energy of the system. The second term proportional to c^{-2} is the lowest order of relativistic correction to the energy. In this chapter, we consider only the nonrelativistic term and ignore the relativistic corrections to the energy.

Using the identity [6,7]

$$(\vec{\sigma} \cdot \vec{\pi})^2 = \vec{\pi}^{\,2} + i\vec{\sigma} \cdot \vec{\pi} \times \vec{\pi}, \tag{10}$$

we obtain

$$\begin{aligned} E_+ &= (\vec{\sigma} \cdot \vec{\pi})^2/2m_{\mathrm{e}} = -(\hbar^2/2m_{\mathrm{e}})\Delta \\ &\quad + (e^2/2m_{\mathrm{e}})(\vec{A}_M^2 + \vec{A}_N^2) + h_{MN}^{\mathrm{DSO}} + h_M^{\mathrm{PSO}} \\ &\quad + h_N^{\mathrm{PSO}} + h_M^{\mathrm{FC}} + h_N^{\mathrm{FC}} + h_M^{\mathrm{SD}} + h_N^{\mathrm{SD}}, \end{aligned} \tag{11}$$

where

$$\vec{A}_a = (\mu_0/4\pi)\hbar\gamma_a r_a^{-3}\vec{I}_a \times \vec{r}_a, \quad a = M \; or \; N, \tag{12}$$

$$\begin{aligned} h_{MN}^{\mathrm{DSO}} &= (\mu_0/4\pi)^2 \left(e^2\hbar^2/m_{\mathrm{e}}\right) \gamma_M \gamma_N r_M^{-3} r_N^{-3} \\ &\quad \times \left[\left(\vec{I}_M \cdot \vec{I}_N\right)\left(\vec{r}_M \cdot \vec{r}_N\right) - \left(\vec{I}_M \cdot \vec{r}_N\right)\left(\vec{I}_N \cdot \vec{r}_M\right)\right], \end{aligned} \tag{13}$$

$$\begin{aligned} h_a^{\mathrm{PSO}} &= 2(\mu_0/4\pi)\mu_{\mathrm{B}}\gamma_a r_a^{-3}\vec{I}_a \cdot \vec{l}_a, l_a = -i\hbar\vec{r}_a \times \vec{\nabla}, \\ a &= M \text{or} \; N, \end{aligned} \tag{14}$$

$$\begin{aligned} h_a^{\mathrm{FC}} &= (8\pi/3)(\mu_0/4\pi)\mu_{\mathrm{B}}\hbar\gamma_a\delta(\vec{r}_a)\vec{\sigma} \cdot \vec{I}_a, \\ a &= M \text{ or } N, \end{aligned} \tag{15}$$

$$\begin{aligned} h_a^{\mathrm{SD}} &= (\mu_0/4\pi)\mu_{\mathrm{B}}\hbar\,\gamma_a \Big[-r_a^{-3}\vec{\sigma} \cdot \vec{I}_a \\ &\quad + 3r_a^{-5}\left(\vec{\sigma} \cdot \vec{r}_a\right)\left(\vec{I}_a \cdot \vec{r}_a\right)\Big], \quad a = M \text{ or } N \end{aligned} \tag{16}$$

and

$$\mu_{\mathrm{B}} = e\hbar/2m_{\mathrm{e}}. \tag{17}$$

h^{DSO} and h^{PSO} are the diamagnetic spin orbital (DSO) and paramagnetic spin orbital (PSO) interactions, respectively. h^{FC} and h^{SD} are the Fermi contact (FC) and spin dipole (SD) interactions, respectively. μ_{B} is the Bohr magneton. In the calculation of $\vec{\pi} \times \vec{\pi}$ in Equation (10), we used the identity [7]

$$\begin{aligned} \nabla_u(r_u/r^3) &= (4\pi/3)\delta(\vec{r})\delta_{uv} + \delta_{uv}/r^3 - 3r_u r_v/r^5, \\ &(u, v \in \{x, y, z\}). \end{aligned} \tag{18}$$

The field-independent splitting of NMR lines, usually described in hertz, is due to the isotropic part J_{MN} of the indirect nuclear spin–spin coupling tensor $\hat{J}_{MN}$. The nuclear spin–spin coupling energy is written as $\sum_{uv} J_{MN,uv} I_{Mu} I_{Nv} (u, v \in x, y, z)$. The (u,v) component $J_{MN,uv}(u, v \in \{x, y, z\})$ of the tensor $\hat{J}_{MN}$ has five different contributions [5], all of which result from electron-coupled interactions between the two nuclear spin components, I_{Mu} and I_{Nv}. Four of these contributions are due to second-order perturbations and depend on the first-order wave function, whereas one contribution is due to a first-order perturbation type and can be expressed using only the zeroth-order wave function. Four of these contributions can be expressed as a sum-over-states (SOS) formula [8]

$$\begin{aligned} J_{MN,uv}^{\mathrm{AB}} &= h^{-1} \sum_{m>0} \left[\frac{\langle 0 \,|H_{M,u}^{\mathrm{A}}|\, m\rangle\langle m \,|H_{N,v}^{\mathrm{B}}|\, 0\rangle}{E_0 - E_m} \right. \\ &\quad \left. +(1 - \delta_{\mathrm{AB}})\frac{\langle 0 \,|H_{M,u}^{\mathrm{B}}|\, m\rangle\langle m \,|H_{N,v}^{\mathrm{A}}|\, 0\rangle}{E_0 - E_m} \right] + \mathrm{C.C.}, \end{aligned} \tag{19}$$

where $|0\rangle$ and $|m\rangle$ represent the many-electron ground and excited states of the unperturbed system, respectively. C.C. means the complex conjugate of the former term. A and B represent the type of interaction Hamiltonians, that is, the PSO, FC, and SD interactions whose one-electron interaction operators are given by Equations (14)–(16). The isotropic part J_{MN} is equal to the diagonal average of the tensor, i.e. $(J_{MN,xx} + J_{MN,yy} + J_{MN,zz})/3$. The FC and SD interactions have matrix elements between the singlet ground state and the triplet excited states, whereas the PSO term has matrix elements between the singlet ground and excited states. So we have the four possible combinations of FC–FC, SD–SD, FC–SD, and PSO–PSO contributing to $J_{MN,uv}$. The FC–FC contribution is fully isotropic, namely, all the diagonal elements of the FC–FC contribution are equal to each other, and all the off-diagonal elements of it are zero. On the other hand, the FC–SD contribution is fully anisotropic and makes no contributions to the isotropic part. The other two combinations, SD–SD and PSO–PSO, yield both isotropic and anisotropic contributions. The last contribution to the tensor component $J_{MN,uv}$ is the DSO term, which is of a different form, being an average value in the ground state of the interaction Hamiltonian $H^{\mathrm{DSO}}_{MN,uv}$ whose one-electron interaction operator is given by Equation (13).

Quantum electrodynamics (QED) [9] tells us that the electronic spin magnetic moment should be changed from $-\mu_{\mathrm{B}}\vec{\sigma}$ to the $-g_{\mathrm{e}}\mu_{\mathrm{B}}\vec{s}$ [7], where g_{e} is called the electronic g factor. The Dirac equation gives us a g_{e} value of exactly 2. However, the QED corrected g_{e} value is

$$\begin{aligned} g_{\mathrm{e}} &= 2 + (\alpha/\pi) - 0.65696(\alpha/\pi)^2 + 1.49(\alpha/\pi)^3 \\ &\quad + O((\alpha/\pi)^4) + \ldots = 2.02319, \end{aligned} \tag{20}$$

where

$$\alpha = e^2/4\pi\varepsilon_0\hbar c = 1/137.0359895. \tag{21}$$

The nondimensional constant α is called the fine structure constant. The four kinds of one-electron interaction operators can be easily written using Equations (13)–(16). The nonrelativistic unperturbed Hamiltonian H_0 is written as

$$H_0 = \sum_k h^{(0)}(k) + \sum_{k<1} \left(e^2/4\pi\varepsilon_0 r_{kl}\right), \tag{22}$$

where

$$h^{(0)}(k) = -\left(\hbar^2/2m_{\mathrm{e}}\right)\Delta_k - \sum_{\mathrm{A}} \left(Z_{\mathrm{A}} e^2/4\pi\varepsilon_0 r_{\mathrm{A}k}\right). \tag{23}$$

Z_{A} is the atomic number of nucleus A. For simplicity, atomic units (au) are used from now, that is,

$$e = 1,\ \hbar = 1,\ m_{\mathrm{e}} = 1,\ 4\pi\varepsilon_0 = 1,\ \mu_0/4\pi = \alpha^2. \tag{24}$$

Coupled Hartree–Fock Approximation

It was stated in the previous section that the nuclear spin–spin coupling tensor components $J_{MN,uv}$ are generally given as the sum of the five different contributions. The calculation of the DSO contribution of the first-order perturbation type is trivial. It can be straightforwardly evaluated following the numerical integration method by Matsuoka and Aoyama [10]. On the other hand, the calculation of the other four contributions of the second-order perturbation type is not easy. So most efforts at calculating the nuclear spin–spin couplings have been devoted to computation of the four contributions of the second-order type, especially to the evaluation of the FC contribution. It is well known that the FC term predominates in the isotropic coupling constants of H–H and C–H in most organic compounds [11,12]. However, the FC contribution to the nuclear spin–spin couplings is one of the most difficult quantities to be evaluated in quantum chemistry because the electronic behavior at the nuclear positions is not described well by most commonly used approximate molecular wave functions based on Gaussian basis sets. In this section, the coupled Hartree–Fock (CHF) method is introduced to calculate the four contributions of the second-order type at the Hartree–Fock (HF) level.

The M–N nuclear spin–spin coupling tensor element $J^{\mathrm{AB}}_{MN,uv}$ due to the A–B type interaction is given by

$$\begin{aligned} J^{\mathrm{AB}}_{MN,uv} = h^{-1} \Bigg\{ & \left[\frac{\partial^2 \left\langle 0 \left| H(\lambda_{\mathrm{A}} H^{\mathrm{A}}_{M,u}, \lambda_{\mathrm{B}} H^{\mathrm{B}}_{N,v}) \right| 0 \right\rangle}{\partial\lambda_{\mathrm{A}}\partial\lambda_{\mathrm{B}}} \right]_{\lambda_{\mathrm{A}}=0,\lambda_{\mathrm{B}}=0} \\ & + (1-\delta_{\mathrm{AB}}) \left[\frac{\partial^2 \langle 0 |\, H(\lambda_{\mathrm{B}} H^{\mathrm{B}}_{M,u}, \lambda_{\mathrm{A}} H^{\mathrm{A}}_{N,v})\, | 0 \rangle}{\partial\lambda_{\mathrm{A}}\partial\lambda_{\mathrm{B}}} \right]_{\lambda_{\mathrm{A}}=0,\lambda_{\mathrm{B}}=0} \Bigg\}, \end{aligned} \tag{25}$$

where λ_{A} and λ_{B} are the nondimensional perturbation parameters. Here,

$$H\left(\lambda_{\mathrm{A}} H^{\mathrm{A}}_{M,u}, \lambda_{\mathrm{B}} H^{\mathrm{B}}_{N,v}\right) = H_0 + \lambda_{\mathrm{A}} H^{\mathrm{A}}_{M,u} + \lambda_{\mathrm{B}} H^{\mathrm{B}}_{N,v}, \tag{26}$$

In the condition that the molecular spin orbitals are determined variationally, the Hellmann–Feynman theorem reduces Equation (25) to a simpler form

$$\begin{aligned} J^{\mathrm{AB}}_{MN,uv} = h^{-1} \Bigg\{ & \left[\frac{\partial}{\partial\lambda_{\mathrm{B}}} \left\langle 0 \left| H^{\mathrm{A}}_{M,u} \right| 0 \right\rangle \right]_{\lambda_{\mathrm{B}}=0} \\ & + (1-\delta_{\mathrm{AB}}) \left[\frac{\partial}{\partial\lambda_{\mathrm{B}}} \right] \left\langle 0 \left| H^{\mathrm{A}}_{N,v} \right| 0 \right\rangle_{\lambda_{\mathrm{B}}=0} \Bigg\}, \end{aligned} \tag{27}$$

where $|0\rangle$ is the single Slater determinant for the ground state of the perturbed Hamiltonian, $H = H_0 + \lambda_{\mathrm{B}} H^{\mathrm{B}}_{N,v}$ or $H = H_0 + \lambda_{\mathrm{B}} H^{\mathrm{B}}_{M,u}$. The perturbed self-consistent field (SCF) spin orbitals $\psi(\lambda_{\mathrm{B}})(p = 1, 2, \ldots)$ are the eigenfunctions of the perturbed Fock operator $\hat{f}(\lambda_{\mathrm{B}})$ for the system whose Hamiltonian is $H_0 + \lambda_{\mathrm{B}} H^{\mathrm{B}}_{N,v}$ or $H_0 + \lambda_{\mathrm{B}} H^{\mathrm{B}}_{M,u}$. The perturbed occupied spin orbitals $\psi_i(\lambda_{\mathrm{B}})(i = 1, 2, \ldots, K)$ can be expanded as

$$\begin{aligned} \psi_i(\lambda_{\mathrm{B}}) = \psi_i^{(0)} + \lambda_{\mathrm{B}} \psi^{(1)}_{i,\mathrm{B}} = \psi_i^{(0)} \\ + \lambda_{\mathrm{B}} \sum_a^{\mathrm{unocc}} d^{\mathrm{B}}_{ai} \psi_a^{(0)}, \quad (i = 1, 2, \ldots, K), \end{aligned} \tag{28}$$

where K is the number of electrons in the system. K must be even here. $\psi_a^{(0)}(a = K+1, K+2, \ldots)$ are the unperturbed unoccupied spin orbitals. Using the unperturbed orbital energies $\varepsilon^{(0)}$, the coefficients d_{ai}^{B} can be determined by

$$\left(\varepsilon_a^{(0)} - \varepsilon_i^{(0)}\right) d_{ai}^{\mathrm{B}} + \sum_{j=1}^{K} \sum_{b=K+1}^{L} \times\left[\langle aj \,||\, ib\rangle\, d_{bj}^{\mathrm{B}} + \langle ab|\,|ij\rangle\, d_{bj}^{\mathrm{B}*}\right] = -\left\langle \psi_a^{(0)} \left|h^{\mathrm{B}}\right| \psi_i^{(0)}\right\rangle, \quad (i = 1, 2, \ldots, K), \tag{29}$$

where h^{B} is $h_{N,v}^{\mathrm{B}}$ or $h_{M,u}^{\mathrm{B}}$, and L is equal to the double of the number of used basis functions. The CHF formula for the tensor component $J_{MN,uv}^{\mathrm{AB}}$ is given by

$$J_{MN,uv}^{\mathrm{AB}} = h^{-1} \sum_{i=1}^{K} \sum_{a=N+1}^{L} \left[\left\langle \psi_i^{(0)} \left|h_{M,u}^{\mathrm{A}}\right| \psi_a^{(0)}\right\rangle d_{ai}^{\mathrm{B}}(N, v) + (1 - \delta_{\mathrm{AB}})\left\langle \psi_i^{(0)} \left|h_{N,v}^{\mathrm{A}}\right| \psi_a^{(0)}\right\rangle d_{ai}^{\mathrm{B}}(M, u)\right] + \mathrm{C.C.} \tag{30}$$

Triplet Instability of Coupled Hartree–Fock Calculation

It is noted that the PSO interaction operator is imaginary and spin independent, the FC one is real and spin dependent, and the SD one is complex and spin dependent. The expansion coefficients $d_{ai}^{\mathrm{B}}(N, v)$s have the same property as the type B interaction operator $h_{N,v}^{\mathrm{B}}$. Therefore, we obtain for example

$$d_{ai}^{\mathrm{B}\alpha} = d_{ai}^{\mathrm{B}\beta} = -d_{ai}^{\mathrm{B}\alpha*} = -d_{ai}^{\mathrm{B}\beta*} \text{ for B } = \text{PSO} \tag{31a}$$

$$d_{ai}^{\mathrm{B}\alpha} = -d_{ai}^{\mathrm{B}\beta} = d_{ai}^{\mathrm{B}\alpha*} = -d_{ai}^{\mathrm{B}\beta*} \quad \text{for } v = z \text{ when B} = \text{FC}. \tag{31b}$$

The diagonal elements of the coefficient matrix (the coefficient of $d_{ai}^{\mathrm{B}\alpha}$) for the simultaneous equations Equation (29) for $h_{N,z}^{\mathrm{FC}}$ are given by $\Delta_{ia}(\mathrm{FC}) = \left[\varepsilon_a^{(0)} - \varepsilon_i^{(0)} - (aa|ii) - (ai|ai)\right]$ where

$$(pq|rs) = \int \psi_p^{(0)*}(1)\psi_q^{(0)}(1)r_{12}^{-1}\psi_r^{(0)*}(2)\psi_s^{(0)}(2)\mathrm{d}\tau_1\, \mathrm{d}\tau_2. \tag{32}$$

It is well known that $\Delta_{ia}(\mathrm{FC})$ yields a triplet excitation energy which is too small, especially for molecules having multiple bonds such as C_2H_4, C_2H_2, etc. Sometimes $\Delta_{ia}(\mathrm{FC})$ becomes negative and the CHF calculation gives us meaningless results [13]. This phenomenon is called the "triplet instability."

Electron Correlation Effects

The triplet instability is due to the lack of electron correlation effects in the HF level calculations. It is known that the electron correlation effects for overcoming the triplet instability are introduced by the multiconfigurational self-consistent field (MCSCF) theory [14] or the coupled-cluster (CC) approach [15–19]. One of the most powerful methods for overcoming the triplet instability is the MCSCF calculation for the FC and SD terms. The first MCSCF calculation of the FC contribution to nuclear spin–spin couplings was performed by Laaksonen *et al.* [20] with the finite perturbation theory (FPT) in which the second-order derivatives of the electronic energy are evaluated numerically. The analytical differentiation of the MCSCF energy is carried out with the use of multiconfigurational self-consistent field linear response (MCLR) theory [14]. The linear response theory is called the propagator theory [21]. For interaction operators P and Q, the linear response function may be written as

$$\langle\langle p; q\rangle\rangle E = [P_1, P_2] \times \begin{bmatrix} ES - A & E\Delta - B \\ -E\Delta^* - B & -ES^* - A^* \end{bmatrix}^{-1} \begin{bmatrix} Q_1 \\ Q_2 \end{bmatrix}. \tag{33}$$

If we define two operators $q_v^+ = a_r^+ a_s$ and $K_n^+ = |n\rangle\,\langle 0|$ for the condition of $r > s$ and $n > 0$,

$$(P_1)_{vn} = \left[\langle 0 \left|\left[P, q_v^+\right]\right| 0\rangle \langle 0 \left|\left[P, K_n^+\right]\right| 0\rangle\right], \tag{34a}$$

$$(P_2)_{vn} = \left[\langle 0 \left|[P, q_v]\right| 0\rangle\; \langle 0 \left|[P, K_n]\right| 0\rangle\right], \tag{34b}$$

$$(Q_1)_{vn} = \begin{bmatrix} \langle 0|[q_v, Q]|0\rangle \\ \langle 0|[K_n, Q]|0\rangle \end{bmatrix},$$

$$(Q_2)_{vn} = \begin{bmatrix} \langle 0|[q_v^+, Q]|0\rangle \\ \langle 0|[K_n^+, Q]|0\rangle \end{bmatrix}, \tag{35}$$

$$(S)_{vn,v'n'} = \begin{bmatrix} \left\langle 0\middle|\left[q_v, q_{v'}^+\right]\middle|0\right\rangle & \left\langle 0\middle|\left[q_v, K_{n'}^+\right]\middle|0\right\rangle \\ \left\langle 0\middle|\left[K_n, q_{v'}^+\right]\middle|0\right\rangle & \left\langle 0\middle|\left[K_n, K_{n'}\right]\middle|0\right\rangle \end{bmatrix}, \tag{36}$$

$$(\Delta)_{vn,v'n'} = \begin{bmatrix} \langle 0|[q_v, q_{v'}]|0\rangle & \langle 0|[q_v, K_{n'}]|0\rangle \\ \langle 0|[K_n, q_{v'}]|0\rangle & \langle 0|[K_n, K_{n'}]|0\rangle \end{bmatrix}, \tag{37}$$

$$(A)_{vn,v'n'} = \begin{bmatrix} \left\langle 0\middle|\left[q_v, \left[H_0, q_{v'}^+\right]\right]\middle|0\right\rangle & \left\langle 0\middle|\left[\left[q_v, H_0\right], K_{n'}^+\right]\middle|0\right\rangle \\ \left\langle 0\middle|\left[K_n, \left[H_0, q_{v'}^+\right]\right]\middle|0\right\rangle & \left\langle 0\middle|\left[K_n, \left[H_0, K_{n'}^+\right]\right]\middle|0\right\rangle \end{bmatrix}, \tag{38}$$

and

$$(B)_{\nu n,\nu' n'} = \begin{bmatrix} \langle 0|[q_\nu, [H_0, q_{\nu'}]]|0\rangle & \langle 0|[[q_\nu, H_0], K_{n'}]|0\rangle \\ \langle 0|[K_n, [H_0, q_{\nu'}]]|0\rangle & \langle 0|[K_n, [H_0, K_{n'}]]|0\rangle \end{bmatrix}. \quad (39)$$

The CC method is an attempt to introduce interactions among electrons within a cluster and to permit the wave function to contain all possible "disjoint couplings" among the clusters. The second-order correction to the wave function due to quadruply excited configurations arises as products of doubly excited configurations. This is an example of disjoint couplings among the two-electron clusters. We write the exact ground state wave function $|0\rangle$ of the system Hamiltonian H as

$$|0\rangle = e^T |\phi_0\rangle , \quad (40)$$

where T is called a cluster operator and $|\phi_0\rangle$ is the normalized HF wave function. It is now assumed that the wave function $|0\rangle$ satisfies the intermediate normalization condition, $\langle\phi_0|0\rangle = 1$. For a system containing an even number of electrons $2n$, the cluster operator T generates one-, two-, ..., $2n$ electron clusters:

$$T = T_1 + T_2 + \cdots + T_{2n}, \quad (41)$$

where T_k is the k-electron cluster. The CC energy E of the ground state is determined by the Schrödinger equation

$$He^T |\phi_0\rangle = Ee^T |\phi_0\rangle , \quad (42)$$

from which the system energy is given by

$$E = \left\langle 0 \left| e^{-T} He^T \right| \phi_0 \right\rangle , \quad (43)$$

or

$$E = \left\langle \phi_0 \left| He^T \right| \phi_0 \right\rangle . \quad (44)$$

An analytical differentiation of the CC energy E is obtained by using the equation-of-motion coupled-cluster (EOM-CC) method [22] or the coupled-cluster polarization propagator (CCPPA) method [23]. As the start of the EMO-CC approach, Perera *et al.* [22] assumed that

$$\langle 0| = \langle\phi_0| (e^T)^\dagger = \langle\phi_0| (1 + \Lambda), \quad (45)$$

where Λ is the de-excitation operator. It is assumed that the energy functional

$$E = \langle\phi_0| (1 + \Lambda)e^{-T} He^T |\phi_0\rangle \quad (46)$$

is variational under the condition that

$$\langle\phi_0 |(1 + \Lambda)| \phi_0\rangle = 1.$$

The operator Λ is expanded as $\Lambda = \Lambda_1 + \Lambda_2 + \cdots + \Lambda_{2n}$. The operator Λ is determined variationally using the stationary condition of E. The CCPPA uses the linear response function in the framework of perturbation theory at the level of CC approximation. The detail is shown elsewhere [24].

Fibrous Proteins

Investigation of Collagen Dynamics by Solid-State NMR Spectroscopy

Göran Zernia and Daniel Huster
Junior Research Group “Solid-State NMR Studies of Membrane-Associated Proteins”, Biotechnological Biomedical Centre, Institute of Medical Physics and Biophysics, University of Leipzig, D-04107 Leipzig, Germany

Introduction

Collagen is the most abundant protein on the earth. It is found in many different tissues of animals and humans. The major property of collagen is to provide tensile strength to tissues such as tendons, ligaments, skin, cartilage, blood vessels, and bone [1].

The remarkable tensile strength of collagen can be understood from its unique secondary structure. The polypeptide chain of collagen forms a slightly twisted left-handed helix with three amino acids per turn. Three collagen chains are coiled together to form the three-stranded collagen triple helix. In the amino acid sequence of each polypeptide chain, every third residue is glycine (Gly). In the triple helix, the Gly residues of two chains come in close proximity to form a hydrogen bond. This structural arrangement is too dense to allow a larger side chain explaining the high Gly content of collagen. Further, collagen consists of approximately 21% proline (Pro) and hydroxyproline (HyPro). These amino acids impart rigidity and stability to the structure, especially by hydrogen bonds between the hydroxyl groups of HyPro. Together with 9% alanine (Ala) and 5% glutamic acid (Glu), these five amino acids account for about 70% of all the residues in collagen. Collagen forms fibrils, which are superstructures of collagen triple helices. The individual structure of this arrangement determines the tensile strength of collagen. The collagen triple helices are linked by covalent lysine–hydroxylysine bridges [1,2].

There are about 30 structural variants of collagen depending on the function of the respective tissue. The most relevant species are collagen type I (as found in bone, tendon, or ligament) and type II (as found in cartilage). Each collagen type has a slightly different amino acid sequence [1].

A characteristic feature of many biological tissues are the viscoelastic properties. Tendons, ligaments, or cartilage must respond quickly, robustly, and reversibly to deformations caused by mechanical load or dynamic stresses [3]. These elastic properties of many biological tissues are a consequence of the structural arrangement of fibrillar collagen and proteoglycans. The versatile molecular dynamics of these different macromolecules, the osmotic pressure, and the flow of aqueous tissue fluids represent the physical basis of the unique viscoelasticity of these tissues. Therefore, to cope with the various compressive stresses, acting on the tissue, these molecules undergo dynamic reorientations of very different geometries within a broad time window [3]. A sketch of the molecular organization in articular cartilage is given in Figure 1.

NMR techniques have been successfully applied to investigate the macromolecular species in tissues and to describe their dynamic properties. This short review focuses on the application of solid-state NMR methods to investigate the dynamical properties of isolated and tissue collagen. Solid-state NMR methods have to be applied since collagen is largely rigid due to its fibrillar structure and large molecular weight. Therefore, the anisotropic NMR interactions such as the chemical shift anisotropy and dipolar couplings are not averaged out by motions and the NMR spectra show the characteristic orientation dependence of the NMR frequency that is observed for solid materials. Solid-state NMR spectroscopy has unique capabilities for studying the molecular dynamics with correlation times from picoseconds to seconds by relaxation time measurements, lineshape analysis, or exchange methods [4,5]. All molecular motions are studied in the absence of an overall tumbling of the molecules that is present in solution NMR and might interfere with the motional analysis [6].

In this chapter, we will discuss static and magic angle spinning (MAS) solid-state NMR methods that have been applied to investigate the dynamics of tissue collagen. Further, recent data of our ongoing research on the dynamics of cartilage collagen will be discussed.

Investigation of Collagen Dynamics by Static Solid-State NMR

First NMR studies on collagen have been published by Torchia and co-workers [7,8]. Because of the rigidity of collagen fibrils, solution NMR fails to resolve their signals and solid-state NMR methods are most appropriate to

Graham A. Webb (ed.), Modern Magnetic Resonance, 87–92.

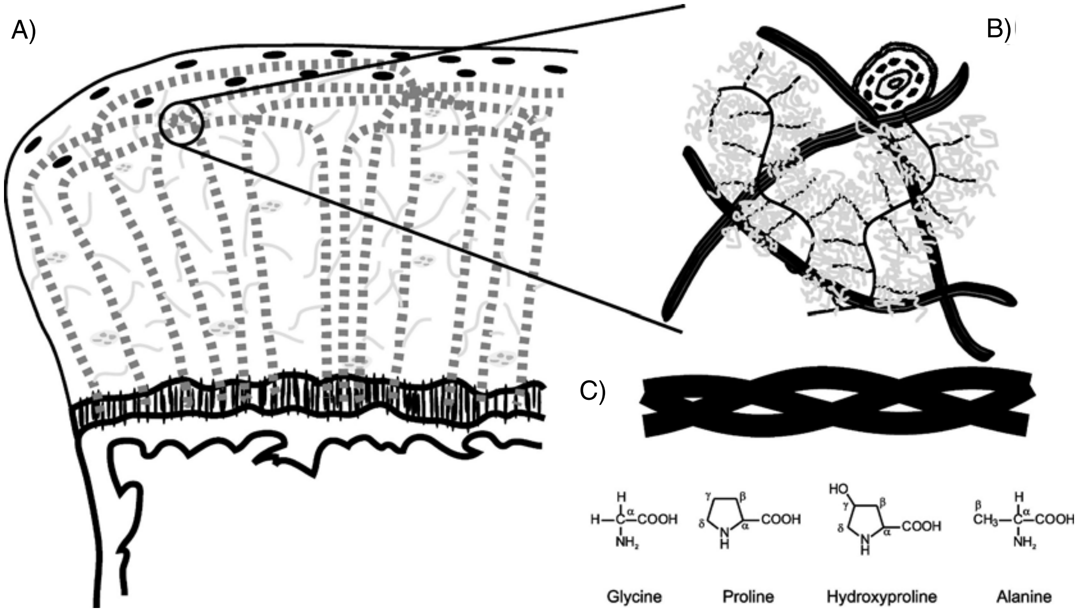

Fig. 1. (A) Schematic structure of articular cartilage with collagen molecules (green) and proteoglycans. (B) Proteoglycans consist of a strand of hyaluronic acid (red), to which a core protein (black) is attached. On the core protein, glycosaminoglycans (blue) such as chondroitin sulfate and keratan sulfate are covalently bound in a bottle-brush fashion. (C) The typical triple helix structure of collagen molecules and the chemical structure of the major amino acids in collagen are depicted. (See also Plate 8 on page XX in the Color Plate Section.)

study these molecules. Typically, solid-state NMR spectra of large molecules consist of a superposition of many broad anisotropic lineshapes that cannot be resolved in one dimension. Therefore, selective isotopic labeling is a prerequisite for any further analysis of the NMR spectra. To this end, collagen fibrils were labeled in animal tissue cultures. ^{2}H-, ^{13}C-, ^{15}N-, or ^{19}F-labeled amino acids were fed or injected to rats, chicken, or rabbits [9]. Thus, isotopically labeled collagen was produced and isolated from tendon, calvaria, tail, or sternum of those animals.

Besides structural data, the static solid-state NMR lineshapes contain information about the dynamics of a respective site. Since molecular motions decrease the strength of anisotropic interactions, they partially or fully abolish the orientation dependence of the NMR frequency. Therefore, lineshape measurements are sensitive both to the amplitude and to the correlation time of the molecular motions. Consequently, the presence of fast motions leads to a reduction of the width of the anisotropic spectrum.

Amplitudes and correlation times of motions can be determined from ^{2}H NMR spectra. The deuterium electric field gradient tensor is axially symmetric along the C–D bond, which simplifies the analysis. For the analysis, experimental ^{2}H NMR spectra are compared to simulated spectra that are calculated by applying a specific motional model. In particular, side chain motions have been studied by ^{2}H NMR spectroscopy. Using collagen molecules with ^{2}H-labeled Ala, leucine (Leu), Pro, or methionine (Met), these spectra showed typical features of motionally averaged lineshapes at ambient temperature [10–13]. Only at low temperature, the characteristic Pake spectra with the full quadrupolar splitting were detected. Application of a two-site jump hop for the Ala side chains in chick calvaria collagen revealed fast reorientations of the Cα–Cβ bond vector over an angle of $\sim 30^\circ$ with a correlation time $\sim 10^{-7}$ s [11,13]. Fast two-site exchange with an amplitude of $\sim 55^\circ$ and a correlation time of 8×10^{-7} s were also found for Leu side chains [10]. For Pro and HyPro puckering motions have been identified from the ^{2}H NMR spectra with root mean square amplitudes in the 11°–30° range [12]. A typical example of static ^{2}H NMR lineshapes for [^{2}H$_{10}$] Leu-labeled collagen as a function of temperature is given in Figure 2.

The backbone motions of collagen molecules have been investigated by static ^{13}C solid-state NMR methods using ^{13}CO Gly-labeled collagen. Similar to ^{2}H NMR lineshapes, anisotropic ^{13}C NMR spectra contain information about motional amplitudes and provide at least an upper limit for the correlation times. Root mean square amplitudes of 41°, 33°, and 14° were calculated for the backbone motions in uncross-linked, cross-linked, and mineralized collagen, respectively [14]. These findings

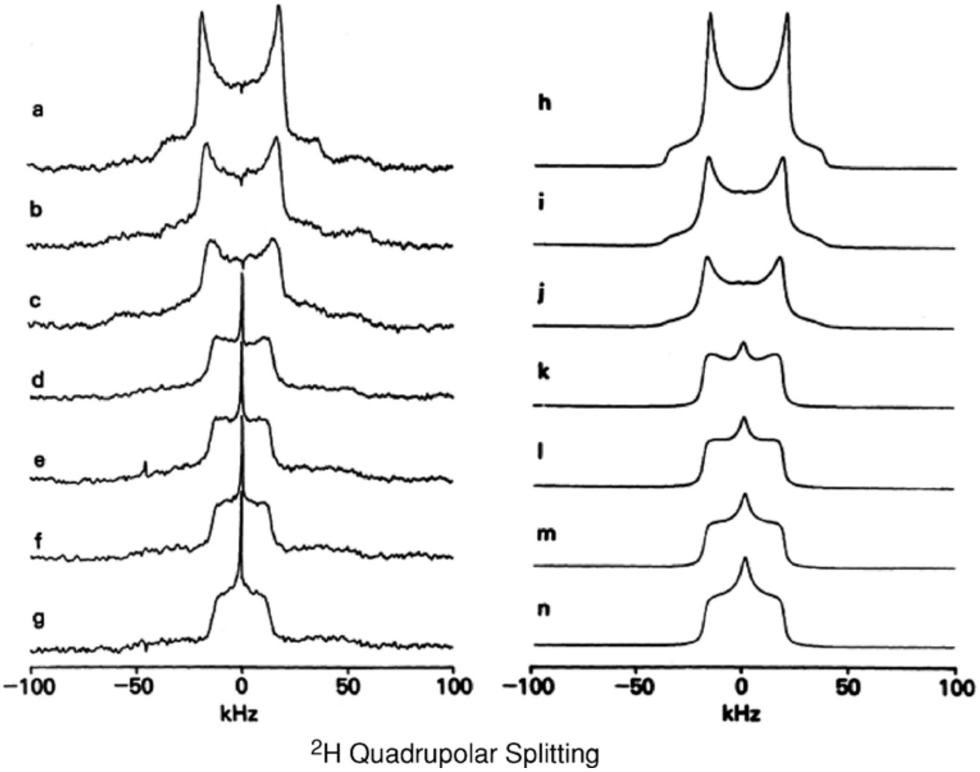

Fig. 2. Static ^{2}H NMR lineshapes of collagen to determine side chain mobility in [$^2H_{10}$] Leu-labeled collagen. The left column shows 38.5 MHz ^{2}H NMR spectra of [$^2H_{10}$] Leu-labeled collagen at various temperatures (a, −85 °C; b, −43 °C; c, −18 °C; d, −6 °C; e, +1 °C; f, +15 °C; g, +30°C). In the right column, lineshape simulations of the experimental spectra are displayed. These simulations assume a two-site hop model in which the Cγ–Cδ bond axes are assumed to hop between two sites separated by 108°–112° and κ defines the hopping rate (h, $\kappa \leq 6 \times 10^3$ rad/s; i, $\kappa = 1.9 \times 10^4$ rad/s; j, $\kappa = 3.1 \times 10^4$ rad/s; k, $\kappa = 3.7 \times 10^5$ rad/s; l, $\kappa = 6.3 \times 10^5$ rad/s; m, $\kappa = 8.7 \times 10^5$ rad/s; n, $\kappa = 1.2 \times 10^6$ rad/s). Reproduced with permission from Ref. [10].

were derived from the anisotropic carbonyl chemical shift tensor measurements indicating that the upper limit for the correlation times of these motions is 10^{-4} s. In addition to these somewhat slower motions, relaxation studies on collagen labeled with ^{13}Cα Gly revealed fast motions with correlation times in the 1–5 ns range exhibiting small amplitudes of 10°, 9°, and 5.5° uncross-linked, cross-linked, and mineralized collagen, respectively [15]. Because of their very fast correlation times, these motions must be segmental. While there is an obvious dependence of the backbone motion on the degree of cross-linking and mineralization, the side chain motions are only slightly affected by mineralization of collagen [12].

Recently, the static NMR data from the Torchia group have been reanalyzed and interpreted in terms of a librational rod model [16]. This analysis revealed that the ^{2}H NMR data are also consistent with small-angle librations about internal bond directions.

Application of CP MAS Methods to Study the Molecular Properties of Collagen

While static solid-state NMR spectra are broad and typically signals of only one or very few sites can be resolved in one dimension, MAS methods allow to resolve many relatively sharp signals at once. The first applications of cross-polarization (CP) MAS solid-state NMR methods have been demonstrated by the groups of Schaefer [17] and Saitô [18,19]. By application of MAS, the spectral intensity of the broad anisotropic solid-state NMR spectra is collected into a sharp central band of a line width on the order of one or a few ppm and a series of spinning sidebands. The number and intensity of spinning sidebands depends on the MAS frequency and the Larmor frequency of the NMR spectrometer. Thus, relatively well-resolved ^{13}C NMR spectra from isolated collagen samples have been obtained at natural abundance. The NMR signals of

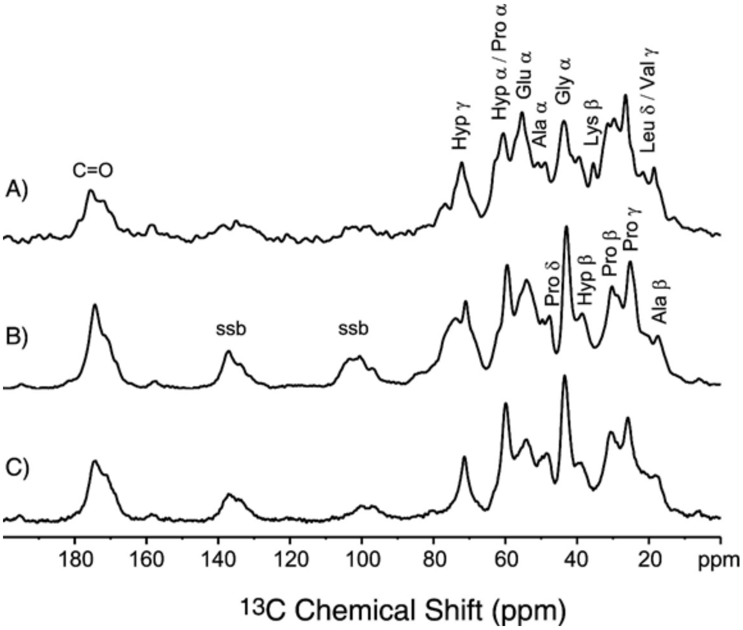

Fig. 3. Proton decoupled 188.6 MHz ^{13}C CP MAS spectra of fully hydrated porcine articular cartilage (A), dried porcine articular cartilage (B), and dry collagen type II (C) at a MAS frequency of 7 kHz and a temperature of 37 °C. The amino acid assignment is given. Spectra were externally calibrated with respect to TMS.

^{13}C CP MAS spectra could be assigned to the most abundant amino acids in collagen (Gly, Ala, Pro, HyPro, and Glu) [18]. Further, in comparison to dry collagen spectra, sharper lines have been detected in hydrated collagen indicating the presence of fast motions [19]. Thus, besides cross-linking and the degree of mineralization, the level of hydration seems to be a determining factor for the molecular mobility of collagen in tissue. This is also consistent with the static NMR spectra that indicated that the collagen dynamics is dependent on the state of the surrounding water [16].

Therefore, a systematic investigation of collagen mobility as a function of hydration has been carried out by ^{13}C CP MAS techniques [20]. While anisotropic NMR lineshapes contain information about the molecular dynamics, the anisotropic contributions to the NMR spectra need to be reintroduced by slow spinning [21] or recoupling methods [22–24] to exploit these quantities to obtain information about molecular dynamics. If carried out as a separated local field experiment [25], these techniques provide comprehensive dynamical information about all resolved signals in one experiment. For instance, in a separated local field experiment, a motional amplitude for each site that provides a resolved signal in the MAS spectrum can be determined.

For the study of collagen mobility as a function of hydration [20], the ^{1}H–^{13}C dipolar couplings have been measured in a DIPSHIFT experiment [26–28]. Thus, the dipolar coupling of each resolved collagen signal could be determined. Fast motions average out dipolar couplings, the amplitude of these motions can be described by a molecular order parameter, which is calculated as the ratio of motionally averaged and full dipolar coupling. Generally, motional amplitudes were found to be larger in the side chains compared to the backbone of collagen underlying the importance of hydration for the molecular dynamics of collagen. Further, with increasing hydration level, a decrease in the order parameters has been observed. The upper limit for the correlation times of motion calculated from motionally averaged ^{1}H–^{13}C dipolar couplings is on the order of 4×10^{-5} s.

With the recent introduction of high field magnets, it is now possible to study collagen in native tissues such as cartilage [29]. This is particularly remarkable since cartilage consists of ~82 wt% water, ~6 wt% proteoglycans, and only ~12 wt% collagen [30–32]. Due to this high water and ion content, the sample volumes have to be restricted to avoid sample heating by the application of high power decoupling fields. This means that only milligram quantities of collagen can be investigated, which calls for extremely sensitive instrumentations. Figure 3A shows a 188.6 MHz ^{13}C CP MAS spectrum of porcine articular cartilage obtained on approximately 15 mg cartilage tissue at natural abundance. While still relatively noisy, the signals of the main amino acid of collagen could be identified and assigned. For comparison, the ^{13}C CP MAS spectra of dried porcine articular cartilage and isolated collagen type II are shown in Figure 3B and C, respectively.

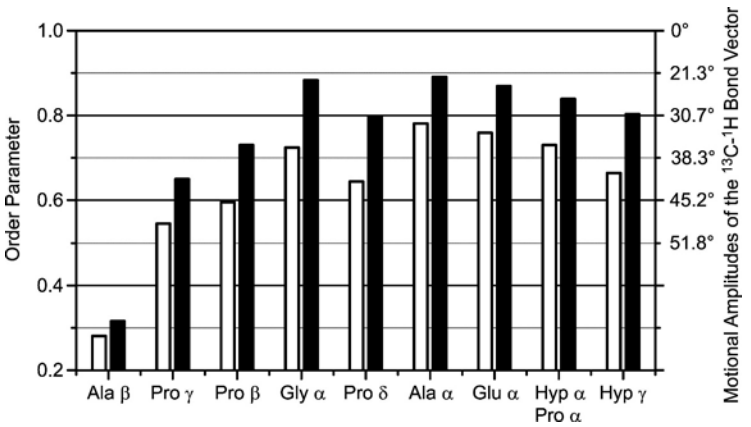

Fig. 4. ^{1}H–^{13}C order parameters of collagen in native (fully hydrated, open bars) and dried porcine articular cartilage (filled bars) at a temperature of 37 °C. Order parameters were determined from DIPSHIFT experiments carried out at a MAS rotational frequency of 7 kHz.

This indicates that almost exclusively collagen signals are detected in ^{13}C CP MAS spectra of articular cartilage. In addition, signals from rigid proteoglycans of cartilage (mostly hyaluronan) can be detected in the ^{13}C CP MAS spectrum of cartilage. These signals are assigned to the ring carbons of the proteoglycans with typical chemical shifts between 65 and 80 ppm [33–35]. In fully hydrated cartilage, these signals are strongly attenuated in ^{13}C CP MAS spectra because of their high mobility, but contribute significantly to the NMR spectrum of dried cartilage.

Figure 4 shows typical order parameters of collagen in dried and native porcine articular cartilage. In the dry sample, the backbone signals exhibit order parameters between 0.9 and 0.94 in agreement with the rigid molecular structure. For the side chains, order parameters between 0.64 and 0.87 indicate motions with root mean square amplitudes between 42.5° and 24.4°. In contrast, much smaller order parameters have been observed in fully hydrated cartilage. For the backbone, order parameters between 0.73 and 0.78 are consistent with motions of amplitudes in the range of 36.1°–32.3°. Even larger amplitudes of 48.6°–41.1° are observed in the side chains of collagen in fully hydrated cartilage with order parameters of 0.55–0.66. For Ala Cβ, order parameters < 0.33 are obtained, characteristic for the fast rotation of methyl groups about the Cα–Cβ bond.

What Has Been Learned from Solid-State NMR Studies of Collagen?

Solid-state NMR techniques have strongly contributed to our understanding of the molecular dynamics in isolated and tissue collagen. The first interesting observation was that even dry collagen is not entirely rigid. The amplitude of collagen motions is not greatly influenced by cross-linking, however, mineralization reduces collagen flexibility in bone. The amino acids in collagen undergo fast segmental reorientations that can be described by root mean square amplitude fluctuations. Very small amplitudes are observed for the collagen backbone, while the motional amplitudes increase into the side chains of the amino acids. For Pro and HyPro, puckering motions of the entire ring structure have been identified. The methyl groups of amino acid side chains undergo fast rotations about the C–C bond axis.

In hydrated collagen, a more versatile molecular dynamics was found. While the segmental motions of dry collagen occur on a fast timescale of the order of a few nanoseconds, in hydrated collagen also slower motions with correlation times of the order of 10^{-4} s have been observed. The motional amplitudes of hydrated collagen are significantly increased in comparison to dry collagen.

Tissue collagen of fully hydrated articular cartilage shows the largest motional amplitudes. This is mostly due to the high water content. Different types of collagen do not show any dynamical diversity as concluded from comparison of collagens I and II. Although most amino acids in collagen are uncharged, there are several polar groups in the backbone and the side chains that represent water binding sites. In particular, the hydroxyl groups of HyPro have been identified as water binding sites according to X-ray studies since they have both hydrogen bond donor and acceptor properties [36]. It has been suggested that the collagen triple helices acquire extra hydrogen bonding capacity by prolyl hydroxylation [37].

The possible functional significance of the collagen mobility has already been suggested [15]. Due to their high tensile strength, collagen fibers provide mechanical stability to connective tissues. When tension is applied, collagen molecules are able to make rapid conformational changes. Thus, stress is distributed uniformly and the mechanical energy can be dissipated and adsorbed by the segmentally flexible molecules. The motions that have been identified so far occur on a sub-microsecond timescale. However, the stress that is exerted on connective tissues by our daily tasks such as walking, climbing the stairs, or exercising stresses the connective tissue on a slower timescale of tens to hundreds of milliseconds. Therefore, motions with these correlation times may also be relevant for collagen. At the moment, only preliminary data for collagen motions in that time window are available [20]. However, several newly developed solid-state NMR methods will allow to investigate such motions in collagen as well [38].

Besides understanding of the basic properties of collagen in regard to the viscoelasticity of biological tissue, recent tissue engineering developments have led to an increasing interest in the quantitative characterization of artificial tissues. For various applications in regenerative medicine (stem) cells are seeded into organic or inorganic scaffolds to produce extracellular matrix *in vitro*. The monitoring and quality control of the engineered tissues represents a major challenge to produce high quality replacements. NMR spectroscopy is very well suited to contribute to this field. Artificially grown tissues need to exhibit very similar properties as the natural tissue in order to be built into cartilage, bone, or other defects. The methods described in this chapter may be used to characterize artificial tissue and compare its properties with those of natural specimen. Thus, the optimal procedures for tissue engineering may be determined aided by a comprehensive monitoring of the dynamical properties of the tissue macromolecules as a prerequisite for a successful implantation.

Solid-State NMR Studies of Elastin and Elastin Peptides

Kristin K. Kumashiro
Department of Chemistry, University of Hawaii at Manoa, Honolulu, Hawaii 96822, USA

Introduction

The skin and blood vessels of a vertebrate have a uniquely resilient and elastic quality to them. These properties are traced to *elastin*, the principal protein component of the fibers that comprise a large portion of these elastic tissues. Numerous reviews have been written on the biology and chemistry of this unique protein [1–3]. Briefly, the elastin gene encodes tropoelastin, which is crosslinked in post-translational modification to form insoluble elastin or, simply, *elastin*. The molecular weight of tropoelastin is large, with molecular weights ranging from 70 to 80 kDa, and its high-resolution structure is not yet solved. Generally, tropoelastin and insoluble elastin are considered to have two "domains," namely, hydrophobic and crosslinking. Much attention has been focused on the hydrophobic regions that are dominated with the small nonpolar amino acids, glycine, alanine, proline, and valine. A number of repeating polypeptide sequences are found in this domain. Among them are $(\mathrm{VPGVG})_n$ and $(\mathrm{PGVGVA})_n$. The crosslinking domain is rich with alanines, with a typical repeat sequence of $(\mathrm{KAAK})_n$ or $(\mathrm{KAAAK})_n$. In portions of tropoelastin, the hydrophobic and crosslinking domains alternate. Figure 1 illustrates several domains of rat tropoelastin, as reported by Pierce *et al.* [4].

To date, there is limited information on the three-dimensional structure of insoluble elastin. If one were to consider the size and nature of tropoelastin, then it would be easy to see why this problem is so difficult. That is, the predominance of the small hydrophobic residues and the presence of the crosslinks are the root causes for the insolubility of amorphous, or "mature," elastin in all but the harshest conditions. Hence, solution nuclear magnetic resonance (NMR) and X-ray crystallography are virtually useless for high-resolution structure determination. Indeed, elastin has more in common with synthetic organic polymers than with many proteins characterized thus far with NMR spectroscopy.

In the past, numerous models have emerged to explain the elasticity of elastin [5–8]. They range from the most disordered and globular to ones with significant degrees of order. As examples of the former, Hoeve and Flory used thermodynamic measurements to suggest that elastin was much like rubber, with long hydrophobic chains interspersed randomly with crosslinks [5]. In contrast, the "oiled coils" from predictive methods [6] and the "β-spiral" from structural studies of elastin-based peptides [7–10] suggest that this polymer has a much greater degree of order. More recent computational studies on the elastin peptides have provided some new insights [11,12]. It is generally accepted, though, that the Ala-rich crosslinking domains are mostly α-helical, whereas the hydrophobic domain's organization is much less clear. Again, the lack of site-, residue-, and sequence-specific data, such as those obtained by solution and solid-state NMR spectroscopy, has greatly hampered the understanding of the native protein's structure–function relationships.

Two basic approaches have emerged as viable ways to characterize this intriguing protein by solid-state NMR spectroscopy. One focuses on the native (or nativelike) elastin, while the other uses smaller model peptides.

Studies of the native protein would be most physiologically relevant, when drawing conclusions regarding structure–function relationships. The preparation of elastin from connective tissue is straightforward [13–15], and large quantities are easily obtained. With purified elastin samples, various groups [13,16–22] have characterized the natural-abundance ^{13}C populations present in the native protein, complete, in most cases, with the waters of hydration. To complement this approach, methods for isotopic enrichment of a given residue type have also emerged [23–25]. These labeling schemes are essential for NMR studies targeting key amino acid types in elastin, and the power of solid-state NMR as a high-resolution structural tool is becoming more evident as these findings are reported.

Alternatively, now-classic approaches in elastin biochemistry have focused on mimetics, most notably, the repeating polypenta and hexapeptides, as studied by Urry [7–10,26] and Tamburro [27–29]. The use of these smaller peptides circumvents the problems associated with the polymeric nature and insolubility of elastin. Typically, the rationale for using these peptides is based on the fact that the hydrophobic regions of elastin have an abundance of these somewhat unusual repeating motifs, and elasticity has been assumed to originate from this domain. In addition, the repeating polypeptides possess properties similar to the native tropoelastin, such as coacervation, and can

Fig. 1. Amino acid sequence of rat tropoelastin as encoded by exons 23–30, as reported by Pierce *et al*. [4]. Exons 23, 25, 27, and 29 are the Ala-rich crosslinking domains. Exons 24, 26, 28, and 30 are the hydrophobic domains, dominated by small hydrophobic residues, such as glycines.

also be crosslinked by reaction with oxidizing reagents or by exposure to γ-irradiation. Modern approaches, such as those based on recombinant methods, has facilitated the synthesis of biopolymers with elastinlike subunits for solid-state NMR characterization. In comparison to the task of labeling native elastin, the isotopic enrichment strategies for the elastin-based peptides or mimetics, whether by synthesis or bacterial expression, tend to be more straightforward. However, by virtue of the inherent simplicity of these systems, one may wonder about the relevance of the repeating polypeptides to the questions surrounding elastin's elasticity. One major and valid concern focuses on the fact that many of the model peptides reported thus far do not contain the Ala-rich crosslinking domains.

In this chapter, we focus on recently reported and current work using solid-state NMR spectroscopy to characterize elastin and elastin peptides. After a short review with a description of important results obtained over two decades ago, recent work by this author's lab and others will be described. Many of these studies are based on techniques in "high-resolution solid-state NMR," utilizing cross-polarization magic-angle-spinning (CPMAS) as a cornerstone, although some projects incorporate non-spinning methods. It will also be shown that the unusual nature of elastin requires new and creative approaches for the continued use of NMR spectroscopy as a powerful tool for characterizing the structure and dynamics of one of nature's most novel and unique elastomers.

Studies of Native Elastin Focus Mainly on the Natural-Abundance ^{13}C Populations

In the 1970s and early 1980s, Torchia and co-workers reported a series of studies using NMR to characterize elastin [16,17,23,24]. Their earliest work [16] used ^{13}C NMR to examine calf ligamentum nuchae, which is rich in elastin. Their results indicated that elastin, unlike collagen, was comprised of "highly mobile chains." A subsequent study [17] provided a more quantitative picture of this unusual mobility in elastin with relaxation data, including T_1 and NOE determinations, for elastin swollen in various solvent environments. With this data, they again concluded that there was significant and unusually high mobility in this amorphous protein, although molecular motion was slightly more restricted in the Ala-rich regions.

Other groups made additional contributions to this early picture of elastin. Urry and Mitchell reported a ^{13}C NMR study of α-elastin and fibrous elastin [30], with most of their focus on qualitative comparisons of the various protein samples with each other and with the elastin polypentapeptide. Ellis and Packer also contributed to this early picture with their ^{2}H relaxation measurements of hydrated elastin [18]. Their work identified the existence of three types of water in these samples. To close out this era, Kricheldorf and Muller reported the ^{13}C chemical shifts for a sample of commercially available elastin [19]. To assist with their interpretation of the elastin spectra, they also looked at the ^{13}C chemical shifts of several Pro-rich polypeptides. Their analysis focused particularly on the backbone carbonyl population. It was concluded that ~25% of the protein was α-helical, another population was "helical segments of unknown pitch," and a third was simply described as an "amorphous phase." Furthermore, they emphasized that elastin's structure possessed no long-range order, although local segments were structured.

In the years since Torchia, Kricheldorf, and others first reported their compelling findings on elastin, the area of biological solid-state NMR has greatly evolved. From the development of progressively higher-field instrumentation and other hardware to the boom in new pulse sequences for defining, e.g. progressively more refined structural data, solid-state NMR spectroscopy has seen a tremendous growth. Furthermore, the tools of molecular biology for protein expression are much more accessible. As a result, many more questions surrounding protein structure and function may be addressed in this day and age.

To begin our review of more recent results, the effects of temperature and hydration on the structure and dynamics of elastin are first discussed [13]. In this study, ^{13}C solid-state NMR experiments were applied to samples of bovine nuchal ligament elastin that were purified using the cyanogen bromide (CNBr) method [13–15]. Samples of elastin at various hydration levels at four different temperatures were first characterized. ^{13}C CPMAS data showed that elastin with little or no water (0–30% hydration) had similar profiles; i.e. in the lyophilized and drier samples, chemical shifts were identified for the center-of-mass of the backbone carbonyl, the aromatic, and 8–9 resolved aliphatic peaks. In contrast, spectra of wetter samples (40–100% hydration) at physiological and room temperatures were observed with markedly lower signal-to-noise than the drier samples. Only the 53 ppm peak was clearly resolved with relatively high signal-to-noise in the C$_\alpha$ region, and several peaks were noted in the upfield region of ca. 10–30 ppm. The differences between the profiles of the wetter and drier samples were negligible as the sample temperature is lowered to $-20\,^{\circ}$C. To further examine the nature of elastin, a number of additional experiments were conducted. For instance, the CPMAS spectrum of the hydrated sample was compared to DPMAS data, as shown in Figure 2. With DPMAS, all sites are observed. In contrast, CPMAS data reflect marked differences for the backbone carbonyl carbons, as well as selected carbons in the aliphatic region. With regards to the latter, the lack of much ^{13}C$_\alpha$-Gly signal is striking. This simple experiment highlighted the heterogeneous nature of elastin; i.e. some segments of elastin, particularly those that are Gly-rich, are so mobile that CP efficiency is greatly compromised. In addition, static experiments showed the presence of unusually narrow lines in the spectrum of the wet sample, clearly unusual for a typical solid. These qualitative measurements were complemented by T$_1$ experiments, which again showed portions of the hydrated sample at 37 °C to have almost *liqidlike mobility* —a term first used by Torchia and coworkers in their examination of elastin in the 1970s [24]. While the drier samples tended to behave more like typical peptides in the solid state, the hydrated samples tended to exhibit more heterogeneity, particularly in terms of their dynamics.

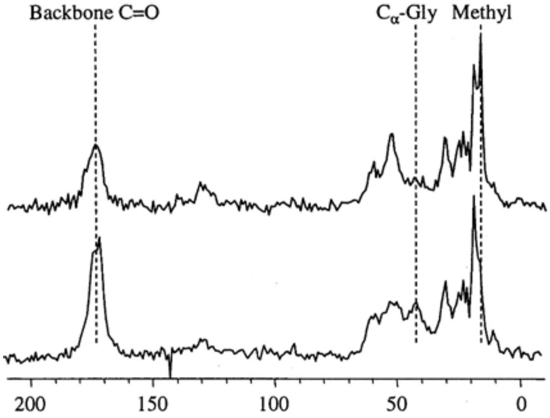

Fig. 2. CPMAS (top) and DPMAS (bottom) spectra of hydrated elastin at 37 °C, as originally reported by Perry *et al.* [13]. Major differences are identified for the backbone carbonyl and in selected regions of the aliphatic carbons, such as the C$_\alpha$-Gly and methyls.

Another recent solid-state NMR study of unenriched elastin samples purified from tissue was also reported by Pometun *et al.* [20]. In their study, solid-state NMR methods were employed to characterize "elastin fibers" obtained from a commercial source. A number of techniques were employed to characterize these samples. First, ^{2}H and ^{17}O NMR were used to identify the dynamics of the exchangeable backbone amides, as well as the waters of hydration. The data showed that there was no evidence for the tightly bound waters of hydration, unlike the work of Ellis and Packer [18]. The ^{2}H spectra were also used to conclude that the entire protein was mobile, whereby typical powder patterns found for most solid peptides were not observed in these conditions. Two-dimensional spectra of dry and hydrated elastin yielded small ^{13}C shielding anisotropies of the resolved carbons in hydrated elastin. The order parameter S (<0.1) was similarly characteristic of high mobility. To explore the structure of this hydrated sample further, ^{13}C chemical shifts were also measured at a carbon resonance frequency of ~200 MHz and with a sample temperature of 75 °C. It was noted that the sample remained elastic at this arguably high temperature for the duration of the experiment. The chemical shifts of all resolved features were assigned to the major amino acids of elastin, and all were identified as having values similar to those of a random coil at this elevated temperature. Finally, a novel method for preparing stretched samples for NMR was reported. This innovation anchored an elastin fiber by its top and bottom, and then the sample could be stretched by means of a captured screw. When the sample of the elastin was stretched, the peaks of the static ^{13}C spectrum broadened. Interestingly, a similar suggestion to that of Kricheldorf and Muller [19] was made, namely, that the high-proline content is a key factor in understanding the structure (or its lack thereof) and dynamics of elastin.

Most of the work in the recent and past literature had focused on elastin obtained from normal tissue. However, two published studies used solid-state ^{13}C NMR to identify structural differences between normal and abnormal elastin. Tarnawski *et al.*, characterized samples of elastin from normal and atherosclerotic human aorta, using 1D methods in ^{13}C NMR [21]. Chemical shifts and the ^{1}H $T_{1\rho}$ reflected very little differences, if any. However, ^{13}C $T_{1\rho}$ measurements reflected subtle differences in the aliphatic region with the accumulation of lipid and calcium deposits. The 43 ppm peak in the atherosclerotic elastin, for example, had a higher ^{13}C $T_{1\rho}$ than normal, whereas the peaks at 32 and 23 ppm had lower values. This result suggested that the latter sites have some type of hydrophobic interaction with the additional lipids found in the affected tissue.

More recently, this author's group published a study of the α-elastin obtained from normal and undercrosslinked pig aorta [22]. The crosslinking in normal vertebrate systems occurs by means of post-translational modification *via* the copper-dependent enzyme lysyl oxidase. If the animal is deprived of copper in its diet, then fewer crosslinks form, and aortic rupture typically results. α-Elastin is prepared by solubilizing elastin with oxalic acid [31,32]. In contrast to other methods of obtaining soluble elastin peptides from the amorphous protein, this scheme retains peptides of significant molecular weight (>10 kDa). Also, α-elastin retains properties of the native system, such as coacervation.

As with the above-described study of the normal versus atherosclerotic elastin [21], there were no discernible differences in ^{13}C chemical shift for the normal versus undercrosslinked [22]. (Indeed, it has been shown that the chemical shifts of the key amino acid types have nearly identical chemical shifts over a broad range of samples.) However, it was noted that the differences in peak intensities of the two samples did not correspond to the simple change in composition, i.e. fewer desmosine and isodesmosine crosslinks and more underivatized lysines. Few differences were observed for the two types of samples based on ^{13}C T_1 and ^{1}H $T_{1\rho}$ measurements. However, ^{13}C $T_{1\rho}$ values indicated that motion on the kHz scale was slowed in the undercrosslinked sample, leading to the arguably counterintuitive conclusion that some mobility is lost with fewer crosslinks. As with the study on the elastin from atherosclerotic tissue, impaired function of the elastic fiber is correlated with a change in dynamics, again lending support to the idea that mobility of the protein is a salient feature of its elasticity.

A New Approach for Production of Isotopically Labeled Elastin Utilizes a Mammalian Cell Culture

This section begins with a description of the earliest successful attempts of isotopic enrichment of elastin, as established by Torchia and co-workers [23,24]. In these early experiments, chick aorta was cultured with media containing the isotopic label. First, ^{14}C-labeled glycine or alanine was used to show that isotopic scrambling was relatively low (>10%) and also to provide a basis for estimating incorporation (10–20%) [23]. Subsequently, results were reported for chick aortic elastin that was labeled at the carbonyl carbons of Ala, Val, and Lys. Incorporation of the ^{13}C label was modest, with 6.4, 10.5, and 19.5% enrichment for [1-^{13}C]Ala, [1-^{13}C]Val, and [1-^{13}C]Lys, respectively. However, these levels were enough to observe these key amino acids. As with their natural-abundance results on the nuchal ligament, Torchia and co-workers obtained T_1, linewidth, and NOE values for the various residue types. In addition, the CP efficiency and the effect of dipolar decoupling were also observed to obtain a model that was slightly more refined than the ones obtained previously. Specifically, these experiments indicated that all of the Val, ~75% of the Ala, and ~40% of the Lys residues (and its derivatives) were found in very mobile regions. The remaining Ala and Lys residues were attributed to the crosslinking domains that were "motionally restricted." Linewidth and NOE data were also recorded as a function of temperature.

More recently, this author's lab has shown that a cell line well-known in cardiovascular biology could be successfully exploited for isotopic labeling and, hence, NMR spectroscopy [25]. The neonatal rat smooth muscle cell (NRSMC) line had been well-documented as a viable means of studying elastin synthesis [33,34]. These primary cultures are grown in a mixture of standard growth medium components that have been supplemented with the appropriate isotopically enriched amino acid. The label is introduced upon seeding of the cells. Normally, after 6–8 weeks of growth, the cells and the elastin-rich matrix are harvested, and insoluble elastin is purified from the mixture using the CNBr method. To assay incorporation, we followed the example of Meier and co-workers in their study of isotopically enriched spider silk [35]; acid hydrolysis followed by solution NMR spectroscopy was used to determine the amount of stable isotope that had been incorporated into the protein. For samples of [1-^{13}C]Gly, [2-^{13}C]Gly, and [^{15}N]Gly NRSMC elastin, the product of the acid hydrolysis was dissolved in D_2O and then observed using ^{13}C NMR spectroscopy. Typically, the analysis focused on C_α-Gly peak and the doublets that would result for the enriched sites. Using this approach, 30–40% incorporation of labeled Gly into elastin was confirmed. Solution NMR data were also used to show that isotopic scrambling is minimal. Analysis of other labeled elastin samples is done by an analogous method (unpublished data).

Early NMR results of the elastin samples enriched at the glycines are promising [25]. The ^{13}C CPMAS data tend to be significantly lower in signal intensity than typically seen with samples of this mass and incorporation level, and DPMAS data yield extremely narrow lines for a polymer with the complexity of elastin. Short T_1 values are also consistent with our earlier observations of the natural-abundance ^{13}C populations of hydrated elastin [13]. In addition to earlier work [25], Figure 3 illustrates the ^{2}H spectrum of NRSMC elastin with enrichment at the glycines. The detailed analysis of this sample is forthcoming. However, again we note the remarkably narrow lines observed for this amorphous protein. Finally, we note that this approach has also proven to be feasible for enrichment at the alanines and valines (unpublished data). With the protocols for labeling elastin well in hand, a number of experiments targeting the key amino acids of elastin are underway.

Information on the Hydrophobic Domain of Elastin is Gleaned from Repeating Polypeptides

As noted above, the hydrophobic domains of elastin are rich with repeating polypeptides. Most well-known are the polypentapeptides $(VPGVG)_n$ [9,10,36]. Much attention has been drawn to Urry's model [7,8], in which each (VPGVG) subunit has the structure of a type II, β-turn and the repeating polypentapeptide, hence, forms a "β-spiral."

Recent solid-state NMR results, however, show little support for such a regular and highly ordered structure. Rather, an inhomogeneous structure seems more likely, even for a simplified repeat like $(VPGVG)_n$. A collaborative study between the Asakura and Kumashiro groups [37], for example, used solid-state spectral editing techniques [38] in combination with 2D spin diffusion under off-magic-angle-spinning conditions to provide another structural picture of the (VPGVG) subunit, as it is found in novel, recombinant silk-elastinlike peptides. These results showed that distorted β structures are predominant in the protein, with significant structural disorder about the central glycine residue in the (VPGVG) subunits. Hong and co-workers also reported a number of studies on elastin mimetics that incorporated the (VPGVG) subunit [39–42]. Their earliest report focused on the central glycine residue found in each of the pentapeptidyl subunits of the 81-kDa elastin-mimetic peptide $[(VPGVG)_4(VPGKG)]_{39}$ [39]. This paper utilized a new technique for selective detection of a residue pair to identify the chemical shift anisotropy of a site that is poorly resolved in the 1D spectra. At the end of this article, they concluded that the Gly_3 CSA is consistent with type I and II β-turn structures. A subsequent study [40] found that the type II β-turn was predominant at the Pro–Gly pair of each subunit, based on Pro ^{15}N and ^{13}C chemical shift measurements. The most recent work on this same pair in $(VPGVG)_3$, however, identified a "bimodal structure distribution" of an "extended and distorted β-strand" and a turn, either as a β-turn or a "previously unidentified turn" as its major and minor forms, respectively [41]. The relative populations of the two general types of conformers are 65 and 35%, which is roughly 2:1, consistent with an earlier report for the 1D ^{13}C CPMAS of $(LGGVG)_n$[43] (described below). It appears that the structural studies by Hong and co-workers have evolved to the same general conclusions as those obtained with the silk-elastinlike peptides [37], namely, that the β-spiral model of regular, repeating β-turns is not supported by solid-state NMR studies of peptides incorporating the (VPGVG) motif.

As a final, interesting note, the work from Hong and co-workers [42] also demonstrated that the dynamics of the $[(VPGVG)_4(VPGKG)]_{39}$ peptide were similar to those of the native elastin [13], underscoring the fact that these simplified systems yield results, in terms of structure, relaxation, and mobility, that are reasonably consistent with those of the more complicated biopolymer found in nature.

Other elastin repeats are good candidates for characterization with solid-state NMR spectroscopy. In collaboration with Martino and Tamburro, this author's lab used a series of ^{13}C CPMAS NMR experiments to characterize poly(LGGVG), a repeating motif found in elastin [43]. Martino *et al*. had earlier reported that the solution structure of this peptide is best described as a "conformational ensemble" that includes both type I and type II β-turns, in addition to some unstructured regions [28]. Solid-state spectral editing techniques were employed to assist in making tentative peak assignments [38]; 1D CPMAS spectra showed clearly that two peaks are observed for the C_β-Val carbon. The features at 32.7 and 29.2 ppm are present in the ratio of 2:1, implying that the conformation(s) corresponding to the downfield peak is dominant. Clearly, this simple result eliminates from consideration the possibility that each subunit may fold into only one type of structure. Furthermore, the nature of the backbone carbonyl lineshape supported this picture; i.e. simple deconvolution subroutines found that the backbone carbonyl peak did not yield results that would support a model such as the β-spiral. Finally, it was noted that, although the T_1's obtained were similar to other lyophilized peptides, we found that they tended to be on the shorter end of the range. That is, even though the peptides are lyophilized, simplified mimetics of the native protein, they tend to mirror the characteristics that set elastin apart from other proteins in the solid-state. Namely, they tend towards structurally heterogeneous samples with dynamics that reflect unusually fast motion.

Concluding Remarks

Studies by Torchia and co-workers, among several others, provided the first glimpse of the unusual nature of the structure and dynamics of elastin, using solid-state NMR spectroscopy. Since then, the field has evolved to utilize a wealth of newer approaches, combining techniques like cell culture and recombinant methods with sophisticated ways to manipulate samples and spins. Overall, it appears that the diverse range of philosophies and approaches are leading to a convergence of themes, to some extent. From the relatively straightforward measurement of T_1's and other relaxation parameters to the multidimensional methods for measuring residual anisotropies, it is clear that the molecular dynamics of elastin is unlike most other proteins in the solid-state. Furthermore, the solid-state NMR studies to-date have all but eliminated any structural model with long-range order. Instead, it appears that even the simplest repeating polypeptides based on the amino acid sequence of elastin have structural parameters that call for a "structure distribution" [41] or "conformational ensemble" [1,28] in proposing a three-dimensional model for this protein. In future years, we can expect that the discrepancies that exist amongst the various results will be reconciled with additional NMR experiments and with the growing number of elastin and elastinlike peptides.

Acknowledgments

Various portions of the work presented in this chapter were supported by the NSF, NIH, and the Hawaii Community Foundation. Current and former members of this author's research laboratory and Dr. W.P. Niemczura (NMR facility, University of Hawaii) are also acknowledged for their participation in this ongoing project.

Structural Analysis of Silk Fibroins using NMR

Tetsuo Asakura and Yasumoto Nakazawa

Department of Biotechnology, Tokyo University of Agriculture and Technology, Koganei, Tokyo 184-8488, Japan

Introduction

Recently, much attention has been paid to silks from textile engineers to polymer chemists and biomedical scientists. The silk fibers produced by silkworms or spiders are the nature's most highly engineered structural materials with combinations of strength and toughness not found in today's man-made materials [1]. In addition, there are many kinds of silks from silkworms and spiders with different structures and properties.

The silk fibroin from the domesticated silkworm, *Bombyx mori*, is a well-known fibrous protein whose amino acid composition (in mol%) is 42.9 Gly, 30.0 Ala, 12.2 Ser, 4.8 Tyr, and 2.5 Val. The fibroin consists mostly of the sequence (Ala-Gly-Ser-Gly-Ala-Gly)$_n$ and comes in silk I (the structure before spinning) and silk II (the structure after spinning) structural forms. Despite a long history of studying silk I, the structure remains poorly understood because any attempt to induce a macroscopic orientation of the sample for X-ray diffraction, electron diffraction, or solid-state NMR, readily causes a conversion of the silk I form to the silk II form. Employing several high-resolution solid-state NMR techniques and analyzing ^{13}C CP/MAS NMR chemical shifts quantitatively, in conjunction with molecular simulations, we proposed a repeated β-turn type II structure stabilized by intra-molecular hydrogen bond for the silk I form.

On the other hand, the structure of silk II has been proposed as a regular array of anti-parallel β-sheet firstly by Marsh *et al.* about half century ago, based on a fiber diffraction study of native *B. mori* silk fibroin fiber [1]. Later, Fraser *et al.*, Lotz *et al.*, and Takahashi *et al.* pointed out some intrinsic structural disorder in the silk II structure although they essentially supported the general features of this anti-parallel β-sheet model [2,3]. The solid-state NMR techniques that have been successfully used for the structure of silk I were also used for the detailed structural determination of silk II.

The primary structure of *Samia cynthia ricini* silk fibroin is considerably different from that of *B. mori* silk fibroin [4]. The basic repeat sequence is made of alternating (Ala)$_{12\text{–}13}$ regions and the Gly-rich regions which is similar to the sequence of spider dragline silk (major ampullate) although the length of polyalanine is shorter (Ala)$_{5\text{–}6}$ in the latter case. The use of appropriate stable isotope-labeled model peptides for the repeated sequences of *S. c. ricini* silk fibroin and spider dragline silks coupled with the use of solid-state NMR methods have applied to determination of the precise local structure.

In this chapter, we overview our recent studies on the structural determination of these silks with solid-state NMR.

Structure of *B. mori* Silk Fibroin Before Spinning (Silk I)

The structural features of *B. mori* silk fibroin are conveniently studied using synthetic peptide (AG)$_{15}$, as a model for crystalline region because the lack of Ser in the model peptide (AG)$_{15}$ does not make any difference in the ^{13}C CP/MAS NMR chemical shifts of the Ala and Gly residues in the repeated sequence (AGSGAG)$_n$ of native silk fibroin [5–7]. By combining several solid-state NMR techniques, we have determined the conformation of the model peptide (AG)$_{15}$ in the silk I form: The torsion angles of Ala and Gly residues were ($-60° \pm 5°$, $130° \pm 5°$) and ($70° \pm 5°$, $30° \pm 5°$), respectively. 2D spin-diffusion NMR was used to determine the torsion angles. Figure 1A and B show the observed 2D spin-diffusion NMR spectrum (only the carbonyl region was expanded) of (AG)$_6$A-[1-^{13}C]G^{14}[1-^{13}C]A^{15}G(AG)$_7$ and the spectrum calculated by assuming the torsion angles, $(\phi, \psi) = (-60°, 130°)$, for Ala residue, respectively. Similarly, Figure 1C shows the experimental 2D spin-diffusion NMR spectrum of (AG)$_6$[1-^{13}C]A^{13}[1-^{13}C]G^{14}(AG)$_8$ together with the spectrum D calculated with the torsion angles, $(\phi, \psi) = (70°, 30°)$, for Gly residue. In both cases, the observed spectra could be reproduced well with the calculated spectra. With these torsion angles of Ala and Gly residues determined here, the structural model of an (AG)$_{15}$ chain with silk I form was prepared and shown in Figure 2. This can be called as a repeated β-turn type II structure. In order to confirm this model, REDOR experiments were performed. Namely, the atomic distance between the ^{13}C = O carbon atom of the 14th Gly residue and the ^{15}N nitrogen atom of the 17th Ala residue of (AG)$_{15}$ was determined precisely as shown in Figure 3. The distance was determined to be 4.0 ± 0.1 Å independent of the dilution with unlabeled (AG)$_{15}$ peptide which agrees very well

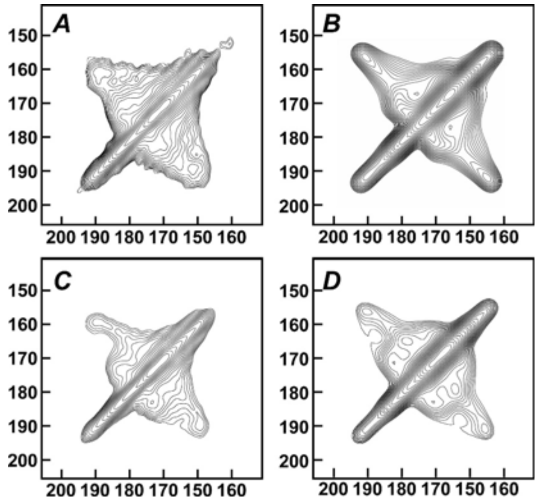

Fig. 1. The (A) experimental and (B) simulated 2D spin-diffusion NMR spectra of $(AG)_6A[1\text{-}^{13}C]G_{14}[1\text{-}^{13}C]A_{15}G(AG)_7$ and the (C) experimental and (D) simulated spectra of $(AG)_6[1\text{-}^{13}C]A_{13}[1\text{-}^{13}C]G_{14}(AG)_8$. The torsion angles of Ala_{15} residue used for the simulation of former spectrum were $(\phi, \psi) = (-60°, 130°)$, while the torsion angles of Gly_{14} residue were $(\phi, \psi) = (70°, 30°)$.

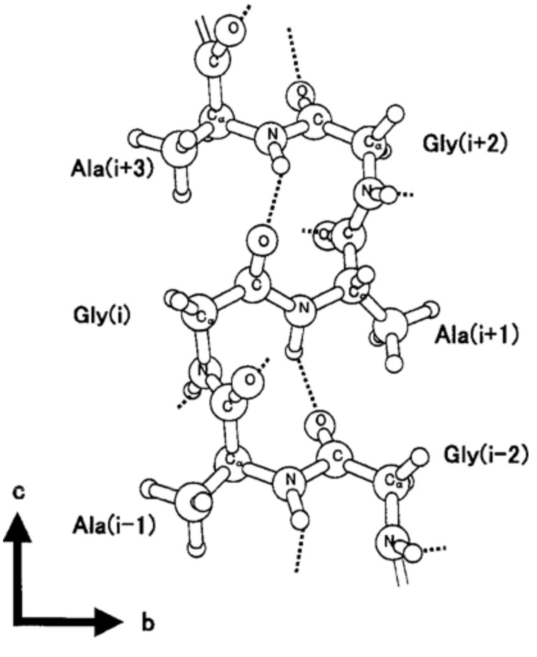

Fig. 2. The conformation of a repeated β-turn type II-like molecule as a model for silk I. There are intra-molecular hydrogen bonds between the carbonyl oxygen atom of the ith Gly residue and the amide hydrogen atom of the $(i + 3)$th Ala residue.

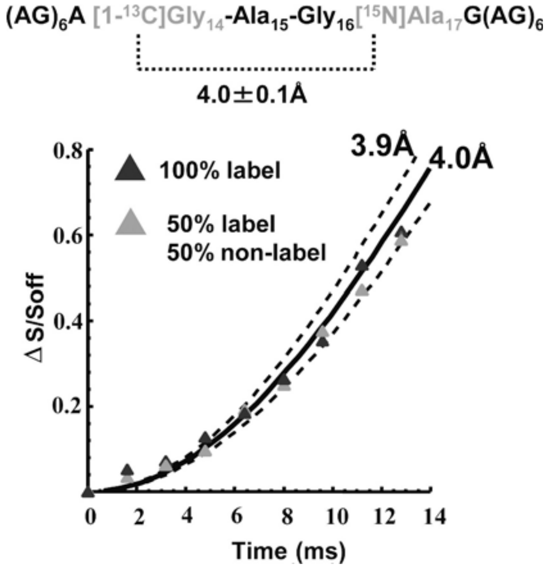

Fig. 3. Observed plots of $\Delta S/S_0 (= 1 - S/S_0)$ values against the corresponding NcTr values for REDOR experiments of $(AG)_6A[1\text{-}^{13}C]GAG[^{15}N]AG(AG)_6$ for the determination of distance between the $^{13}C = O$ carbon of the 14th Gly residue and the ^{15}N nitrogen of the 17th Ala residue. Solid and dotted lines show the theoretical dephasing curves corresponding to the designated distances. The data marked by ○ are observed for the isotope-labeled compound without dilution of natural abundance $(AG)_{15}$ and those by Δ, for a mixture of equivalent amount of the isotope-labeled compound and natural abundance $(AG)_{15}$. By comparing the REDOR data and the theoretical dephasing curve, the ^{13}C–^{15}N inter-atomic distance was determined to be 4.0 ± 0.1 Å, which agrees with the 4.0 Å calculated for intra-molecular hydrogen bond for the repeated β-turn type II-like structure.

with the distance, 4.0 Å, calculated for the corresponding atomic distance of the intra-molecular hydrogen bonding site in the repeated β-turn type II-like structure. This supports the structural model proposed here (Figure 2). By adding X-ray diffraction data of poly(Ala-Gly) in the silk I form to the solid-state NMR data, a more precise model with intra- and inter-molecular hydrogen bond formations alternatively was proposed for the structure in the solid state [8].

Structure of *B. mori* Silk Fibroin After Spinning (Silk II)

As mentioned in the section "Introduction", although Lotz *et al.* [3] and Fraser *et al.*[2] generally supported the anti-parallel β-sheet model proposed by Marsh *et al.* [1], the former researchers also pointed out the presence of an irregular structure in the silk fibers. More recently,

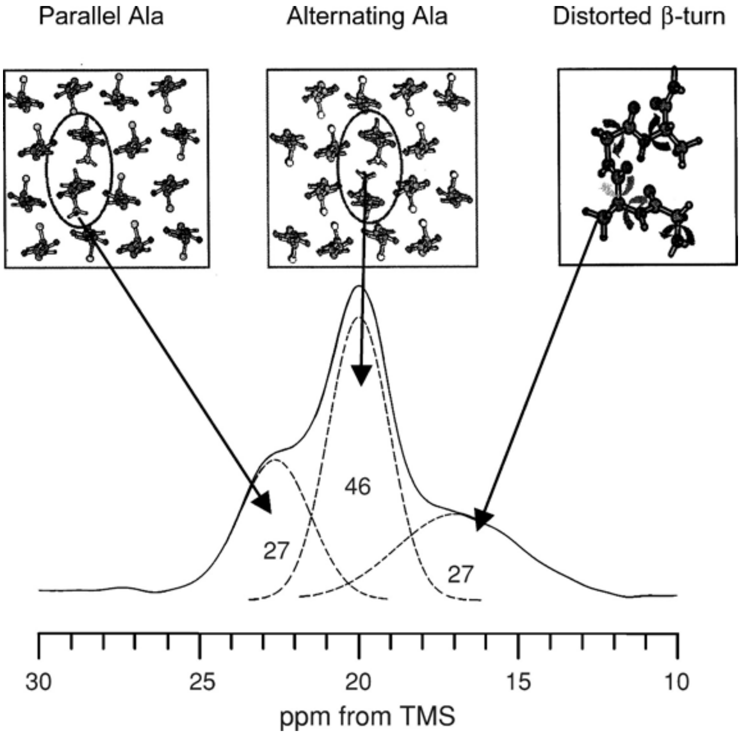

Fig. 4. Expanded Ala C$_\beta$ peak of (AG)$_{15}$ in silk II form, model peptide of the crystalline fraction of *B. mori* silk fibroin fibers. Shown as dotted lines underneath are the spectral deconvolutions with Gaussian peaks.

Takahashi *et al.* [9] proposed that each crystal site of *B. mori* silk fiber is statistically occupied by two anti-parallel β-sheet chains with different relative orientations.

Actually, we recently found out that the Ala C$_\beta$ peak in the ^{13}C CP/MAS NMR spectrum of *B. mori* silk fiber in the silk II form is broad and asymmetric, reflecting the heterogeneous structure of the silk fiber [6,7]. The Ala C$_\beta$ peak of the model peptide (AG)$_{15}$ in silk II form was also asymmetric which consists of three peaks with isotropic chemical shifts of 22.2 (27%), 19.6 (46%), and 16.7 (27%) ppm, respectively (Figure 4). The broad peak at the highest field has essentially the same chemical shift as the sharp Ala C$_\beta$ peak at 16.7 ppm of silk I [7]. Therefore, the broad component at 16.7 ppm in Figure 4 was assigned to distorted β-turn where the averaged ϕ, ψ angles are the same as those of β-turn type II-like structure, but the distribution of the ϕ, ψ angles is larger [10]. The other two components with the chemical shifts of 19.6 and 22.2 ppm can be assigned to anti-parallel β-sheet conformation [7,10,11]. Actually, the 2D spin-diffusion NMR study indicates that the conformation of (AG)$_{15}$ in silk II form is mainly an anti-parallel β-sheet with the torsion angles $(\phi, \psi) = (-150^\circ, 150^\circ)$ of the Ala residue. Since the Ala C$_\beta$ methyl groups are located outside of the protein backbone, the occurrence of two peaks suggests that there is a difference in the mode of side chain packing: The 19.6 ppm peak is assigned to the Ala C$_\beta$ carbons which point in the same direction, while 22.2 ppm peak to the Ala C$_\beta$ carbons which alternately point in opposite directions as shown in Figure 4. The relative peak intensities at 22.2 and 19.6 ppm are approximately 1:2, which is in good agreement with the ratio of different packing modes suggested from X-ray diffraction analysis of *B. mori* silk fiber [9].

Structure of Silk Fibroin from *S. c. ricini* Before Spinning

The ^{13}C CP/MAS NMR chemical shifts of Ala residue clearly indicate that the silk fibroin prepared from the silk gland of *S. c. ricini* and then dried mildly, take a typical α-helix structure and that the structure changed to β-sheet after spinning. This was also supported using the 2D DOQSY (double-quantum single-quantum correlation experiment) NMR measurements [12]. In order to obtain more precise structural information for the sequence of the poly-Ala region, several stable isotope-labeled peptides with the sequence, GGAGGGYGGDGG(A)$_{12}$GGAGDGYGAG, were synthesized. The torsion angles of the central Ala residue, Ala$_{19}$, in the peptide, GGAGGGYGGDGG (A)$_5$-[1-^{13}C]

$A^{18}[1\text{-}^{13}C]A^{19}(A)_5$GGAGDGYGAG were determined using 2D spin-diffusion NMR after TFA treatment. The angles were determined to be $(\phi, \psi) = (-59^\circ, -48^\circ)$ which are typical angles of α-helical structures [13,14]. The torsion angles of the N- and C-terminal Gly residues adjacent to poly-Ala region were also determined using the 2D spin-diffusion NMR method for two model peptides, GGAGGGYGGD$[1\text{-}^{13}C]G^{11}[1\text{-}^{13}C]G^{12}(A)_{12}$GGAGDGYGAG and GGAGGGYGGDG-$G(A)_{11}[1\text{-}^{13}C]A^{24}[1\text{-}^{13}C]G^{25}$GAGDGYGAG. From the error analysis of the observed and calculated spin-diffusion NMR spectra [14], the torsion angles of the Gly^{12} and Gly^{25} residues were determined to be $(\phi, \psi) = (-70^\circ, -30^\circ)$ and $(\phi, \psi) = (-66^\circ, -22^\circ)$, respectively. In order to obtain further structural information on the C-terminal region, REDOR experiments were performed for GGAGGGYGGDGG $(A)_8[1\text{-}^{13}C]A^{21}$-AAA$[^{15}N]G^{25}$GAGDGYGAG. The ^{13}C–^{15}N inter-atomic distance of the stable isotope-labeled site was determined to be 4.8 ± 0.1 Å. When the torsion angles of Ala^{22} residue are $(\phi, \psi) = (-59^\circ, -48^\circ)$ and those of the other two Ala residues, Ala^{23} and Ala^{24}, are $(\phi, \psi) = (-66^\circ, -22^\circ)$, the atomic distance between the $[1\text{-}^{13}C]A^{21}$ and $[^{15}N]G^{25}$atoms was calculated to be 4.8 Å. The similar REDOR method was applied to determination of the local structure at the N-terminal region. With the torsion angles determined here, the structure of the model peptide, GGAGGGYGGDGG$(A)_{12}$GGAGDGYGAG, was proposed in Figure 5. As shown in the left side, the local structure of N- and C-terminal residues besides the α-helical poly-Ala chain is more strongly wound than those found in a typical α-helix. Namely, at the terminals of the helical region, five residues, Gly^{12}, Ala^{21}, Ala^{22}, Ala^{23}, and Ala^{24} contribute to the formation of $i \rightarrow i + 3$ hydrogen bonding (see right side in Figure 5), suggesting that there are mechanisms to stabilize the α-helix structure of poly-Ala region of the silk fibroin in *S. c. ricini* silkworm.

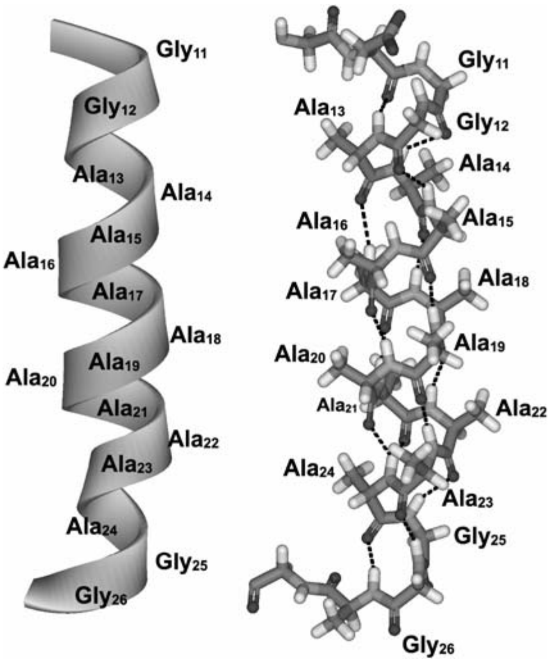

Fig. 5. The structure of poly (L-alanine) region of the model peptide, GGAGGGYGGDGG$(A)_{12}$GGAGDGYGAG of polyalanine region of *S. c. ricini* silk fibroin before spinning. Both structures are the same, but different presentation. The left side presentation shows that α-helix structure of polyalanine region tend to be winded strongly at the both terminal ends. The right side presentation shows the corresponding intra-molecular hydrogen bonding pattern by broken lines.

Structure of *Nephila clavipes* Dragline Silk (MaSp1)

The dragline filaments produced by orb weaving spiders have been the focus of numerous recent studies because they are the toughest protein fibers known [15–17]. The dragline silk of the golden orb web spider *N. clavipes* contains two structural proteins, designated spidroin 1 (MaSp1) and spidroin 2 (MaSp2) [18,19]. The dominant MaSpl protein can be described as a block copolymer consisting of poly-Ala and Gly-rich regions, which is similar to the primary structure of *S. c. ricini* silk fibroin.

Several kinds of solid-state NMR [20–30] and X-ray diffraction methods [31,32] have been applied to clarify the structure and dynamics of native spider silk fibers. It has been shown that silk fibroins undergo substantial structural change from gland silk to native dragline silk. In particular, it has been shown using conformation-dependent ^{13}C chemical shifts of Ala residues that the poly-Ala region in dragline silk fiber adopts a β-sheet structure [21–25]. In contrast, the Gly-rich region in the final silk has been described as: rubber-like [33] or amorphous [31], or recently as mainly 3_1-helical as shown by 2D spin diffusion [22] and by DOQSY and DECODER (direction exchange with correlation for orientation-distribution evaluation and reconstruction) solid-state NMR techniques [27]. However, it is still difficult to judge their precise local structure by solid-state NMR, because heterogeneity in the repeated sequences and resulting large variations in structural distributions must also be taken into account. To avoid the large variations in structural distributions resulting from the heterogeneity in the primary structure, we prepared both a non-labeled peptide with a sequence containing

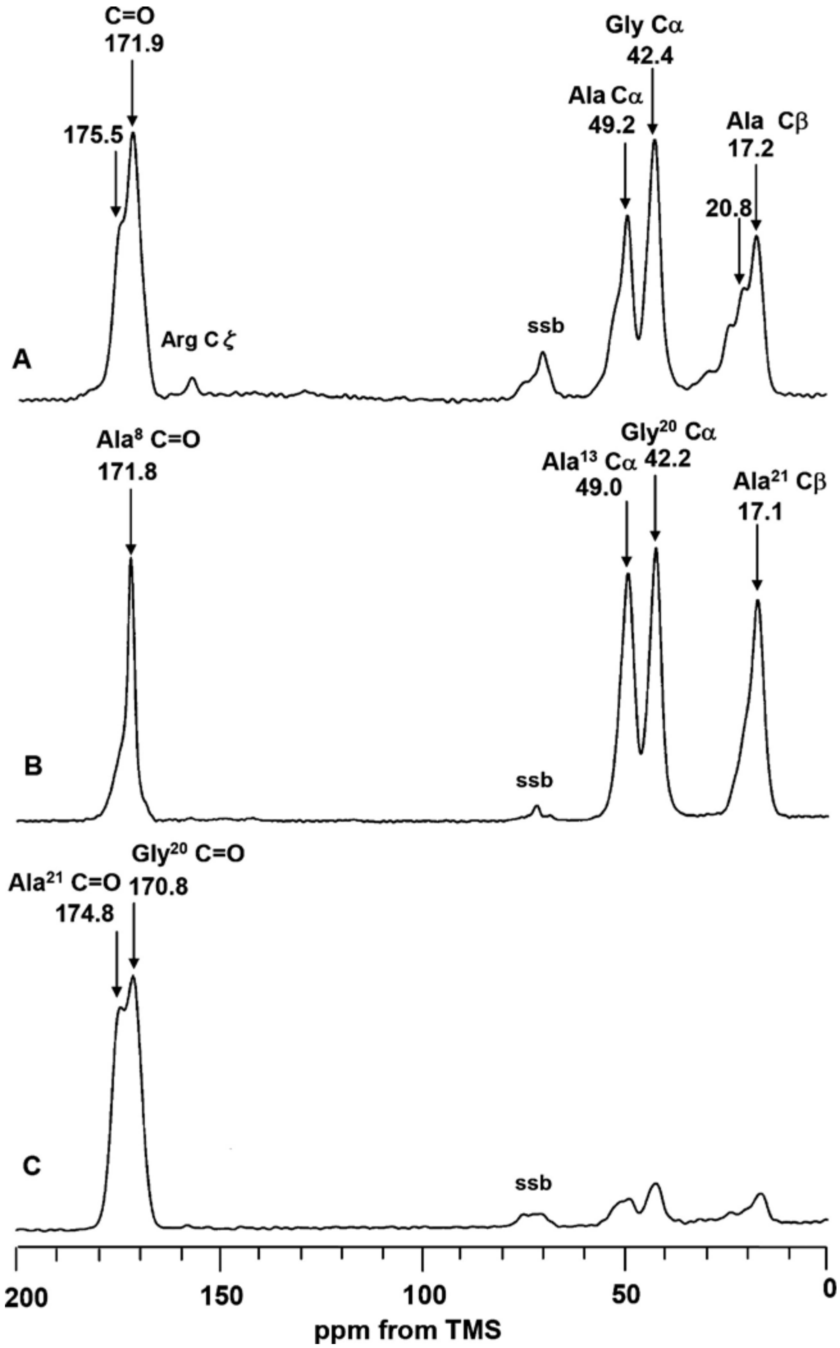

Fig. 6. ^{13}C CP/MAS NMR spectra of I (A), Ia (B), and II (C) after dissolving these peptides in 9 M LiBr and then dialyzing against water (ssb means spinning side band).

both the polyalanine and the repeated GGA regions, QGAG(A)$_6$GGAGA(GGA)$_3$GAGRGGLGG (I), and the ^{13}C-labeled peptides, QGAGAAA[1-^{13}C]A^{8}AAGG[2-^{13}C]A^{13}GAGGAG[2-^{13}C]G^{20}[3-^{13}C]A^{21}GGAGAGRG-GLGG (Ia) and QGAGAAAAAAGGAGAGGAG[1-^{13}C]G^{20}[1-^{13}C]A^{21}GGAGAGRG-GLGG (II), as a local structural model of MaSpl protein. Solvent treatments prior to the NMR measurements induce structural change of these model peptides and provide a model to reproduce the structure of the silk fiber. Conformation-dependent ^{13}C NMR chemical shifts were mainly used to determine the local structure, including the evaluation of the fraction of several conformations. As shown in Figure 6, the characteristic structure; 65% β-sheet for Ala^8 residue in poly-Ala region, and 70% 3_1-helix for Ala^{21} residue and mainly 3_1-helix for Gly^{20} residue in the GG^{20}A^{21} sequence was observed after dissolving the peptides (Ia) and (II) in 9 M LiBr followed by dialysis against water. The 2D spin-diffusion ^{13}C solid-state NMR spectrum of the Ala^{21} residue of the peptide (II) after this treatment was also reproduced by 70% 3_1-helix ($\phi, \varphi = -90^\circ, 120^\circ$) and 30% β-sheet structure ($\phi, \varphi = -150^\circ, 150^\circ$). However, the Ala C$_\beta$ peak assigned to 3_1-helix in the spectrum of (Ia) is broad, implying that the torsion angles of Ala^{21} residue are distributed, but with an average that corresponds approximately to the torsion angles of the 3_1-helix. Increase in the fraction of β-sheet in both poly-Ala and GG^{20}A^{21} regions was observed for (Ia) after dissolving it in formic acid and then drying in air. Moreover, after dissolving (Ia) in formic acid and then precipitating it in methanol, the spectrum showed a tightly packed β-sheet structure with further increase in the fraction of β-sheet although 15% 3_1-helix still remained in the GG^{20}A^{21} region. The β-sheet structure of poly-Ala region, and both 3_1-helix and β-sheet structures in the repeated GGA sequence is in agreement with the structural model for the native spider dragline silk fiber from *N. clavipes* from a previous NMR study. On the other hand, α-helical conformation was found to be dominant for the peptide treated with trifluoroacetic acid together with a significant contribution from other structures. The fraction of the other structures was 20–40% depending on the position of ^{13}C-labeled Ala residue.

Field Gradient NMR

NMR Diffusometry

William S. Price
Nanoscale Organization and Dynamics Group, College of Science, Technology and Environment,
University of Western Sydney, Penrith South, NSW 1797, Australia

Diffusion as a Probe

Translational diffusion is inherently important in the chemical and biological world since it constitutes the most basic form of transport. But its study is also important by virtue of the translational motion of a species being affected by molecular interactions (e.g. binding) or restricted diffusion by physical barriers (e.g. within a pore). Thus, the diffusion of a species provides a rich source of information regarding the interactions of a species with other molecules and its environment. NMR provides a conceptually simple but direct and extremely powerful method for measuring diffusion down to about 10^{-14} m^2/s. In contrast to traditional methods, and of particular significance since the species of interest is likely to be a small molecule or ion, the NMR method (generally) does not require labeling and is effectively non-invasive. This chapter provides a brief introduction to the Pulsed Gradient Spin-Echo (PGSE) NMR method (also commonly referred to as Affinity NMR, DOSY, or PFG NMR) for measuring diffusion and its application to solution dynamics and probing porous media.

Already a very large literature exists on NMR diffusometry and applications, and thus the literature cited here is only as an example and is in no way comprehensive. A number of reviews have already appeared including of a general nature [1–8] and specializing in supramolecular and combinatorial chemistry [9], polymer gels [10], proteins [11], transport and binding [12–14], and surfactants [15,16].

Gradient-Based Diffusion Measurements

Although technically difficult the concept underlying the PGSE technique is breathtakingly simple. All PGSE sequences are, as the name suggests, based on some form of spin-echo sequence. We will illustrate the operation of the PGSE sequence with the simplest case, that of a Hahn spin-echo based sequence. From the earliest days of NMR it was realized that the refocusing of the echo in the Hahn sequence could be compromised by the effect of magnetic field gradients. Since should a spin move to a region with a different magnetic field during the sequence, the phase change acquired during the first τ period would not be counteracted by that experienced in the second τ period (recall that the effect of the π pulse is to reverse the sign of the phase change that has accumulated prior to its application). Theoretical modeling of this attenuation of the echo due to spins experiencing different magnetic fields is facilitated if the applied magnetic gradient is constant (often mistakenly referred to as "linear").

The imposition of a magnetic field gradient during the rf pulses and acquisition is deleterious: much stronger rf pulses are required to overcome the gradient induced spreading of the spectrum and chemical shift information is lost during acquisition. Further, it would also result in the timescale of the diffusion measurement being tied to τ. A much better, albeit technically more demanding solution, is to apply the magnetic gradient in the form of two equal pulses of length δ and magnitude and direction $\mathbf{g}$ as depicted in Figure 1. The area of such gradient pulses (i.e. $\delta\mathbf{g}$) leads to the definition of the reciprocal space vector

$$\mathbf{q} = (2\pi)^{-1}\,\gamma\mathbf{g}\delta\left(\mathrm{m}^{-1}\right). \tag{1}$$

It is easily imagined that an infinitely short gradient pulse (SGP) (i.e. $\delta \to 0$ and $|\mathbf{g}| \to \infty$ while $\delta\mathbf{g}$ remains finite) with $\mathbf{g}$ directed along the long axis of a cylindrical sample would wind (i.e. spatially encode) the transverse magnetization into a helix with pitch q^{-1} (m). If instead the pulse had finite duration, the effect of translational diffusion during the pulse would corrupt the helix formation.

Assuming the SGP condition so that motion during the gradient pulse can be neglected, but accounting for motion during the period Δ between the first gradient pulse and the second (i.e. spatially decoding) gradient pulse leads to the SGP relation for the spin-echo attenuation [17]

$$E = \iint \rho(\mathbf{r}_0)\; P(\mathbf{r}_0, \mathbf{r}_1, \Delta)\, \mathrm{e}^{\mathrm{i}2\pi\mathbf{q}(\mathbf{r}_1-\mathbf{r}_0)}\, \mathrm{d}\mathbf{r}_0\, \mathrm{d}\mathbf{r}_1 \tag{2}$$

where $\rho(\mathbf{r}_0)$ is the equilibrium spin-density and $P(\mathbf{r}_0, \mathbf{r}_1, \Delta)$ is the diffusion propagator [18] (or Green function [19]) derived using appropriate boundary conditions and a delta function initial condition. The integral

© 2008 *Springer.*

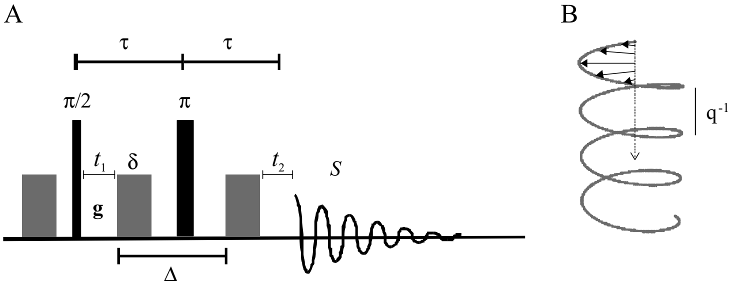

Fig. 1. (A) A PGSE sequence based on a Hahn-spin echo where two equal gradient pulses of duration δ and magnitude **g** are inserted into each τ period. Typically δ is in the range of 1–10 ms, whilst the separation Δ between the leading edges of the gradient pulses is normally in the range of 10 ms to 1 s. The second half of the echo is used as the NMR signal. Normally the echo attenuation, defined by $E(\mathbf{g}) = S(\mathbf{g})/S(\mathbf{g} = 0)$, is used to determine the diffusion coefficient as it allows the effects of spin relaxation to be normalized out. A gradient pre-pulse is included before the $\pi/2$ rf pulse to reduce eddy current and gradient mismatch effects. (B) An example of a magnetization helix (the arrows represent nuclear spins and the spiral curve is a guide for the eye), with pitch q^{-1} that would be formed by applying a gradient pulse along the long axis of a cylindrical sample. Any imperfection in gradient constancy or motion during the pulse results in a distorted helix.

is taken over all starting ($\mathbf{r}_0$) and finishing ($\mathbf{r}_1$) positions. Equation (2) states that the echo attenuation is given by the Fourier transform of the diffusion propagator with respect to q. In the case of free diffusion, Equation (2) leads to

$$E = \exp\left(-4\pi^2 q^2 D\Delta\right). \tag{3}$$

Importantly, diffusion is measured along the direction of the gradient. Equation (3) states that the echo attenuation for the simple case of free diffusion is given by a single exponential. Despite the relative simplicity of the SGP approximation, apart from free isotropic diffusion, solutions to Equation (2) are only available for simple symmetrical geometries, such as between reflecting planes separated by a distance a, viz [17].

$$\begin{aligned} E = {} & \frac{2[1-\cos(2\pi q a)]}{(2\pi q a)^2} + 4(2\pi q a)^2 \\ & \times \sum_{n=1}^{\infty} \exp\left(-\frac{n^2\pi^2 D\Delta}{a^2}\right) \frac{1-(-1)^n\cos(2\pi q a)}{\left[(2\pi q a)^2-(n\pi)^2\right]^2} \end{aligned} \tag{4}$$

At long Δ, the second term in Equation (4) disappears leaving the long-time diffractive behavior with diffractive minima, which arise from the first term, appearing at $q = n/a\,(n = 1, 2, 3, \ldots)$.

In cases where $P(\mathbf{r}_0, \mathbf{r}_1, \Delta)$ is unknown, expansion of Equation (2) reveals that for small q with respect to the characteristic distance of the restricting geometry, R, the echo attenuation is given by,

$$E\left(\mathbf{q} \ll R^{-1}, \Delta\right) \approx 1 - \frac{(2\pi q)^2 \left\langle z^2(\Delta)\right\rangle}{2} \tag{5}$$

where $\left\langle z^2(\Delta)\right\rangle$ is the mean squared-displacement along the direction of the gradient (i.e. taken to be along the z-axis) and in such cases the PGSE data can be analyzed on the basis of an effective diffusivity [20,21]

$$D_{\mathrm{eff}}(\Delta) = \frac{\left\langle z^2(\Delta)\right\rangle}{2\Delta}. \tag{6}$$

Experimental Complications

Here we consider some experimental complications peculiar to PGSE NMR measurements. In almost all cases experimental imperfections lead to faster "apparent" diffusion coefficients.

Finite Gradient Pulses

Experimentally, the SGP approximation is never completely justified and including its effect in the theoretical analysis is difficult. For example, the analytical solution obtained from solving the Bloch equations is [22,23]

$$E = \exp\left(-\gamma^2 g^2 D(\Delta - \delta/3)\right). \tag{7}$$

Comparison with Equation (3) reveals that the $\delta/3$ term is a correction for the finite length of the gradient pulses. In general, analytical solutions are impossible and numerical approaches are indicated [24,25].

Background Gradients

Due to magnetic susceptibility differences resulting from sample heterogeneity and sample interfaces, the presence of background magnetic gradients is unavoidable. And their effects are insidious on the PGSE measurement [26]. Assuming a simple case of a constant background gradient through the sample of direction and magnitude $\mathbf{g}_0$, the analytical solution starting from the Bloch equations is [22,27]

$$E(g, g_0) = \exp\left(-\gamma^2\left[\underbrace{g^2 D\delta^2(\Delta - \delta/3)}_{\mathbf{g}\ \text{term}} + \underbrace{\mathbf{g}\cdot\mathbf{g}_0 D\delta\left[t_1^2 + t_2^2 + \delta(t_1 + t_2) + \frac{2}{3}\delta^2 - 2\tau^2\right]}_{\mathbf{g}\cdot\mathbf{g}_0\ \text{cross terms}}\right]\right) \tag{8}$$

where the delays t_1 and t_2 are defined in Figure 1A. The difference between Equations (7) and (8) is that the inclusion of the $\mathbf{g}\cdot\mathbf{g}_0$ cross terms results in the attenuation being no longer described by a single exponential. The presence of background gradients can be detected by reversing the sign of the applied gradient and thus the cross term. Consequently, sequences incorporating bipolar pulses have been devised to ameliorate PGSE measurements in the presence of background gradients [28–30].

Radiation Damping

In samples with a high concentration of spins (e.g. a sample of water), a feedback loop can arise in which the precessing spin magnetization generates an oscillating current in the receiver coil, which in turn generates an oscillating magnetic field, which rotates the magnetization back to its equilibrium position—generally much more rapidly than that would occur due to longitudinal relaxation. The effect increases with the strength of the static magnetic field. In the PGSE experiment, radiation damping is active in the periods in which the magnetization is not spatially encoded (i.e. during the periods t_1 and t_2 in the sequence as depicted in Figure 1A). Radiation damping complicates the performing of diffusion measurements of strong NMR resonances and can cause effects similar to those caused by background gradients except that the non-exponential behavior is insensitive to the polarity of the applied gradient [26]. Apart from using a very small sample, the only three practicable and generally applicable means by which accurate PGSE experiments can be conducted in conditions that radiation damping will occur are: (1) by keeping all transverse magnetization spatially encoded during as much of the sequence as possible, (2) allowing part of the magnetization to (reproducibly) decay before starting the diffusion part of the sequence or (3) to use Q-switching [31].

Convection

In PGSE measurements of low viscosity samples away from ambient temperature, convective motion can have particularly deleterious effects [32,33]. Importantly, whereas the diffusion coefficient depends on molecular size, the (convective) flow velocity is common to all of the species in the sample. Whereas a net flow of spins along the direction of the gradient is clearly indicated by the resulting net phase change in the PGSE spectra, convection currents do not produce a phase change since the flow of the spins along the direction of the gradient is exactly matched by the flow in the anti-parallel direction [34,35]. Convection causes a cosine modulation of the PGSE signal attenuation (for a single diffusing species). But due to the similarity between the cosine and Gaussian functions, the PGSE data appears to be well described by an exponential [e.g. Equation (3)] but with an apparent diffusion coefficient that increases with Δ. Apart from improving the temperature regulation to decrease any temperature gradients modifying the sample holder to limit flow, convection can also be minimized by using specialized pulse sequences (e.g. Ref. [36]).

Gradient Constancy

Small deviations from constancy of the applied gradient throughout the sample volume do not generally cause serious errors [37]. Nevertheless, as gradient coils only produce a constant gradient over a small volume, to ensure reasonable constancy, the NMR active volume of the sample must be restricted. Often the effective sample volume will be sufficiently restricted by virtue of the size of the rf coils. More generally it is necessary to physically limit the sample volume (although care must be taken not to introduce background gradients) or by including a slice selective element in the PGSE sequence (e.g. Ref. [38]).

Eddy Currents and Gradient Mismatch

Eddy currents in the surrounding conducting surfaces around the gradient coils (e.g. probe housing, etc.) arise from the rapid rise and fall of the gradient pulses and their severity increases with the speed of the rise time and the strength of the gradient pulses. The advent of shielded gradient coils has greatly decreased their effects, but they can still be significant when using large rapidly rising and falling gradient pulses. The decay time of the eddy currents (and their associated magnetic fields) determine the minimum delay required between the end of the gradient pulse and the start of spectral acquisition. Eddy currents can result in: (i) gradient induced broadening of the observed spectrum, (ii) phase changes and anomalous changes in the attenuation, and (iii) time-dependent but spatially invariant B_0 shift effects (which appears as "ringing" in the spectrum).

Gradient pulse mismatch can produce similar artifacts to eddy currents [39]. Even extremely small mismatches can cause a severe loss in echo signal intensity due to the resulting phase twist. If the mismatch increases as a function of gradient strength it has the potential to produce artifactual "diffraction" peaks. The presence of such phase-based artifacts is verified, for example, by performing measurements on a freely diffusing sample with a very small diffusion coefficient (e.g. large polymer).

Apart from the obvious solution of better gradient generation, the easiest means for removing eddy current and gradient mismatch effects is to use shaped gradient pulses [40] or prefixing a number of Δ-spaced gradient prepulses (see Figure 1A) [41]. In the case of gradient mismatch it is also possible, although considerably less convenient, to empirically match the gradient pulse pairs, or, at the expense of chemical shift information, use the imaging-based MASSEY sequence approach [42].

Diffusion in Complex Systems

In the absence of restriction, the diffusion coefficient of a species reports directly on its size, geometry, and the medium in which it is diffusing. This connection is conveniently formulated using the Stokes–Einstein equation, which is derived assuming that the solute sees the solvent as a continuum (e.g. see Ref. [43]),

$$D^0 = \frac{kT}{f} \tag{9}$$

where D^0 is the diffusion coefficient of the solute at infinite dilution (hence the superscript 0), k is the Boltzmann constant, and T is temperature. For the particularly simple case of a sphere under stick boundary conditions the friction coefficient, f is given by (Stokes law)

$$f = 6\pi\eta R \tag{10}$$

where R is the effective hydrodynamic (or Stokes) radius, η is the solvent viscosity. Since f is determined by the overall dimensions of the diffusing species (which may include the effects of solvation and rugosity), few species are well described by a simple geometry. Consequently, f must normally be determined numerically (e.g. Ref. [44])—indeed exact solutions are only known for some simple geometries (e.g. see Table 1 in Ref. [45]). When NMR diffusion measurements are used to separate mixtures on the basis of diffusion differences, it is often referred to as DOSY NMR [7] with the resulting data presented in a two-dimensional format with the diffusion coefficient on one axis and the chemical shift on the other. Some examples of the applications of diffusion measurements are given in the following subsections.

Solution Dynamics and Surfactants

NMR diffusometry finds particular application in studying solution dynamics—especially since it is capable of determining the diffusion behavior of many of the species in a solution simultaneously. For example, the diffusion coefficient of all species in an ethanol–water solution are given in Figure 2. Such detailed data allows inferences to

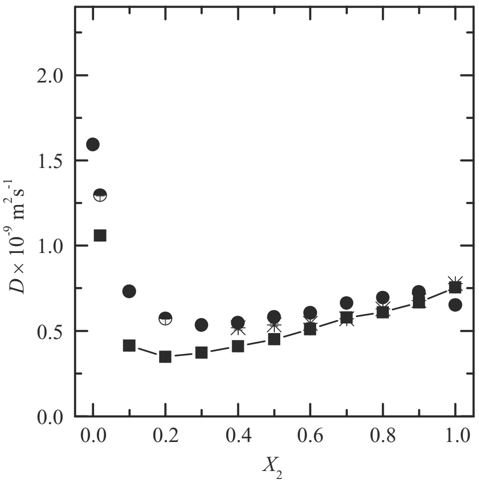

Fig. 2. Diffusion coefficients of the alkyl (■), hydroxyl (∗), water (●), and water-hydroxyl (◑) groups at 285 K at various ethanol mole fractions, X_A, in the ethanol–water system.

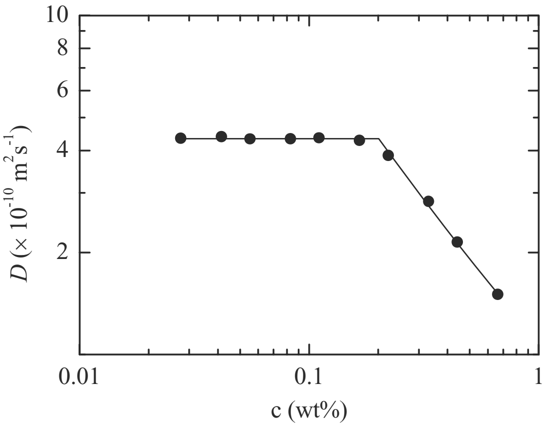

Fig. 3. Determination of the cmc of SDS in D_2O from NMR diffusion measurements as a function of surfactant concentration. The break in the data at $C_t = 0.2$ wt% represents the cmc (modified from Ref. [48]).

be drawn regarding the complicated solution chemistry of this system [46].

Since the diffusion coefficient directly reflects molecular size, diffusion measurements have been used to great effect in determining the critical micellar concentration (cmc) of surfactants. Typically the associating surfactant solution is modeled using a two-site exchange model, in which the observed diffusion coefficient is expressed as a population weighted average between "free" and "bound" (i.e. surfactants in micelles) surfactant [47]:

$$D = D_\mathrm{f}\frac{C_\mathrm{f}}{C_\mathrm{t}} + D_\mathrm{b}\left(1 - \frac{C_\mathrm{f}}{C_\mathrm{t}}\right) \tag{11}$$

where $D_\mathrm{f,b}$ are the diffusion coefficients of free and micellized surfactants, respectively. $C_\mathrm{f,t}$ is the concentration of free and total concentration of surfactant (NB C_f/C_t is the free population), respectively. An example of determining the cmc from diffusion data is given in Figure 3.

Ligand Binding and Aggregation

Since diffusion is an excellent probe of molecular size and mobility, NMR diffusometry is becoming an increasingly important tool in drug development where it is sometimes referred to as "affinity NMR" [49].

As an illustration, consider the simple two site system where a drug (i.e. ligand, L) exchanges between being in free solution to any one of n equivalent binding sites on the protein (P) with a dissociation constant K_d (i.e. $\mathrm{PL} \overset{K_\mathrm{d}}{\rightleftharpoons} \mathrm{P} + \mathrm{L}$). The coupled differential equations describing the echo signal intensities at the free and bound sites are (e.g. see [21,39–41]),

$$\begin{aligned}\frac{\mathrm{d}S_\mathrm{f}}{\mathrm{d}t} &= -\gamma^2 g^2 D_\mathrm{f}\delta^2 S_\mathrm{f} - \frac{S_\mathrm{f}}{\tau_\mathrm{f}} + \frac{S_\mathrm{b}}{\tau_\mathrm{b}}\\ \frac{\mathrm{d}S_\mathrm{b}}{\mathrm{d}t} &= -\gamma^2 g^2 D_\mathrm{b}\delta^2 S_\mathrm{b} - \frac{S_\mathrm{b}}{\tau_\mathrm{b}} + \frac{S_\mathrm{f}}{\tau_\mathrm{f}}\end{aligned} \tag{12}$$

where τ_f and τ_b are the lifetimes in the free and bound sites, respectively. The initial conditions are given by $S_\mathrm{f}\,|_{t=0} = P_\mathrm{f} = (1 - P_\mathrm{b})$ and $S_\mathrm{b}\,|_{t=0} = P_\mathrm{b}$ where P_f and P_b are the populations in the free and bound sites, respectively. At $t = \Delta$ and in the case of fast exchange, this reduces to the particularly simple single exponential form,

$$E = S_\mathrm{b} + S_\mathrm{f} = \exp\left(-\gamma^2 g^2 D_\mathrm{obs}\delta^2\Delta\right) \tag{13}$$

where

$$D_\mathrm{obs} = (1 - P_\mathrm{b})\,D_\mathrm{f} + P_\mathrm{b}D_\mathrm{b} \tag{14}$$

is the population-weighted average diffusion coefficient. In the case of this simple two-site model, the bound population is given by

$$P_\mathrm{b} = \alpha - \sqrt{\alpha^2 - \beta} \tag{15}$$

and

$$\alpha = \frac{(C_\mathrm{L} + nC_\mathrm{P} + K_\mathrm{d})}{2C_\mathrm{L}} \quad \text{and} \quad \beta = \frac{nC_\mathrm{P}}{C_\mathrm{L}} \tag{16}$$

where C_L and C_P are the total concentrations of drug and protein, respectively. D_f can be determined by measuring the diffusion of the drug in protein-free solution, and D_b can normally be taken as equal to the protein diffusion coefficient since the binding of the drug should have negligible effect on the diffusion coefficient of the (much larger) protein molecule. An example of an NMR diffusometry study of drug binding is given in Figure 4.

Restricted Diffusion

As noted above, when diffusion occurs within a restricting geometry, the geometrical restrictions result in characteristic echo attenuation curves. Thus, diffusion measurements provide a powerful means of probing porous materials. An example of probing a simple pore in which water is diffusing between two parallel planes is given in Figure 5.

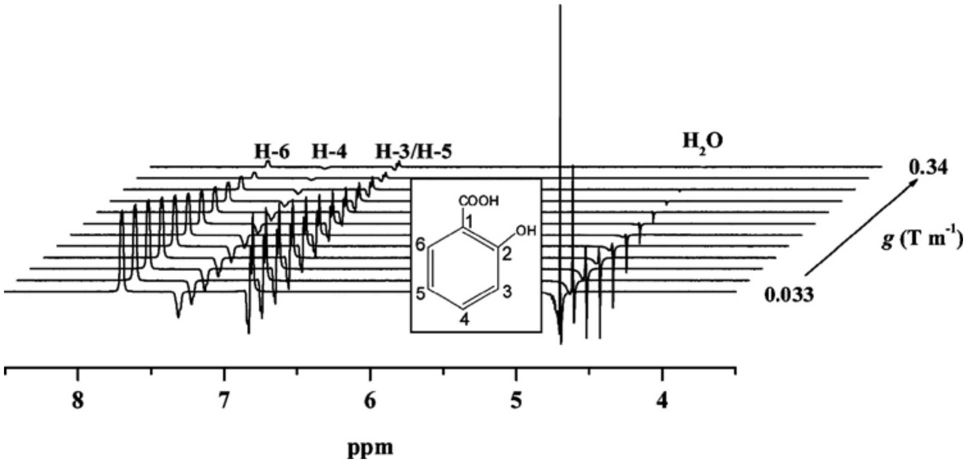

Fig. 4. An example of an NMR diffusion measurement for studying drug binding: A 500 MHz ^{1}H PGSE-WATERGATE spectra of 80 mM salicylate and 0.5 mM bovine serum albumin in water at 298 K. The (residual) water resonance gives rise to the peak at 4.7 ppm and the three peaks to the left originate from salicylate (from left to right: H-6, H-4, H-3/H-5; also see inset) (modified from Price *et al*. [50]).

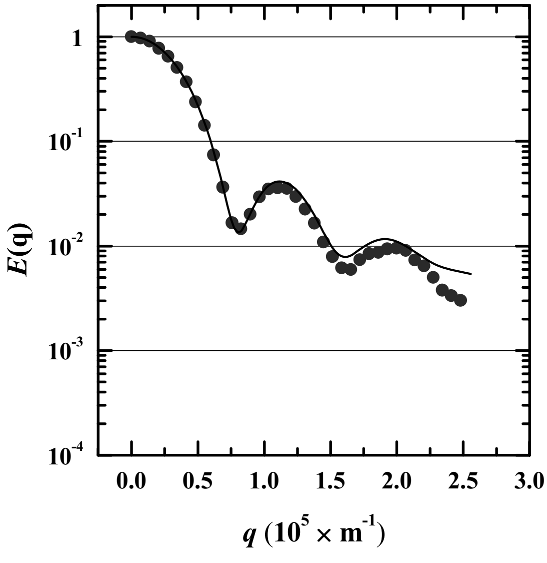

Fig. 5. ^{1}H PGSE NMR attenuation profile for water diffusing between planes separated by distance $a = 128$ μm at 318 K. The gradient is directed perpendicular to the planes. The experimental parameters were $\Delta = 2$ s and $\delta = 2$ ms. The solid black line denotes the result of fitting the data with the SGP formula [Equation (4)]. The diffractive minima appear at $q = n/a (n = 1, 2, 3, \ldots)$ (modified from Ref. [51]).

Field Gradient NMR of Liquid Crystals

István Furó[1] and Sergey V. Dvinskikh[2]

Abstract

Field-gradient NMR applications in liquid crystals (LCs) are dominantly experiments that detect the translational self-diffusion of the various structural units of the liquid crystalline phases. The anisotropy of LCs often leads to line broadening effects that must typically be suppressed in order to accommodate sufficient gradient dephasing of the nuclear spins. Having dealt with this problem, diffusion studies provide important insights into both lyotropic and thermotropic liquid crystal systems.

Introduction

Liquid crystals (LCs), although anisotropic, consist of highly mobile molecules just like "usual" isotropic liquids. Hence, all NMR methods that are used for extracting molecular information in isotropic liquids could, in principle, furnish the same type of information in LCs, with one important difference: anisotropy of LCs results in tensor instead of scalar properties. Thus, for example, translational self-diffusion, characterized by a scalar diffusion coefficient D in the isotropic case, becomes instead dependent in LCs on a diffusion tensor $\mathbf{D}$ [1–5]. By diagonalizing $\mathbf{D}$, one can in general extract three pieces of information, represented by the principal components $D_{\alpha\alpha}$, $D_{\beta\beta}$, and $D_{\gamma\gamma}$ of $\mathbf{D}$ [4,6]. Of these three components, two are equal for LCs with a symmetry axis of higher than threefold symmetry.

Here, we intend to provide a brief survey, with representative examples and directions to relevant reviews, of magnetic-field-gradient-based NMR investigations of LCs. Most of the involved studies aimed at measuring self-diffusion in those materials and therefore diffusion studies dominate here, with a few other gradient applications mentioned at the end. Our survey is not chronological and, with over 10^3 relevant publications, cannot be comprehensive. Neither can we elaborate upon related issues, such as the large and still emerging area of diffusion tensor imaging [4,7–10].

With very few exceptions (such as lyotropic cubic phases), LCs [11] are formed by anisomeric objects, often called mesogenic units. Liquid crystalline ordering stems from the anisotropic pair potential among those objects [12]. In thermotropics, one of the two broad classes of LCs, the mesogenic units are typically elongated or flat molecules with no other principal system component. A typical example is 4-pentyl-4′-cyanobiphenyl (5CB) where a rigid central biphenyl group lends the molecule an elongated shape. The other broad LC class contains the lyotropic systems where the common element is a solvent (typically water) that embeds the mesogenic units that can be multi-molecular aggregates but also single molecules. Typical example for the former are lyotropic LCs formed by elongated (e.g. in hexagonal phases) or flat (e.g. in lamellar phases) aggregates of amphiphilic molecules, either surfactants or lipids. Lipid-based LCs, akin to lipid bilayer [13] structures of cells, have a clear biological relevance.

NMR Methods and Diffusion in LCs

Since LCs are anisotropic, their NMR properties depend on the orientation with respect to the applied magnetic field [1,2,4,5,14]. Moreover, anisotropic spin couplings, such as the dipole–dipole or quadrupole interactions, are not averaged by molecular motions to zero but to a residual value. Often, the relation between the instantaneous and residual couplings is simply defined by a scalar order parameter S of the LC phase while in some phases, such as in biaxial ones, this relation may take instead a more complex form [2]. In some LCs, with cubic phases as an example, the residual coupling may vanish by symmetry and the spectra containing narrow lines become similar to those recorded in isotropic liquids.

The manifestation of non-vanishing residual couplings depends on the macroscopic orientational order within the sample. For simplicity, we exemplify this with a uniaxial LC phase where the average orientation of molecules in a given spatial region is defined by a unique direction, the LC director $\mathbf{d}$. The NMR signal given by those molecules depends on the orientation of $\mathbf{d}$ with respect to the applied static magnetic field $\mathbf{B_0}$. Some LCs can be prepared, either through mechanic [15–18] or electromagnetic [19–25] interactions, in a homogeneous state with the same $\mathbf{d}$ all over the sample volume. Such macroscopically oriented LCs are contrasted to "powder" samples with $\mathbf{d}$ that varies randomly from domain-to-domain: if the domain

Graham A. Webb (ed.), Modern Magnetic Resonance, 117–122.
© 2008 *Springer.*

size is small, on the experimental time scale translational diffusion may average the residual coupling to zero.

The appearance of the spectra also depends on the involved spin couplings. The pairwise dipole–dipole interaction typically acts in LCs among a manifold of nuclei. Hence, static spectral splitting typically renders the spectra of dipole–dipole coupled ^{1}H nuclei wide and featureless, even in macroscopically oriented samples, because it consists of many overlapping lines. The only exception is having the director of a macroscopically oriented sample at the "magic angle" to $\mathbf{B_0}$, where all static splitting vanishes. In contrast to the dipole–dipole case, single-spin quadrupole interactions for spin $I > 1/2$ nuclei in a macroscopically oriented LC may result in spectra split into $(2I + 1)$ sharp lines. Powder samples exhibit large static broadening, both for the dipole–dipole and quadrupole cases but often with a discernible "powder pattern" line shape [26] for the latter one.

Spectral broadening translates into a quick decay of spin coherences in the time domain that has a direct bearing on field-gradient NMR experiments for diffusion [27–31]. Irrespective of the specific experiment (pulsed-field-gradient spin or stimulated echo and variations, the former ones often abbreviated as PGSE and PGSTE), NMR detects displacement via gradient-assisted de- and re-phasing of spin coherences. In the absence of motion, all de-phased magnetization can be recovered. Random diffusive displacement of individual molecules introduces random re-phasing errors that manifest themselves in an increasing signal loss upon increasing de-phasing ($\sim\gamma g\delta$, where g and δ are the strength and the length of the applied gradient pulses, respectively and γ is the gyromagnetic ratio), diffusion time Δ, and diffusion coefficient D. In isotropic liquids, the result is described by the well-known Stejskal-Tanner [32–34] expression

$$I(g, \delta, \Delta) \sim \exp[-D\gamma^2 g^2 \delta^2(\Delta - \delta/3)], \qquad (1)$$

whose Gaussian appearance is a direct consequence of the Gaussian spatial propagator for translational self-diffusion. In anisotropic systems this expression is straightforwardly modified to accommodate for the anisotropy of the system as [1,2,4,33]

$$I(\mathbf{g}, \delta, \Delta) \propto \exp[-(\gamma\delta)^2(\Delta - \delta/3)\mathbf{gDg}]; \qquad (2)$$

note that the relative orientation of the gradient vector $\mathbf{g}$ ($g = \sqrt{\mathbf{g}^2}$) and the principal axes of the diffusion tensor $\mathbf{D}$ affects the experimental outcome. Clearly, diffusion can be measured only if the spins can be sufficiently de-phased which is strongly limited in LCs with quick decays of spin coherences. For the same reason, most diffusion experiments were performed in nuclei with large γ (such as ^{1}H and ^{19}F).

The presented solutions suppress the spectral broadening effects by residual spin couplings and involve either the mechanical manipulation of the sample orientation or the radiofrequency (rf) manipulation of the involved spins or both. The simplest and earliest [35–37] method in the former class involves preparation of a homogeneously oriented sample which is then placed by its director at the magic angle with respect to $\mathbf{B}_0$ which often results in a sufficient reduction of the static line broadening [1,38,39]. The disadvantage with the technique is its demand on homogeneous orientation that must be both settable and sustainable at the magic angle. An offspring of this technique is a diffusion experiment performed under MAS conditions [40–43] with the gradient field set along the spinning axis. The other broad option involves various decoupling or echo-based refocusing techniques applied under the de-phasing and re-phasing periods of a diffusion experiment [44–52]. The difficulty with those experiments is to maintain the performance of the selected rf pulse sequences under the far-offset conditions set by the simultaneous application of the field gradient. Slice selection, although at the cost of signal-to-noise ratio, is a straightforward option [45–52]. Spatial slice selection and decoupling can also be replaced by spectral slice selection by long selective pulses [53]. Finally, we note that instead of suppressing line broadening one may try to use stronger field gradients; one way of obtaining such is to use static instead of pulsed ones [54,55]. The disadvantage of that technique is the additional line broadening and connected reduction in signal-to-noise ratio caused by the static gradient.

In whichever case, a full characterization of the diffusion tensor $\mathbf{D}$ requires experiments performed at several relative gradient orientations. This can be achieved on two principally different ways. First, in a homogeneously oriented sample several experiments can be performed with different gradient directions [56–58] with respect to the sample. Conventionally, $D_{||}$ and $D_{\perp}$ denote diffusion along and perpendicular to $\mathbf{d}$. Our examples, shown in Figure 1, are taken from such type of studies. The other option, applicable in unoriented powder samples, exploits the spectral broadening itself by anisotropic spin interactions. In favorable cases, those interactions provide correspondence between the spectral frequency and domain orientation. Hence, differential decay of powder spectra (either by quadrupole interaction [59] or by chemical shift anisotropy [48,60]) for just one gradient direction reveals the complete diffusion tensor $\mathbf{D}$.

If diffusion within individual domains of unoriented powder samples cannot be orientationally assigned (as is typical for ^{1}H nuclei), the diffusional decay becomes the composite of decays for different gradient orientations [4,62–66]. If the orientational distribution is completely random and other effects, such as restricted diffusion, do not complicate the evaluation, the diffusion tensor can also

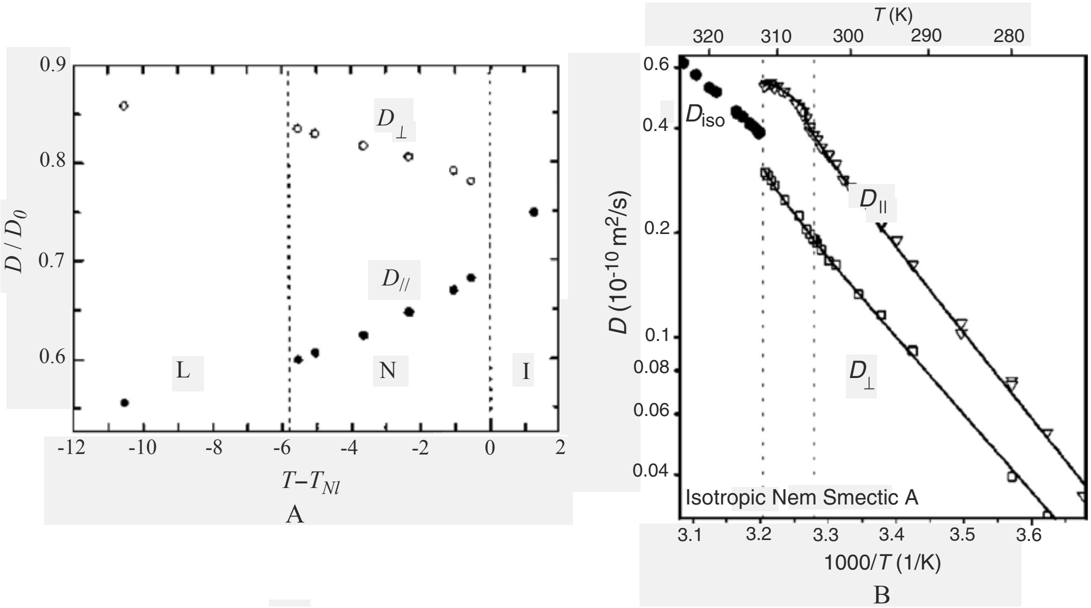

Fig. 1. (A) Temperature dependence of anisotropic diffusion across several lyotropic, [61] and (B) thermotropic [51] phases, measured by pulsed-field-gradient spin-echo-type experiments. In (A), ^{2}H pulsed-field-gradient quadrupole-echo experiment is applied to heavy water in its mixture with cesium perfluorooctanoate (CsPFO). This fluorinated surfactant forms in water flat aggregates, which exhibit nematic order (with their short axis along the field direction) upon cooling below the isotropic–nematic transition temperature T_{NI}. Upon further cooling, the system enters into a lamellar phase (L) consisting of defective CsPFO-bilayers. In (B), the diffusion of the mesogenic unit 4-octyl-4′-cyanobiphenyl (8CB) is followed by ^{2}H pulsed-field-gradient stimulated-echo experiments performed under simultaneous decoupling. be extracted either from the composite decay [4,62–66] or from more advanced diffusion–diffusion correlation (or exchange) experiments [67–69].

Lyotropic Applications

Although some molecular lyotropic phases have been investigated by NMR, here we restrict ourselves to systems where the mesogenic units are aggregates of simple surfactants and/or lipids (and thereby also exclude discussion of, e.g. block-copolymer-based lyotropic materials [64,65,70]). The corresponding isotropic phase, typically termed as micellar, has a liquid-like orientational order of the aggregates; diffusion NMR in micellar or related systems has been extensively studied and reviewed [71–74]. Among the LC phases, there exist many different symmetries with an underlying variation of aggregate geometry [24,75–81]. Irrespective of that, the NMR properties of the two main system components, water (solvent) and amphiphile differ: if any, the residual coupling and thereby the static broadening/splitting of water is typically small. Hence, water diffusion is accessible by conventional diffusion experiments, modified if necessary to ascertain refocusing in presence of static dipole or quadrupole splitting [61]. The same is also frequently the case for hydrophobic solubilizates within the amphiphile phase [82,83]. On the other hand, the broadening by residual coupling for the amphiphiles is typically large and must be suppressed in a diffusion experiment. The only exception is formed by cubic phases that, although crystalline, exhibit no static broadening. Hence, most amphiphile diffusion data are from cubic systems [1,3]; those ones from bicontinuous phases where curved amphiphile bilayers separate water- and oil-rich regions are relevant for and representative of bilayer diffusion in lamellar phases, too. Diffusion experiments were also carried out on some surfactant counterion species.

As concerning anisotropic lyotropic LCs, we discuss below nematic phases that consist of orientationally ordered anisomeric micelles, hexagonal phases where elongated aggregates (or water channels in the inverse versions) arrange themselves in a 2D hexagonal lattice, and lamellar phases where flat amphiphilic bilayers exhibit a 1D translational order. In all those systems, there are two issues that have decisive influence on the obtained diffusion data. First, D varies with the molecular environment and molecules exchange quickly among those; therefore, the observed diffusion coefficient is typically a population average. For water, the two environments are the bulk (fast diffusion) and the amphiphilic headgroup region (slow diffusion), while for the amphiphile there exists a small population of quickly diffusing monomers and a large population of slowly diffusing aggregates. The second consideration is topological [84–86]. Pathways for diffusion of water, for example, are obstructed from the hydrophobic interior the aggregates and therefore the spatial average of the diffusion coefficient is lower than the bulk value. If the obstruction is topologically enclosing (or directionally limiting) a region, the diffusion there becomes restricted that may result in very low average diffusion coefficient and/or to a composite diffusional decay.

In nematic lyotropics that consist of closed (finite) aggregates, diffusion in the hydrophobic domain [66], although informative, is less representative of the phase and aggregate structure (except in the region of phase transition into continuous aggregate topologies). Instead, water diffusion can be used to report on these issues but to draw quantitative conclusions require very high accuracy and precision (see data example in Figure 1A) [56]. In the CsPFO/water mixture, large obstruction by flattened aggregates for diffusion parallel to their axis has been used to calculate average aggregate size and the orientational order of the aggregates as function of temperature [61]. The same system forms, upon cooling, a lamellar phase where the bilayer structural unit is pierced by water-filled defects; similar structures appear in lipid-based systems, where amphiphile lateral diffusion becomes indicative of the defects [66,87]. Water diffusion along the defective lamellar phase director (and therefore across the bilayers) is much higher [61,66,86,88–92] than in defect-free lamellar phases [58,93]. In the latter systems, lateral diffusion of the amphiphilic molecules along the bilayers has been addressed by several different methods [1,3,4,36–38,60,94–96] yielding liquid-like mobilities and activation energies where the latter is often dominated by the strong headgroup–headgroup interactions. In contrast to lamellar phases, defects in hexagonal lyotropic LCs break the continuity of the aggregate [82,97]. Since the aggregate shape in hexagonal phases is elongated, obstruction to water diffusion [84,85,98] is weaker than in systems consisting of flattened aggregates.

Thermotropic Applications

Diffusion in thermotropic LCs [11] has been addressed by a broad range of NMR techniques [4,99,100]. These include combining pulse-field-gradients with (i) "nematic" echo [101–103], (ii) multiple pulse decoupling [45–52,104–106], magic-angle sample orientation [25,35,57,102,107–112], (iii) deuterium stimulated (alignment) echo [50], (iv) soft-pulse excitation [53], and (v) multiple quantum NMR [51,113,114]. Besides, static field gradient techniques have also been used [115,116].

Most experiments have been performed in nematic phases that lack translational but possess orientational order. Nematic phases were also frequent choices for development and testing of new techniques for self-diffusion LCs: the nematic phase of 5CB is a benchmark compound. Recently, diffusion data in 5CB obtained by several methods, including also non-NMR techniques, have been compared [49]. While earlier results strongly disagree, obviously due to methodological problems, more recent studies [49,53,115] by advanced NMR techniques demonstrate a better agreement: the diffusion coefficient in 5CB ranges from 10^{-9} to 10^{-10} m^2/s, depending on temperature and diffusion directions. The diffusion anisotropy, $D_{||}/D_{\perp}$ decreases from 2.7 to 1.5 toward the nematic–isotropic transition and, hence, it reflects the decrease of molecular orientational order; the elongated mesogenic units diffuse easier along the director than across it. In the isotropic–nematic transition region, the average diffusion coefficient matches the diffusion coefficient in the isotropic phase, with similar (~30 kJ/mol) activation energies. Clearly, diffusional transport in the nematic phase is liquid-like and broadly consistent with some available diffusion models [49,51]. Conventional PGSE NMR measurements performed on the isotropic side of the isotropic–nematic phase transition indicate the formation of locally ordered nematic clusters [117,118].

The temperature dependencies of the principal components of diffusion tensors were also reported for homologous series of alkoxy–azoxy benzenes and nOCB [111,112]. Characteristic alternation of diffusion coefficients and activation energies as functions of the number of chain segments, i.e. the familiar odd–even effect, has been observed. In a cholesteric–nematic phase [119], PGSTE NMR has detected diffusion anisotropy ($D_{||}/D_{\perp} \approx 1.7$) similar to that in 5CB but $\mathbf{D}$ was strongly dependent on the diffusion time.

Since smectic phases have layered structures with 2D liquid-like order within the layers, their diffusion anisotropy typically becomes $D_{||}/D_{\perp} < 1$ [99], opposite to that in nematics. Exceptions are smectics that exhibit a significant temperature range of a nematic phase: for them $D_{||}/D_{\perp} > 1$ may occasionally be found in the vicinity of the nematic region [51,108] and upon cooling deeper into the smectic phase the diffusion anisotropy changes sense [102]. As concerning activation energies, the relation $E_{||} \geq E_{\perp}$ is always fulfilled in smectics. At the nematic–smectic phase transition $D_{\perp}$ changes nearly continuously, while $D_{||}$ and/or its activation energy may jump, in accordance to the layer-like smectic structure with liquid-like in-layer diffusion and solid-like jumps between adjacent layers [51,99,116]. In contrast to conventional thermotropics built by elongated mesogenic units, discotic materials are formed by flat molecules. In a columnar (smectic) phase of those, ^{2}H PGSE NMR detected very slow ($\sim 10^{-14}$ m^2/s) diffusion with a large activation energy (115 kJ/mol) that suggest solid-like or, perhaps, collective diffusion mechanisms in discotics [52].

Thermotropic LC behavior can also be found for polymeric molecules. Hence, anisotropic diffusion with $D_{||} > D_{\perp}$ relative to α-helical chain axis has been observed in LC phase formed by rod-like polypeptides [120–123], with activation energies recorded as function of the main-chain length [122]. In the polymeric LC formed by the less rigid poly(diethysiloxane), the diffusion was found faster than that in the isotropic phase: this interesting effect was attributed to more entanglements between the polymer chains in the isotropic phase [124].

Due to much lower orientational order, small organic solute molecules in LCs exhibit long decays of spin coherences. Hence, conventional PSGE experiments are typically sufficient to access the diffusion coefficients of solutes [99,125]. In nematic phases, the solute diffusion is fast and the diffusion anisotropy is small [99,100]. This contrasts the strong diffusion anisotropy $D_{||}/D_{\perp} \ll 1$ observed in smectic phases [99]. A particularly interesting and simple solute is the noble gas ^{129}Xe, whose diffusional behavior was studied in detail [126–130]. While no diffusion anisotropy ($D_{||}/D_{\perp} \sim 1$) was detected in a nematic phase [126], weak anisotropy with $D_{||}/D_{\perp} > 1$ has been observed in a related mixture [127]. This contrasts the $D_{||}/D_{\perp} \ll 1$ found in smectic phases of ferroelectric LCs [128,129].

Other Applications of Field Gradients

Magnetic field gradients are useful in high-resolution NMR for selecting and filtering coherence transfer pathways and may advantageously replace or be combined with phase cycling [131]. Hence, magnetic-field-gradient pulses have been used for various multidimensional [42,132,133] and multiple-quantum experiments [134,135] in LCs and for selective suppression of, e.g. water signals in ^{1}H HR-MAS NMR in lipid membrane samples [136]. As another tool for improving spectral quality, field-gradient pulses have been applied in combination with frequency-selective rf pulses to limit the sensitive volume in liquid-crystalline sample in multiple-pulse decoupling PGSE experiments [45,46,48–52,60].

There are also examples of NMR imaging experiments applied to LCs. Velocity imaging of liquid crystalline polymers flowing through an abrupt contraction was performed by pulsed-field-gradient NMR techniques [137]. Magnetic-field-gradient pulses were also incorporated in rheo-NMR experiments on various LC samples as reviewed by Callaghan [138].

Field Gradient NMR for Polymer Systems with Cavities

Yuji Yamane and Sunmi Kim
Department of Chemistry and Materials Science, Tokyo Institute of Technology, 2-12-1 Ookayama, Meguro-ku, Tokyo 152-8552, Japan

Introduction

Pulse field gradient (PFG) NMR method has become a useful technique for studying self-diffusion of probe molecules in polymer systems. Recently, high field-gradient NMR system with a maximum strength of more than 1,000 G/cm and new pulse sequences are possible to measure the diffusion coefficient (D) with the order of 1–10^{-11} cm^2/s in polymer systems. It is expected that the use of this system leads to sophisticated knowledge on nature of polymer systems as well as diffusional behavior of probe molecules in polymer systems. A number of papers, reviews, and monographs in this field have appeared [1–7]. In this section, some of most recent topics especially characterization of the polymer systems such as polymer gels and polymer media with controlled cavity through the diffusion experiments rather than principle of PFG NMR system and diffusional behavior of polymer chains have been described.

Diffusion in Polymer Gel Systems

Probe Diffusion in Polymer Gel Systems

Polymer gel systems consist of network polymer chains, solvents, and probe molecules, and also apply to many industrial fields. These functionalities are closely associated with diffusional behavior of solvents and probe molecules, and intermolecular interactions between networked polymer chains and probe molecules. Matsukawa, *et al.* have studied the diffusional behavior of water and poly(ethylene glycol) (PEG) in chemically cross-linked hydrogels. The D values of HDO ($D_{(\mathrm{HDO})}$) in gels are well explained by modified free volume theory in a wide range of the degree of swelling ($Q = M_{\mathrm{swollen}}/M_{\mathrm{dry}}$) [1], and the D_{PEG} values in gels are followed by $D/D^0_{\mathrm{PEG}} = \exp(-\kappa R)$, the dynamical screening length κ^{-1} is proportional to $c^{-0.71}$. The value of -0.71 is close to that proposed theoretically by de Gennes [8,9].

Masaro, *et al.* have studied the diffusional behavior of PEG in aqueous poly(vinyl alcohol) solution and gels as functions of the polymer concentration and molecular size of the diffusant. Several theoretical models based on different physical concepts have been used to fit the experimental data [10,11], and intermolecular interactions of probe molecules with networked polymer chains have been elucidated from the diffusion data [12–15]. Further, they have studied the effect of shapes of the diffusant on the diffusional behavior in gels [16–18]. Most recently, some groups have measured the D values of ^{7}Li and ^{19}F ions in polyelectrolyte gels to understand deeply the mechanism of ionic conduction [19–23].

Characterization of the Inhomogeneities in Polymer Gels

Polymer gels have generally inhomogeneity of the network size, and then properties of polymer gels depend on their spatial inhomogeneity. The existence of spatial inhomogeneity has been studied by light scattering as speckles [24,25]. One of the clearest manifestations of the inhomogeneity is an appearance of speckle pattern. As for chemically-crosslinked polymer gels, the relationship between speckles and spatial inhomogeneity has been elucidated [26]. Nevertheless, some problems on intermolecular interactions between the network and probe molecules associated with inhomogeneity of the network size in polymer gels remain. The measurement of D by PFG NMR has emerged as a powerful method for detecting inhomogeneities in gels. The method is based on the interpretation of the dependence of D on the time Δ ("diffusing time" or "observation time") between the two gradient pulses in the pulse sequences. The time dependens and the distribution of D are observed in gels [27] and other heterogeneous systems [28,29].

For convenience, we consider a probe molecule in a gel with homogeneous network size distribution (homogeneous gel) and with inhomogeneous network size distribution (inhomogeneous gel). As for probe molecules diffusing within a network cell in both of the gels the D value depends on Δ. If a probe molecule is diffusing through sufficiently many network cells in the homogeneous gel, the diffusion component is a single and the D value is independent of Δ, but in inhomogeneous gel the diffusion components are two or more and then the D value is dependent of Δ. When observed over longer times, the diffusion component becomes a single because the D values that comes from the distribution of the network size

Graham A. Webb (ed.), Modern Magnetic Resonance, 123–127.
© 2008 *Springer.*

are averaged out, and are independent of Δ. Therefore, if appropriate Δ in the PFG experiments is selected, useful information on the inhomogeneous network size distribution of gels can be obtained.

The inhomogeneity of polymer gels such as polystyrene (PS) gel and cross-linked ethoxylate acrylate (CLEAR) gel with deuterium dimethylformamide (DMF-d_7) as solvent has been characterized by using time-dependent diffusion NMR [30]. From the experimental results on the D values of probe amino acid, *tert*-butyloxylcarbonyl-L-phenylalanine (Boc-Phe), in the gels, it is cleared that in the short diffusion time range the amino acid in the gels has two components in diffusion as influenced by the distribution of network size, but in the long diffusion time range has a single component in diffusion. Here, we focus on the diffusing time Δ that the diffusion changes from the two components to the single component in diffusion. This specified Δ value is named as the "specific" diffusion time (S_{time}). Then, the diffusion distance is $d = \sqrt{2D\Delta}$ and the "specific" diffusion distance (S_{distance}) is defined as $S_{\mathrm{distance}} = \sqrt{2DS_{\mathrm{time}}}$. Figure 1 shows the Δ dependence of the fraction of the slow diffusion component (f_{slow}) value for Boc-Phe in $\mathrm{PS}_{(2)}$ gels, $\mathrm{PS}_{(1)}$ gels and CLEAR gels with DMF-d_7 as solvent at 30 °C, where $\mathrm{PS}_{(2)}$ and $\mathrm{PS}_{(1)}$ gels are cross-linked by 1 and 2% divinylbenzene (DVB), respectively, and the Boc-Phe concentration is 10 wt%. As seen from this figure, the f_{slow} value increases with an increase in Δ and changes from the two components to the single component at larger Δ. The S_{time} as estimated from these plots for Boc-Phe in $\mathrm{PS}_{(2)}$ gels, $\mathrm{PS}_{(1)}$ gels, and CLEAR gels are 20, 40, and 30 ms, respectively. It is found that the S_{time} depends on the kinds of gels. As for Boc-Phe in $\mathrm{PS}_{(2)}$ gels, $\mathrm{PS1}_{(1)}$ gels and CLEAR gels at 30 °C, the S_{distance} are 1.1, 1.7, and 2.7 μm, respectively. It can be said that the S_{distance} depends on the kind of gels, and that the S_{distance} of Boc-Phe in CLEAR gels is much larger than that of Boc-Phe in PS gels. The cross-linker of PS gels is DVB, and the cross-linker of CLEAR gels is acrylate.

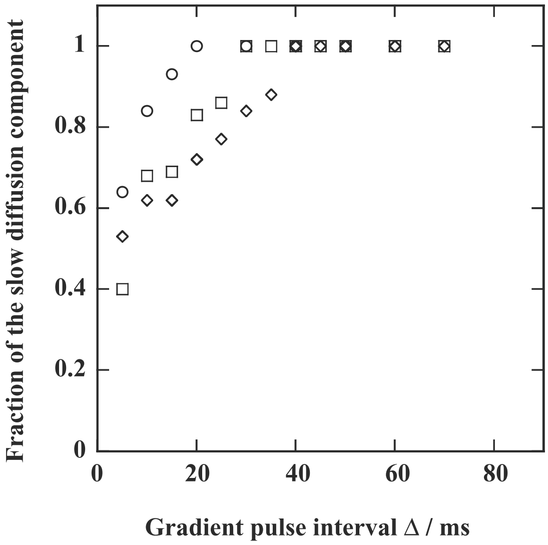

Fig. 1. Dependence of the fraction of the slow diffusion component of Boc-Phe in $\mathrm{PS}_{(2)}$ gels (◯), in $\mathrm{PS}_{(1)}$ gels (◇) and CLEAR gels (□) with DMF-d_7 as solvent at 30 °C on the gradient pulse interval Δ.

One of the goals of this study is to detect inhomogeneities in polymer gels differing in their degree of cross-linking [31]. Then, the networks are prepared at 70 °C by simultaneous polymerization and cross-linking of a mixture of acrylic acid (AA), sodium carbonate, cross-linker (1,4-butanedioldiacrylate), and the redox couple sodium persulfate/sodium isoascorbate as the initiator. Two types of networks are prepared, using the same monomer and sodium carbonate concentrations, but different amounts of the cross-linker, 1.1 and 0.5 wt%, respectively, in the monomer mixture. The corresponding notations are $\mathrm{PAA}_{(1.1)}$ and $\mathrm{PAA}_{(0.5)}$, respectively. Detection of inhomogeneities is based on measuring the D of the probe molecule PEG by time-dependent diffusion NMR. Diffusion measurements are performed as a function of the degree of swelling, $Q = M_{\mathrm{swollen}}/M_{\mathrm{dry}}$, with Q in the range 2.8–10.0.

The different diffusional behavior of the two gel systems emerged as their degree of swelling is varied. For $\mathrm{PAA}_{(1.1)}$ gel with $Q = 10.0$ and 5.2, and for $\mathrm{PAA}_{(0.5)}$ gel with $Q = 10.0$, 5.1, and 4.5, only single diffusion component is detected, independent on the Δ in the range 30–500 ms. For less swollen gels (Q in the range 2.9–4.5 for $\mathrm{PAA}_{(1.1)}$ gel and 2.8–3.9 for $\mathrm{PAA}_{(0.5)}$ gel), two diffusion components (D_{fast} and D_{slow}) are detected as influenced by the distribution of network size, and both of the D_{fast} and D_{slow} values depend on Δ. Here, for all gels, The d_{fast} and d_{slow}, f_{fast}, and f_{slow} values are calculated as a function of Δ. A useful parameter in the interpretation of results is the "specific" degree of swelling (S_{Q}) above which the diffusion of the probe in the two gel systems changed from single to two components. A larger value of S_{Q} in $\mathrm{PAA}_{(1.1)}$ gel is taken as an indicator of a more inhomogeneous gel. Analysis of the effect of Δ on the D, d, and f of the slow and fast diffusion components indicates that both of the gels form a highly cross-linked region in a narrow Q range. In this Q range, the polymer chains interact and form a highly restricted diffusion region. The density and distribution of the cross-links form different restricted diffusion regions in $\mathrm{PAA}_{(1.1)}$ and $\mathrm{PAA}_{(0.5)}$ gel systems, and the heterogeneity in terms of the network size distribution and corresponding populations is higher in the gel with the higher degree of cross-linking.

Characterization of Smart Gels with Regular Structure

Recently, it is necessary to prepare and characterize the smart gel with regular structure, and PFG NMR is more powerful tool for characterizing the soft materials such as gels. It has been reported that highly-oriented poly(γ-benzyl L-gultamate) (PBLG) gel is prepared by cross-linking reaction of highly-oriented PBLG chains in 1,4-dioxane with cross-linker in the magnetic field of an NMR magnet, by monitoring the orientation of the PBLG chains with solid-state static ^{13}C NMR by using the relationship between the observed ^{13}C chemical shift of the main-chain carbonyl carbon in PBLG [32], and then solvents and rod-like molecules in the PBLG gel are anisotropically diffusing in the direction parallel and perpendicular to the α-helix axis by PFG NMR [32,33]. The degree of orientation is 0.81, and the D of 1,4-dioxane molecule in the direction parallel to the α-helical PBLG axis($D_{||}$) to be 5.4×10^{-6} cm^2/s is larger than that perpendicular to the α-helical PBLG axis($D_\perp$) to be 4.5×10^{-6} cm^2/s and the $D_{||}/D_\perp$ value is 1.20. This shows that there exist long channels with small diameter of 15–20 Å (the interchain distances between the nearest-neighboring two PBLG chains determined by the wide angle X-ray diffraction pattern) in the highly-oriented PBLG gel, and that the diffusional behavior of solvents and probe molecules is significantly influenced by the microstructure of network polypeptide chains in gels.

Further, highly-oriented PBLG gels having channel cavities with μm-scale diameters due to phase separation in cross-linking reaction process have been prepared and characterized the structure of the polypeptide gels by PFG NMR and three-dimensional (3D) NMR imaging [34,35]. PBLG gel with channel cavity has two regions consisting of long channel cavity (with μm-scale diameters) region and the remaining gel matrix region without long channel cavity. In the PFG ^{1}H NMR experiments, spin echo signals coming from solvent molecules in the corresponding two regions are observed. In the PBLG gel matrix region, the $D_{||}/D_\perp$ value is 1.29. This shows that the PBLG gel matrix region has anisotropic channel cavity in a nm-scale, and that nm-scale structure of the PBLG gel matrix region in PBLG gel with channel cavity is similar to nm-scale structure of highly-oriented PBLG gel with no μm-scale channels. While, in μm-scale channel cavities of PBLG gel, the 1,4-dioxane molecules may be trapped in channel cavities or may permeate partially and slowly from the channel cavity region to the gel matrix region and from the gel matrix region to the channel cavity region through network of the wall of the channel cavity because the network density near the wall of the channel cavity as formed by cross-linking reaction with phase separation may be higher than that in the PBLG gel matrix region. Thus, if 1,4-dioxan in channel cavity is trapped and mainly diffuse in channel, this reflecting model on diffusion in the space between two infinitely large perfectly reflecting parallel planes (separation $2R$) [36–40] may be approximately used to analyze the diffusion behavior of 1,4-dioxane in the channel cavity of the PBLG gel. The plots of PFG spin echo attenuation $E(q, \Delta = 5$ ms) for diffusion of 1,4-dioxane in PBLG gels with channel cavities against “tunable” parameter $q(= (2\pi)^{-1}\gamma g\delta)$ show the two diffraction minima (not shown) [33]. Here, γ is the gyromagnetic ratio of proton, g is the strength of the field gradient pulse and length δ. When the probe molecules are trapped in restricted space, the diffraction minima corresponding to the size scale of restricted space are often observed as seen from Equation(1).

$$E\,(q,\,\Delta = \infty) = \frac{2\,[1 - \cos{(4\pi q R)}]}{(4\pi q R)^2} \qquad (1)$$

The tendencies for the simulated curves ($2R = 50$ and 60 μm) and the experimental plots are very similar to each other. The slight difference between the experimental and simulated curves may come from the fact that solvent molecules may permeate partially. From this, it can be said that the simulated results do not conflict with the experimental results and thus the mode diameter of the long channel cavities may be estimated to be about 50–60 μm. This is very close to the result by 3D NMR imaging (about 70 μm). Further, it can be said that most of the 1,4-dioxane molecules is reflected at the surface of the wall of channel cavities.

Characterization of the Polymer Media with Nano Cavities

Polymer media with nano cavities has potential as smart membrane, and we need to understand deeply the diffusional behavior of probe molecules and property of cavities. Kärger, *et al.* have shown that PFG experiments gives useful information on zeolites, the molecular dynamics simulations have reasonably explained with the experimental results on self-diffusivity for a binary mixture adsorbed inside zeolite [41–44] and for zeolite and porous media [45,46]. In this section, characterization of the media with controlled nano cavities has been briefly described. The channels in poly(p-biphenylene terephthalate) with long n-dodecyl side chains(PBpT-O12) have been characterized in order to elucidate the nature of the inside of the cylindrical channel cavities as studied by PFG NMR [47]. PBpT-O12 forms the hexagonal columnar phase, and honeycombed network is formed and then has cylindrical cavity channels with diameter of about 3 nm. They aim to prepare PBpT-O12 charged methane and ethane molecules into the cylindrical channel cavities in the hexagonal columnar phase, to measure the D values of the gas in the directions perpendicular ($D_{\perp}$) and parallel ($D_{||}$) to the channel cavity axis.

Methane and ethane molecules in the cylindrical channel cavities have a single diffusion component in the Δ used here. The $D_{||(\mathrm{ethane})}$ value in the cylindrical channel cavities at $\Delta = 6$ ms is determined to be 2.9×10^{-7} cm^2/s. This D value is extremely much smaller than that of ethane gas (0.22 cm^2/s). This means that the diffusion of the ethane molecules is strongly restricted by the nature of the inside of cylindrical channel cavity by intermolecular interactions between the ethane molecules and, especially, long n-dodecyl side chains of the polyester. While, $D_{\perp(\mathrm{ethane})}$ value in the cylindrical channel cavities at $\Delta = 6$ ms is determined to be 9.5×10^{-9} cm^2/s. This D value is extremely much smaller than that of the $D_{||(\mathrm{ethane})}$ value, and also shows that the ethane molecules are not trapped, but diffuse through the wall of the cylindrical channel cavity to the neighboring cylindrical channel cavities. By using $D_{\perp} = 9.5 \times 10^{-9}$ cm^2/s, $\Delta = 6$ ms, we can estimate the d to be 107 nm. Therefore, it can be said that the wall of cylindrical channel cavity has some defects and the ethane molecules are possible to pass through these defects, and that the furthermore ethane molecules in the cylindrical channel cavities are clearly moving through the wall of the cylindrical channel cavity to neighboring cylindrical channel cavities in the direction perpendicular to the cylindrical channel cavity axis in a rod piece of oriented PBpT-O12 polyester media with a diameter of 0.6 mm ($=6.0 \times 10^5$ nm). The ratio of $D_{||(\mathrm{ethane})}/D_{\perp(\mathrm{ethane})}$ is 31, thus, it can be said that the inside of cylindrical cannel cavity is anisotropic field for gas diffusion.

As compared with the $D_{(\mathrm{methane})}$ values in the channel cavities, the $D_{||(\mathrm{ethane})}$ and $D_{\perp(\mathrm{ethane})}$ values are much smaller than those of methane($D_{||(\mathrm{methane})} = 4.2 \times 10^{-7}$ cm^2/s and $D_{\perp(\mathrm{methane})} = 6.5 \times 10^{-8}$ cm^2/s), and then the ratio of $D_{||(\mathrm{ethane})}/D_{\perp(\mathrm{ethane})}$ for ethane is much larger than that for methane($D_{||(\mathrm{methane})}/D_{\perp(\mathrm{methane})} = 6.5$). This means that the cylindrical cannel cavities of PBpT-O12 have high anisotropy in diffusion and the ability for the recognition of the molecular size.

Diffusional Behavior of Linear Molecules in Channels

In general, the inclusion compound is defined as a chemical substance consisting of a lattice of one type of molecule (host) trapping and containing a second type of molecule (guest). The host molecules form a cavity such as a crystal lattice containing spaces with long tunnels or channels in a crystal. According to many kinds of pairs between host and guest molecules, many kinds of inclusion compounds can be formed. Urea usually forms tetragonal structure in the crystalline state. However, in the case of urea adducts, the structure of urea changes to the hexagonal form that is a parallel channel with diameter of about 5.5 Å by strong hydrogen-bonds between urea molecules and n-paraffin molecules are included in the channel. When the host molecule is urea, the inclusion compounds are often called “urea adducts” instead of “urea inclusion compounds.” As a consequence of the requirement for the size and shape compatibilities between the guest molecules and the host channels, typical guest molecules for the urea channel structure are linear molecules such as higher n-alcohols and n-paraffins (with six or more carbon atoms), some n-olefines, n-carboxylic acids, ketones, and esters. The structure and dynamics of urea adduct which has n-paraffin molecules as a guest molecule has been widely studied by various methods such as X-ray diffraction, neutron scattering, Raman, IR, solid-state NMR, molecular dynamics calculation, etc. However, there is little work for elucidating whether guest molecule diffuses in urea channels or not. It is very interesting to think that if guest molecules diffuse in urea channels, how is diffusional behavior? Most recently, the phenomenon that n-paraffins diffuse in urea channels has been successfully detected. It is found that n-paraffin molecules are diffusing in long urea channels and has the two diffusion components such as the fast diffusion component ($D = 10^{-6}$ cm^2/s) and the slow diffusion component ($D = 10^{-7}$ cm^2/s) by using PFG NMR [48]. According to the single-file diffusion model applied in case that molecules cannot pass each other, it can be explained that the two diffusion components such as D_{fast} and D_{slow} are correspond to n-paraffin molecules in the two external regions near the ends of the urea channel and n-paraffin molecules in the central inner region of the urea channel. Furthermore, D of the fast and slow diffusion components of n-paraffin molecules in urea channel are greatly decreased as the carbon number is increased from 8 to 21, but the diffusion coefficients D are slowly decreased as the carbon number is increased from 21 to 32, and from the activation energy of self-diffusion, they say intermolecular interactions between n-paraffin chains and urea channels wall are very smaller than those between n-paraffin chains in the rotator phase [49]. From the diffusing-time (Δ) dependence of the diffusion coefficients, it is cleared that n-paraffin molecules are diffusing colliding with molecules on sides within urea channel. Consequently, the diffusion process of n-paraffins in urea channels is cooperative diffusion such as single file diffusion from the time-dependent diffusion NMR by compared the results of the simulation [50] of the relationships between single file diffusion and diffusion experiments.

Conclusion Remarks

It is demonstrated that PFG experiments gives useful information on the characterization of the polymer systems as well as probe diffusion, and also will have a great potentiality for applications to characterization of smart media with controlled cavities [51,52], aggregation process, lattice-forming process, phase separation systems, and heterogeneous systems [53] as well as gels. Especially, it is important to consider the diffusing time, if so, information about the structure of polymer system and nature of diffusant can be derived from PFG experiments.

NMR Measurements Using Field Gradients and Spatial Information

Shingo Matsukawa
Department of Food Science and Technology, Tokyo University of Marine Science and Technology,
Minato-ku, Tokyo 108-8477, Japan

Introduction

An application of field gradient attaches a spatial information in NMR signal, therefore, it can produce a spatial distribution of nuclei, that is, NMR imaging [1,2]. When two field gradients for the diphase and rephrase applied, the NMR signal decays due to the displacement of nucleus during the time between two field gradients [3,4]. This gives the diffusion coefficient for Fickian diffusion in free space and the space size for a spatially restricted diffusion [5]. Recently, the field gradient is used for the selection of desired coherence pathway by rephasing the desired coherence and dephasing the undesired coherence [6]. In this chapter, these three important uses of field gradient are described.

Diffusion Coefficient Measurements

The Larmor precession frequency depends on the magnetic field experienced by the nucleus, therefore, it has a spatial dependence under the field gradient. The spatial dependent Larmor frequency $\omega(\mathbf{r})$ at the position $\mathbf{r}$ under a spatially linear field gradient $\mathbf{g}$ is expressed as follows

$$\omega(\mathbf{r}) = \gamma(H_0 + \mathbf{gr}) = \omega_0 + \gamma\mathbf{gr} \tag{1}$$

where H_0 is the externally applied magnetic field and $\mathbf{gr} = 0$ at the position of $\mathbf{r} = 0$. When the duration time of the gradient is δ, the difference of the phase angle at r from that at r = 0 is

$$\phi(\mathbf{r}) = \gamma\mathbf{gr}\delta \tag{2}$$

The distance in the direction of $\mathbf{g}$ where $\phi(\mathrm{r}) = 2\pi$ is

$$q^{-1} = 2\pi/\gamma g\delta \tag{3}$$

q^{-1} is the scale of *length* with the gradient. For example, q^{-1} becomes 235 μm for $g = 10$ G/cm with $\delta = 1$ ms. When the sample size, or the size of detection area, is several times larger than q^{-1}, the total signal intensity vanishes because of the dephasing. For the diffusion coefficient measurements, a second gradient is applied in order to rephase the dephased magnetization. Figure 1 shows a typical pulse sequence with two pulsed field gradients (PFG) with rectangular shape along the z-axis, and the dephasing and rephasing behavior of the magnetization when the individual nucleus did not change their positions in the interval Δ between the two PFG. In Figure 1 (a) The magnetizations are aligned along the y-axis by an rf $\pi/2$ pulse. (b) Under the first PFG, the magnetizations precess at the angular velocity of $\gamma\mathbf{gr}$ corresponding to the z coordinate. (c) At the end of the first PFG, the magnetizations are spirally twisted at a pitch of q^{-1}. (d) The application of an rf π pulse along the y-axis rotates the individual magnetizations along the y-axis through 180°, which makes the mirror-symmetrical arrangement of the magnetizations with respect to the y–z plane. (e) Under the second PFG, the individual magnetizations precess at the same angular velocity with that under the first PFG. (f) At the end of the second PFG, the magnetizations are aligned along the y-axis. When the nucleus has a displacement of Δz in the z direction during Δ, it has a phase angular shift

$$\phi(\Delta z) = 2\pi\frac{\Delta z}{q^{-1}} = \gamma g d\Delta \mathrm{z} \tag{4}$$

The echo signal intensity $I(2\tau, g\delta)$ at 2τ is proportional to the vector sum of magnetizations in the sample, therefore, expressed as follows

$$I(2\tau, g\delta) = I(2\tau, 0)\iint \cos(\phi(\Delta z)) \times\rho(\mathbf{r})\, p(\mathbf{r}, \Delta z)\, \mathrm{d}\mathbf{r}\, \mathrm{d}\Delta z \tag{5}$$

where $\rho(\mathbf{r})$ is the density of the nucleus and is constant for homogeneous sample, $p(\mathbf{r}, \Delta z)$ is the probability of the displacement during Δ for the nucleus at $\mathbf{r}$ and $I(2\tau, 0)$ is the total signal intensity without PFG and expressed as follows

$$I(2\tau, 0) = I(0, 0)\exp(-2\tau/T_2) \tag{6}$$

where $I(0,0)$ is the initial signal intensity just after the rf $\pi/2$ pulse. For the free diffusion in an isotropic medium,

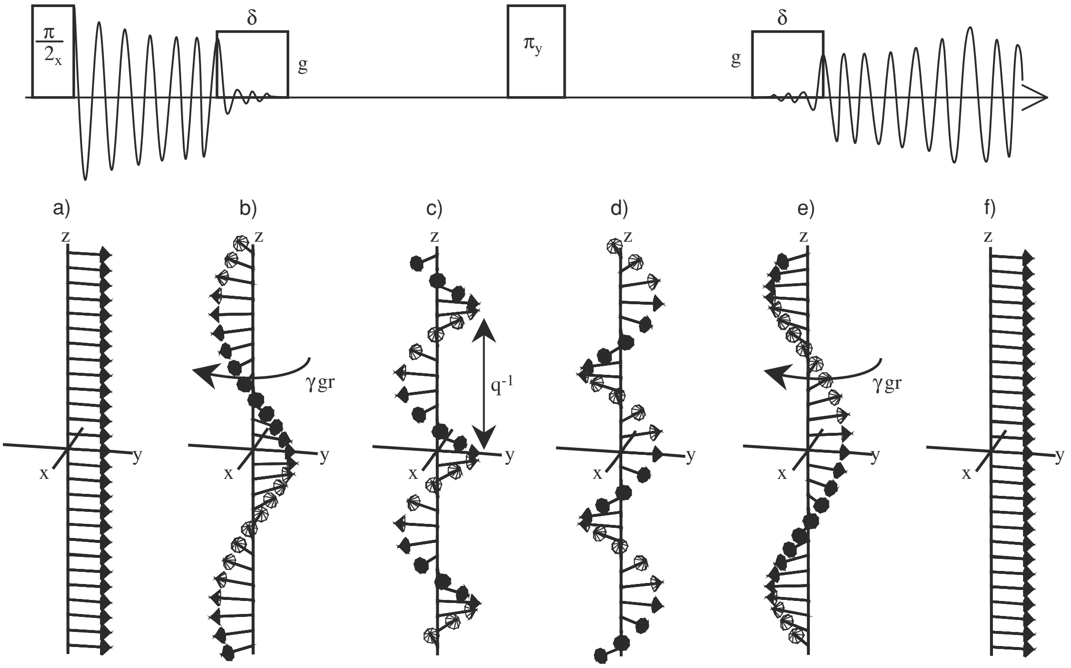

Fig. 1. A typical pulse sequence with two PFG of rectangular shape and the dephasing and rephasing behavior of the magnetization. (a) The magnetizations are aligned along the y-axis by an rf $\pi/2$ pulse. (b) Under the first PFG, the magnetizations precess at the angular velocity of $\gamma\mathbf{gr}$ corresponding to the z coordinate. (c) At the end of the first PFG, the magnetizations are spirally twisted at a pitch of q^{-1}. (d) An rf π pulse along the y-axis rotates the individual magnetizations along the y-axis through 180 degree. (e) Under the second PFG, the individual magnetizations precess at the same angular velocity with that under the first PFG. (f) At the end of the second PFG, the magnetizations are aligned along the y-axis.

$p(\mathbf{r},\Delta z)$ becomes the Gaussian distribution

$$p\,(r,\,\Delta z) = (4\pi\,D\Delta)^{-1/2}\exp\left(-\frac{\Delta z^2}{4D\Delta}\right) \tag{7}$$

where D is the diffusion coefficient. Taking the diffusion during δ into account, Equation (5) is rewritten as follows

$$I(2\tau,g\delta) = I(0,0)\exp\left(-\frac{2\tau}{T_2} - (\gamma g\delta)^2\,D\left(\Delta - \frac{\delta}{3}\right)\right) \tag{8}$$

In common measurements of the free diffusion, $g\delta$ is varied under constant Δ.

For the diffusion in restricted space, the D value obtained by applying Equation (8) is an apparent diffusion constant

$$D_{\text{app}}\,(\Delta) = \frac{\left\langle\Delta z^2\right\rangle(\Delta)}{2\Delta} \tag{9}$$

where $\langle\Delta z^2\rangle(\Delta)$ is the mean square of Δz^2 during Δ. $\langle\Delta z^2\rangle(\Delta)$ is proportional to Δ for the free diffusion, however, becomes smaller than the proportional value due to the spatial restriction, which gives the information of the space size of the restriction.

The signal decay by the displacement under the field gradient can be used to remove peaks for small molecules from the mixture spectrum of small and large molecules. Conversely, the spectrum of peaks for small molecules can be obtained by the subtraction of the decayed spectrum for large molecules from the mixture spectrum. The mixture spectrum is composed of the peaks contained in different molecules that exponentially decay with the square of $\gamma g\delta$ according to individual diffusivity. By changing Equation (8) into a sum of each component, the intensity at each frequency in the mixture spectrum is expressed as follows,

$$I(2\tau,\,g\delta) = I(0,0) \times \sum_i f_i\exp\left(-\frac{2\tau}{T_{2,i}} - (\gamma g\delta)^2\,D_i\left(\Delta - \frac{\delta}{3}\right)\right) \tag{10}$$

where f_i and $T_{2,i}$ are fraction and T_2 for the component with the diffusion coefficient D_i. By using the T_2 weighted fraction of i-th component

$$F_i(2\tau) = f_i \exp(-2\tau/T_{2,i}) \tag{11}$$

Equation (10) is rewritten as follows,

$$I(2\tau, g\delta) = I(0,0) \times \sum_i F_i \exp\left(-(\gamma g\delta)^2 D_i\left(\Delta - \frac{\delta}{3}\right)\right) \tag{12}$$

When F is expressed as a continuos function of D, Equation (12) is rewritten as follows,

$$I(2\tau, g\delta) = I(0,0)\int F(D_i)\exp(-KD)\mathrm{d}D \tag{13}$$

where $K = (\gamma g\delta)^2(\Delta\text{-}\delta/3)$. $F(D)$ is a T_2 enhanced distribution of D. Equation (13) shows that $I(2\tau, g\delta)$ is the Laplace transformation of $F(D)$, therefore, an inverse Laplace transformation of $\mathrm{I}(2\tau, g\delta)$ will give $F(D)$. The 2D spectrum with dimensions of frequency and D, diffusion-ordered NMR spectroscopy (DOSY), gives separated spectrum for each species in the mixture on the diffusivity and the distribution of the diffusivity for each species [7].

NMR Imaging

An application of field gradient along one direction gives one-dimensional profile of spin density. The use of gradients along three direction of x, y and z gives a three dimensional NMR imaging. Figure 2 shows a typical pulse sequence with field gradients of g_x, g_y and g_z along x, y and z, respectively. The g_z applied during rf pulse selects the layer where the Larmor frequency $\omega(\mathbf{r})$ expressed by Equation (1) is equal to the rf frequency. The rf pulse is shaped into sine form $(\mathrm{Sin}(t/d)/(t/d))$ which has a rectangular shape in the frequency domain, which is a Fourier transform of the rf pulse in time domain, and slices the selected layer sharply (Figure 3). The thickness of the layer d is inverse to the rf duration, therefore, a weak rf pulse with long duration is applied for a thin slice of the layer. The g_z causes the phase shift corresponding to the excess magnetic field at $\mathbf{r}$, therefore, a reversed gradient is set after the $\pi/2$ rf pulse in order to rephase the phase shift. The phase shift during the first half of g_z at the π pulse is rephased during the latter half of the period. The pairs of the dephasing and rephasing followed by the slice selection gradient are represented as shadowed portions with upper right and left in Figure 2.

The g_x is applied when the magnetizations are aligned along the y-axis. At the end of the gradient, the magnetization has a phase shift depending on the position along the x-axis, which is given by the rewriting Equation (2) as follows,

$$\phi(x) = \gamma g_x x t_x = 2\pi k_x x \tag{14}$$

where $k_x = \gamma g_x t_x/2\pi$. Then the signal intensity is

$$I(k) = I(0)\int \rho(x)\exp(-2\pi ikx)\mathrm{d}x \tag{15}$$

where, $I(0)$ is the signal intensity without the gradient of g_x and $\rho(x)$ is the projection of the spin density along x-axis in the slice. Equation (15) indicates that $I(k)$ is the Fourier transform of $\rho(x)$, therefore, an inverse Fourier transformation on a series of measured data varying k value (usually varying g_x) gives $\rho(x)$. Figure 4 illustrates the phase shift of magnetization under various g_x. The

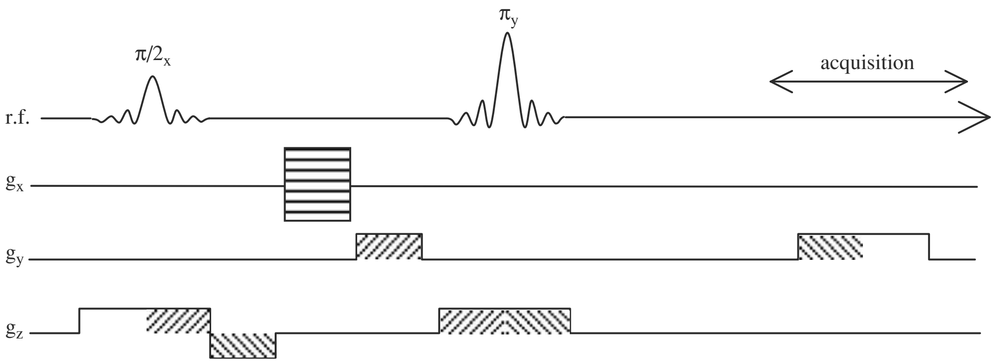

Fig. 2. A typical pulse sequence for three dimensional NMR imaging.

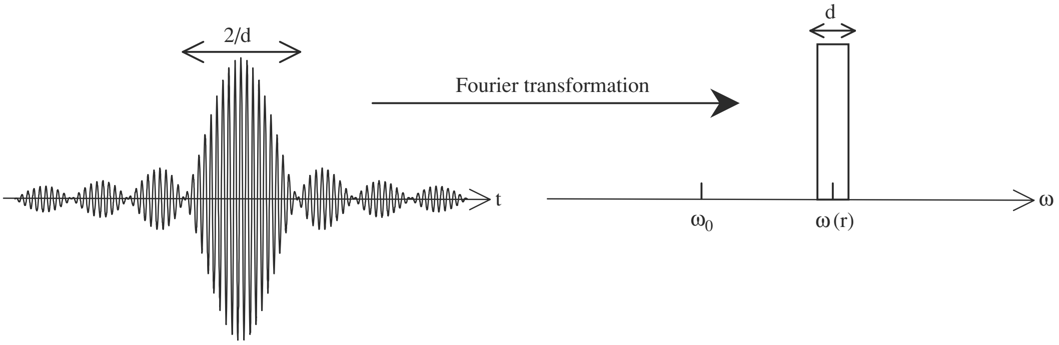

Fig. 3. The rf pulse with the shape of sinc form $(\mathrm{Sin}(t/d)/(t/d))$ and its Fourier transform which has a rectangular shape in the frequency domain.

magnetization without the gradient has an intensity profile corresponding to the projection of the spin density along x-axis in the slice. The application of g_x induces the excessive magnetic field with the strength of $g_x x$ at the x coordinate, which is indicated by gray arrow in Figure 4. The excessive magnetic field rotates each magnetization at the individual rate of $\gamma g_x x$ and the magnetization has the phase shift corresponding to the x coordinate. The pitch of the phase shift k^{-1} is decreased with increasing g_x, and the total magnetization under each g_x is a Fourier component of $\rho(x)$ at k.

The application of g_y during the acquisition period gives each magnetization the difference of precession rate corresponding to the y coordinate, which is reflected in the frequency in spectrum. Therefore, the spectrum obtained by the Fourier transformation of the echo signal is the projection of the spin density along y-axis $\rho(y)$ in the slice. The echo signal $S(k, t)$ is a Fourier component of $\rho(x)$ at k, therefore, the two-dimensional Fourier transform of $S(k, t)$ gives the spin density $\rho(x, y)$ in the slice.

When there are nuclei in different environments, the effect of the excessive magnetic field induced by the field gradient coexist with the shielding effect of surrounding electron clouds, which is the origin of the chemical shift in spectra without field gradients. By using a chemical shift selective pulse, it is possible to obtain NMR imaging of desired nuclei at the chemical shift. It is also possible to remove the undesired signal by a presaturation of the nuclei.

Selection of Coherence

The field gradient is used for the selection of coherence pathways. The coherence selection also achieved by phase cycling, which causes a subtraction of undesired peaks. On the other hand, the field gradient method is based on a spin echo method, which rephases desired peaks and dephases undesired peaks, needs only one scan for a spectrum or an increment in multidimensional measurements.

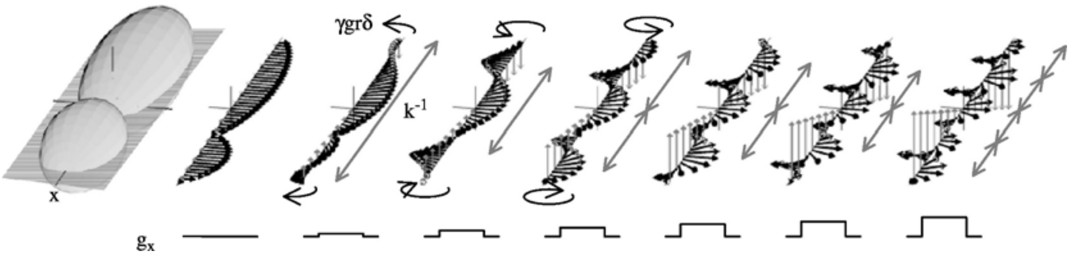

Fig. 4. The phase shift of magnetization under various g_x. The magnetization without the gradient has an intensity profile corresponding to the projection of the spin density along x-axis in the slice. The application of g_x induces the excessive magnetic field with the strength of $g_x x$ (gray arrows), which rotates each magnetization at the individual rate of $\gamma g_x x$ and induces the phase shift corresponding to the x coordinate. The pitch of the phase shift k^{-1} is decreased with increasing g_x.

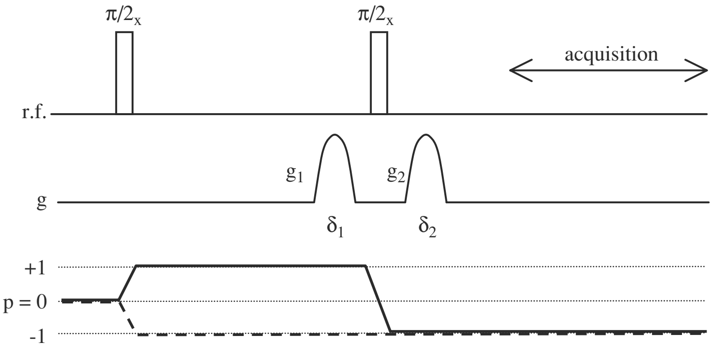

Fig. 5. A pulse sequence for Gradient Selected COSY in magnitude mode. The solid line and dotted line indicate coherence pathways that have the coherence order of –1 at the acquisition period. The former is rephased and the latter remains a phase shift when the gradients are set as $g_1\delta_1 = \gamma_2\delta_2$.

Further, three is no problem of the residue for undesired peaks caused by imperfection of the subtraction in the phase cycling method. Because of this, the application of the gradient gives remarkable improvement for many measurements developed on the basis of the phase cycling method. The gradient method takes advantage of the fact that the space dependent phase shift caused by the gradient depends on the coherence order p. The phase shift is expressed by Equation (2) when $p = 1$. For general orders of p, the phase shift is expressed as follows,

$$\phi(\mathrm{r}) = p\gamma \mathbf{gr}\delta \tag{16}$$

In a homonuclear spin system, the final phase shift after the gradient pulses becomes

$$\phi(\mathrm{r}) = \gamma \sum_{i}^{n} p_i g_i \delta_i r \tag{17}$$

Therefore, the desired coherence pathway corresponding a set of coherence orders $p_1, p_2, \ldots p_i, \ldots p_n$ is rephased by using the set of gradients $g_1\delta_1$, $g_2\delta_2, \ldots g_i\delta_i, \ldots g_n\delta_n$, which satisfies $\phi(\mathrm{r}) = 0$. Other pathways remain the dephase expressed by Equation (17). Figure 5 shows a pulse sequence for *gs* (Gradient Selected)-COSY in magnitude

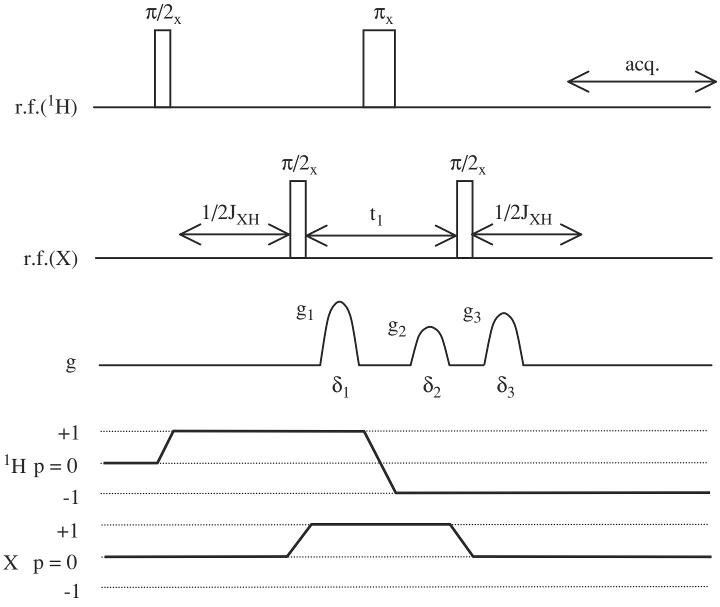

Fig. 6. A pulse sequence for Gradient Selected HMQC. The coherence pathway of solid line is selected when $(\gamma_{\mathrm{H}} + \gamma_{\mathrm{X}})\gamma_1\delta_1 + (-\gamma_{\mathrm{H}} + \gamma_{\mathrm{X}})\gamma_2\delta_2 - \gamma_{\mathrm{H}}\gamma_3\delta_3 = 0$.

mode. The interval of gradients should be short in order to reduce the decay of the signal for the desired pathway by the molecular diffusion. The sinusoidal shaped gradients are used in order to reduce the effect of the eddy current induced by the gradient on the rf pulses. The solid line and dotted line in Figure 5 indicate two coherence pathways that have the coherence order of –1 at the acquisition period. When the gradients are set as $g_1\delta_1 = g_2\delta_2$, $\phi(\mathrm{r}) = 0$ for the coherence pathway of the solid line, on the other hand, $\phi(\mathrm{r}) = 2\gamma g_1\delta_1\mathbf{r}$ for that of the dotted line. Consequently, the former pathway is selected. In a homonuclear spin system, the final phase shift after the gradient pulses becomes

$$\phi(\mathbf{r}) = \sum_{i}^{n}\sum_{j}\gamma_j p_{i,j} g_i \delta_i \mathbf{r} \qquad (18)$$

Figure 6 shows a pulse sequence for gs-HMQC. For the selection of coherence pathway indicated the solid line, the gradients is set as satisfies the equation

$$(\gamma_H + \gamma_X)g_1\delta_1 + (-\gamma_H + \gamma_X)g_2\delta_2 - \gamma_H g_3\delta_3 = 0 \qquad (19)$$

When the nuclear X is $^{13}\mathrm{C}$, $\gamma_{13\mathrm{C}}/\gamma_{\mathrm{H}} \fallingdotseq 0.25$. By using same duration time for each gradient, Equation (19) becomes

$$1.25g_1 - 0.75g_2 - g_3 = 0 \qquad (20)$$

For example, Equation (20) is satisfied when $g_1{:}g_2{:}g_3 = 2{:}2{:}1$, 5:3:4 or 3:5:0. The ^{1}H signals of other pathways such as ^{1}H attached to ^{12}C, which gives a main peak in usual measurements, remains the phase shift and vanishes.

Theoretical Aspects

Concepts of diffusion

Self-diffusion is the random translational motion of molecules driven by their internal kinetic energy [1]. Translational diffusion and rotational diffusion can be distinguished.

Diffusion is related to molecular size, as becomes apparent from the Stokes–Einstein equation:

$$D = k_B T/f \tag{1}$$

where D is the diffusion coefficient, k_B is the Boltzmann constant, T is the temperature, and f is the friction coefficient. If the solute is considered to be a spherical particle with an effective hydrodynamic radius (i.e. Stokes radius) r_S in a solution of viscosity η, then the friction coefficient is given by:

$$f = 6\pi \eta r_S \tag{2}$$

Pulse Sequences for PFG NMR Diffusion Measurements

Using the pulsed-field gradient (PFG) method, motion is measured by evaluating the attenuation of a spin echo signal [2]. The attenuation is achieved by the dephasing of nuclear spins due to the combination of the translational motion and the imposition of gradient pulses. In contrast to relaxation methods, no assumptions concerning the relaxation mechanism(s) are necessary.

The PFG NMR sequence (Figure 1) is the simplest for measuring diffusion [2].

During application of the gradient, which is along the direction of the static, spectrometer field, B_0, the effective magnetic field for each spin is dependent on its position. Therefore, the precession frequency is also position dependent which leads to the development of position dependent phase angles. The 180° pulse changes the direction of the precession. Hence, the second gradient of equal magnitude will cancel the effects of the first and refocus all spins, provided that no change of position, with respect to the direction of the gradient, has occurred. If there is a change of position, the refocusing will not be complete. This results in a remaining dephasing which is proportional to the displacement during the period Δ between the two gradients. Since diffusion is a random motion, there is a distribution of gradient-induced phase angles. These random phase shifts are averaged over the ensemble of spins contributing to the observed NMR signal. Hence, this signal is not phase shifted but attenuated, with the degree of attenuation depending on the displacement. In Ref. [1], this phenomenon is explained in more detail.

It is shown in Ref. [1] that the signal intensity $S(2\tau)$ after the total echo time 2τ is given by:

$$\begin{aligned} S(2\tau) &= S(0)\exp\left(-\frac{2\tau}{T_2}\right)\exp\left(-\gamma^2 g^2 D\delta^2\left(\Delta-\frac{\delta}{3}\right)\right) \\ &= S(2\tau)_{g=0}\exp\left(-\gamma^2 g^2 D\delta^2\left(\Delta-\frac{\delta}{3}\right)\right) \end{aligned} \tag{3}$$

where $S(0)$ is the signal intensity immediately after the 90° pulse, T_2 is the spin–spin relaxation time of the species, γ is the gyromagnetic ratio of the observed nucleus, g is the strength of the applied gradient, and δ and Δ are the length of the rectangular gradient pulses and the separation between them, respectively. Typically, δ is in the range of 0–10 ms, the diffusion time Δ is in the range of milliseconds to seconds, and g is up to 20 T/m [1].

To determine diffusion coefficients, a series of experiments is performed in which either g, δ, or Δ is varied while keeping τ constant to achieve identical attenuation due to relaxation. Normally, the gradient strength g is incremented in subsequent experiments. Non-linear regression of the experimental data can be used for the determination of D.

Nowadays, the BPPLED pulse sequence (see Figure 2) is most often used for measuring diffusion since it allows eddy currents to decay and uses bipolar gradients which enables double effective strength as well as compensation for imperfections. This sequence is not affected by spin–spin coupling since it is based on the stimulated echo sequence.

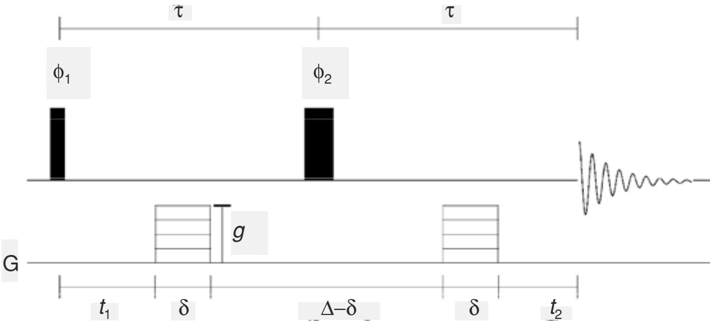

Fig. 1. The Stejskal and Tanner pulsed-field gradient NMR sequence. Narrow and wide filled bars correspond to 90° and 180° pulses, respectively. Open bars with horizontal stripes correspond to pulsed-field gradients whose strength is varied during the experiment. The pulse phases are $\phi_1 = x$ and $\phi_2 = y$. Phase cycling can be included to remove spectrometer artifacts.

The signal intensity of the BPPLED sequence is given by:

$$S = S_{g=0} \exp\left(-\gamma^2 g^2 D \delta^2 \left(\Delta - \frac{\delta}{3} - \frac{\tau_g}{2}\right)\right) \qquad (4)$$

Processing of Diffusion Data

In the chemical shift dimension(s), Fourier transformation (FT) is applied as usual. For each frequency ν, the signal can (in general) have contributions from several components $(1, \ldots n)$ which individually decay with their respective diffusion coefficient:

$$S(g, \nu) = \sum_{i=1}^{n} S_i(0, \nu) \exp\left(-\gamma^2 g^2 D_i \delta^2 \left(\Delta - \frac{\delta}{3}\right)\right) \qquad (5)$$

The individual diffusion coefficients D_i and the signal intensities $S_i(0, \nu)$ have to be extracted in order to construct the diffusion spectra. The name DOSY (diffusion ordered spectroscopy) refers to the presentation of the data obtained in PFG NMR measurements where the chemical shift is plotted in one (or two) dimension and the diffusion coefficient in the other dimension. This presentation allows the identification of signals belonging to one component (or at least to components showing the same diffusion coefficient). Because of this separation, DOSY can be considered as "non-invasive chromatography" [4].

Applications of Diffusion NMR

In PFG spin echo NMR experiments, the interesting observable variable is the diffusion coefficient, therefore, in principle, any phenomena that affects the diffusion coefficient can be studied with this technique. The concept behind the application to the study of molecular interactions is very simple and is based on the fact that the diffusion coefficient of a molecule is altered upon addition of another molecule if there is an interaction between them.

Diffusion NMR has been applied to the study of intermolecular interactions both qualitatively, to identify compounds that bind to a specific receptor in NMR screening

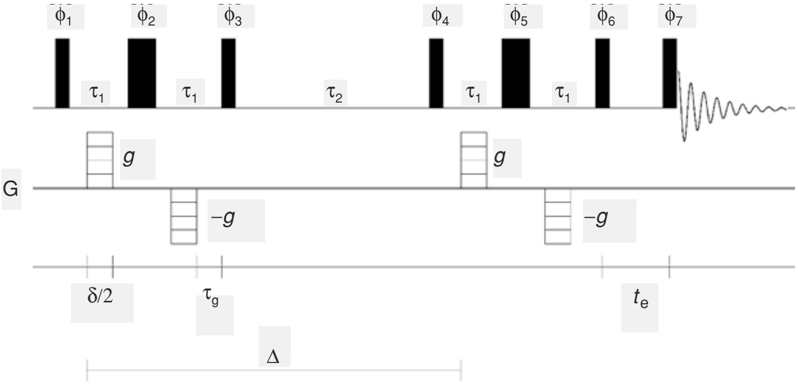

Fig. 2. The LED pulse sequence using bipolar gradients [3]. Narrow and wide filled bars correspond to 90° and 180° pulses, respectively. Phase cycling: $\phi_1 = \phi_2 = \phi_5 = x$; $\phi_3 = 2(x), 2(-x)$, $\phi_4 = \phi_7 = 4(x), 4(-x), 4(y), 4(-y)$; $\phi_6 = x, -x, x, 2(-x), x, -x, x, y, -y, y, 2(-y), y, (-y), y$.

or in studies related to host–guest chemistry [5–8], and quantitatively, in the determination of association constants [9–12] and complex or aggregate sizes [13–18].

For binding and screening studies it is usually sufficient to identify compounds that bind to a certain receptor from a mixture of non-binding compounds, or to establish a relative binding affinity, but the determination of association constants or size requires quantitative determination of the diffusion coefficients with precision and accuracy. A very comprehensive work about the factors that affect data quality in PFG spin echo NMR methods for chemical mixture analysis was published recently by Antalek [19], both data acquisition (including a discussion about experimental conditions and available pulse programs) and data analysis were considered in detail by the author. This chapter complements well the previous work of Price on the experimental aspects of PFG spin echo NMR [2]. After completing this article, an outstanding and comprehensive review on NMR diffusion experiments by Cohen *et al.* has been published [20].

Size and Shape Determination by Diffusion Measurements

Since diffusion NMR allows spectral resolution by size or shape, and this resolution being especially visible in DOSY experiments, it is not surprising that the qualitative or semi-quantitative application of DOSY to the distinction of compounds according to their size is one of the most popular [21]. Examples of this type of application of DOSY can be found in many diverse areas such as in the characterization of polymer additives [22], hydrocarbon mixtures [23], in food chemistry [24,25], or carbohydrate mixture analysis [26,27], just to name a few examples. If some cautions are taken, the experimental diffusion coefficients can be used to obtain quantitative information about the size and shape of a molecule or a particular assembly.

As was already mentioned, the connection between the diffusion coefficient (D) and structural properties arises because diffusion coefficients depend on friction factors (f) which are associated with the molecular size and the viscosity of the solution. The Stokes–Einstein equation [Equation (1)] relates the translational self-diffusion coefficient at infinite dilution of a spherical particle to its hydrodynamic radius r_S, and in spite of the difficulty to justify this equation at a molecular level [28], its simplicity and success in relating experimental diffusion coefficients to molecular radii is the basis for its extensive use in the literature. Examples of the application of experimental diffusion coefficients and the Stokes–Einstein equation for size determination can be found in fields ranging from organometallic chemistry to biochemistry. This relation is usually also the starting point for the development of other models that connect the diffusion coefficient with shapes different from spherical and to expressions related to the molecular weight of the diffusing species.

A simple but very elucidative example is the characterization of THF solvated n-butyllithium aggregates by DOSY [29]. Diffusion ordered spectroscopy was used to distinguish the tetrasolvated dimeric and tetrasolvated tetrameric aggregates (see Figure 3) in THF solution. Theoretical diffusion values for the dimer and tetramer, calculated from the Stokes–Einstein equation, predict measurable differences in diffusion coefficients. For the calculation of the theoretical diffusion the viscosity of neat THF was used, and the hydrodynamic radii were determined from molecular volumes based on crystal structures and gas-phase minimized structures. A good agreement between experimental diffusion coefficients and theoretical values was obtained [29].

As was shown by Waldeck *et al.* [30], by considering the relation between the Stokes radius of a molecule (r_S), its experimentally determinable partial specific volume, V, and its molecular weight, M, a useful expression relating diffusion to molecular weight can be derived:

$$\frac{D_1}{D_2} = \sqrt[3]{\frac{M_2}{M_1}} \tag{6}$$

This general relationship shows that for "ideal" spherical models there is a reciprocal cube dependence of the diffusion coefficient on molecular weight and this allows the calculation of a set of theoretical diffusion coefficients using a reference diffusion (experimental) value. It is therefore worth considering when accounting for the effect of molecular association on the apparent diffusion coefficient, expected to be measured in an experiment.

Another impressive example of the applicability of the Stokes–Einstein equation is found in a study dealing

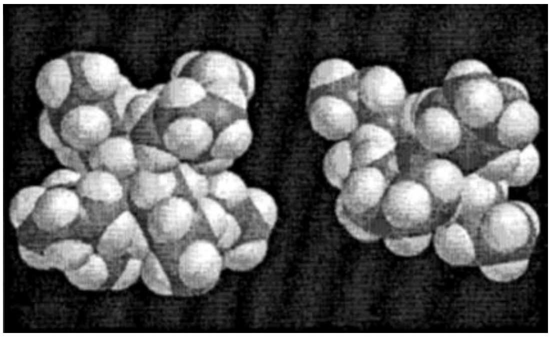

Fig. 3. PM3 optimized structures of $[n\text{-BuLi}]_4{\cdot}\text{THF}_4$ and $[n\text{-BuLi}]_2{\cdot}\text{THF}_4$. Reprinted with permission from Ref. [29]. Copyright (2000) American Chemical Society.

with ubiquitin [32]. The hydrodynamic radius of this protein was calculated from its diffusion coefficient determined by DOSY-HSQC experiments using an accurately calibrated temperature and the viscosity calculated for this temperature. Using Equations (1) and (2) yielded $r_S = 15.8$ Å. Furthermore, the NMR structure of ubiquitin [33] was used for the calculation of its size, which was then converted to $r_S = 16.3$ Å, which is in reasonably good agreement with the value found in DOSY experiments. Thus, the numerical factor 6 given in Equation (2) also holds true for complex situations such as a protein in aqueous solution. This demonstrates that the assumption of a spherical solute moving in a continuous solvent is fulfilled fairly well in this case, which can be verified by inspecting Figure 4.

The field of organometallic chemistry provides several examples of the application of diffusion measurements for size determination, since this is one of the fields where the use of diffusion NMR is becoming more and more popular. Pregosin is among the leaders in the application of PFG diffusion methods in organometallic chemistry and his contributions and perspectives about the technique as well as the most important applications in this field have been the subject of several publications [34].

^{13}C detected DOSY was used by Schlörer *et al.* to study the unstable intermediate **(2)** in the reaction of CO_2 with $[Cp_2Zr(Cl)H]$ **(1)** (see Scheme 1) which was impossible to characterize by other means [35]. $^{13}CO_2$ was used for the reaction which was observed *in situ* by ^{13}C NMR. Following the formation of sufficient amounts of **2**, the mixture has been cooled to −78°C, and ^{13}C INEPT DOSY spectra were recorded. The intermediate **2** was shown to have a smaller diffusion coefficient than the mononuclear complex **3** (see Figure 5) and was therefore proven to be binuclear. Furthermore, its hydrodynamic radius calculated from the experimental results was found to be in good agreement with an estimation based on a minimized gas-phase structure.

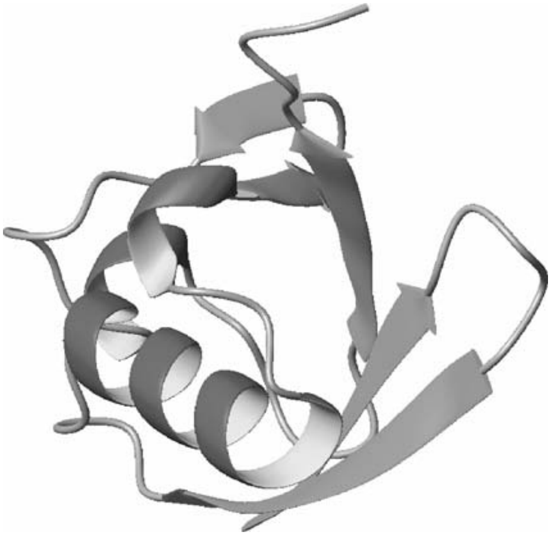

Fig. 4. Schematic representation of the three dimensional structure of ubiquitin. The structure presented here is taken from the data set “1D3Z” [33] in the pdb data bank [31]. (See also Plate 9 on page XXI in the Color Plate Section.)

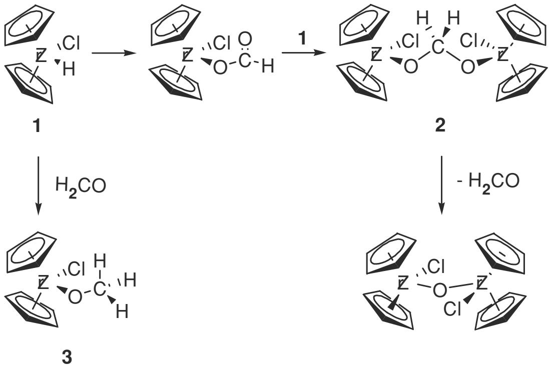

Scheme 1. The reaction of $[Cp_2Zr(Cl)H]$ **(1)** with CO_2 [35].

Still in the field of ionic interactions, a very recent paper from the group of Pregosin explored the application of PGSE NMR studies within the context of chiral cation/anion recognition [36]. According to the authors, this is the first reported example that shows that the diffusion data are sensitive enough to recognize a subtle diastereomeric structural effect on ion translation. The work investigated the dependence of the diffusion value on the diastereomeric structure of the ion pair for chiral organic salts (see Scheme 2). Investigated were the pairs of diastereomers formed between two novel chiral hexacoordinate phosphate anions, known to induce efficient NMR chiral-shifts, and chiral quaternary ammonium cations. Diffusion constants were determined for the salts [**6**][Δ**-4**], [**6**][Δ**-5**], [**6**][PF_6], [**7**][Δ**-4**], [**7**][Δ**-5**], and [**7**][PF_6] at different concentrations and in chloroform, dichloromethane, acetone, and methanol. To facilitate the comparison of results, hydrodynamic radii derived from the Stokes–Einstein equation, using the viscosity of the non-deuterated solvents, were calculated. The methanol data were employed to estimate the size of solvated and independently moving anions and cations. For the cations in methanol, the r_S values were found to be independent of the anion (5.2–5.3 Å for **6** and 5.0 Å for **7**). The values for the anion Δ**-5** are 7.0 Å both in [**6**][Δ**-5**] and [**7**][Δ**-5**], whereas for PF_6^- the values are 2.7 Å in [**6**][PF_6^-] and 2.6 Å in [**7**][PF_6^-] in agreement with previous results for other salts of PF_6^- from the same group [37,38].

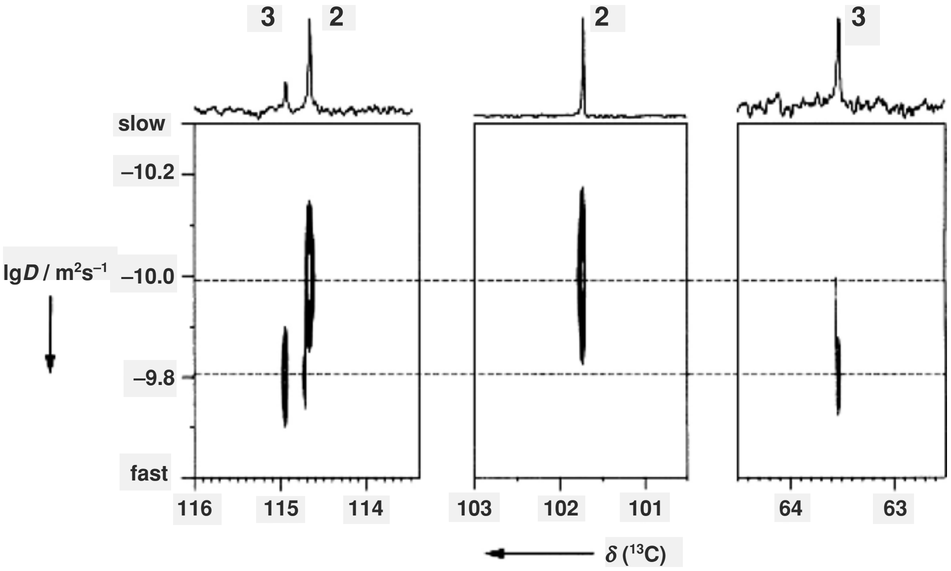

Fig. 5. 100 MHz ^{13}C INEPT DOSY spectrum obtained during the reaction of **1** with $^{13}CO_2$ at –78 °C in [D_8] THF. The sections show the signals of **2** (δ_C = 114.6 ppm (Cp) and 101.7 ppm (CH_2)) and **3** (δ_C = 114.9 ppm (Cp) and 63.5 ppm (OCH_3)). See Scheme 1 for the chemical structure of **1**, **2**, and **3**. Figure taken from Ref. [35]. Reproduced with permission of John Wiley & Sons Limited.

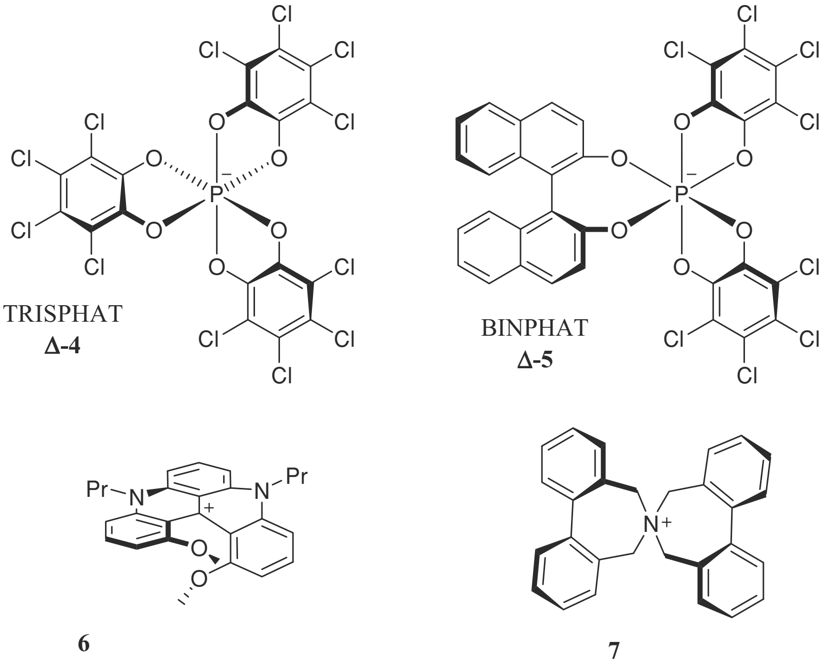


Scheme 2. Chiral anions and cations investigated by Pregosin and coworkers [36].

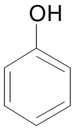
Internal Standards for Diffusion Measurements

The direct determination of hydrodynamic radii, and thus size, through the Stokes–Einstein equation requires a knowledge of the solution viscosity at the measurement temperature. Additionally, in order to have accurate information about size in studies related to molecular interactions where the comparison of diffusion coefficients obtained in different conditions is usual, it is crucial to be able to separate contributions due to changes in viscosity and effective changes in hydrodynamic radii.

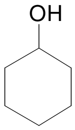
In PFG NMR, two major approaches are frequently used to avoid additional experimental work to measure the viscosity of the solution. The simplest approach is to consider that the viscosity of the solution is approximately the same as the viscosity of the pure non-deuterated solvent. This approximation has been shown to be legitimate in a number of cases, especially when considering pure solvents and diluted solutions and some examples have already been mentioned above for the determination of hydrodynamic radii of, *n*-butyllithium aggregates [29] and solvated anions and cations [36] but many more can be found in the literature. In complex solutions it may be more difficult to obtain a value for the viscosity of the exact solvent mixture, and in these cases the interpretation of size or molecular mass derived from diffusion data has to take into account the validity of the approximations made and the possibility of under/over valuating the viscosity.

The other solution to the problem is the back calculation of the solution viscosity, through the Stokes–Einstein equation, by using the diffusion measured for a non-interacting reference compound of known hydrodynamic radius. This internal probe should be of similar size with respect to the molecules of interest so that it experiences a similar microscopic environment and can act as an internal viscosity standard. The use of such a standard allows the estimation of size even in complex solution mixtures and the comparison of diffusion coefficients in series of experiments where the composition of the solution is altered, a situation that commonly arises in studies related to molecular interactions. The use of a diffusion standard allows one also to separate the contributions due to changes in viscosity and effective changes in hydrodynamic radii even if the hydrodynamic radius of the standard is not known. In fact, the ratio of the diffusion of a particular solute and the reference compound will be independent of the viscosity ($D/D_{\text{ref}} = r_{\text{Sref}}/r_{\text{S}}$) and relative information about changes in hydrodynamic radius can be obtained when comparing ratios measured in different conditions.

This procedure is well exemplified in a study by Cabrita *et al.* where tetramethylsilane (TMS) was used as a standard for the diffusion measurements to account for viscosity changes, and was proposed as a reference for the study of intermolecular interactions involving hydrogen bonds in organic solutions [14]. Kapur *et al.* [39] have shown that DOSY can be a useful technique for the qualitative study of the relative strengths of hydrogen bonds in solution. Since the formation of an intermolecular H-bond leads to a decrease of the diffusion coefficient of a certain molecule, the relative decrease in the diffusion coefficient of a particular molecule in a mixture of molecules, interacting by H-bond with a common H-bond acceptor or donor, was interpreted in terms of the tendency for the molecules in the mixture to be involved in association by H-bonds with the H-bond donor or acceptor. As an example, it was shown that when dimethylsulfoxide (DMSO), a strong H-bond acceptor, is added to a solution containing phenol **(8)** and cyclohexanol **(9)**, two molecules with a similar shape, a higher relative decrease in the diffusion coefficient of phenol was observed. This different behavior was attributed to the greater tendency of phenol to be involved in H-bonding with DMSO, since phenol is more acidic than cyclohexanol [39].



8



9

Binding, Screening, and Determination of Association Constants

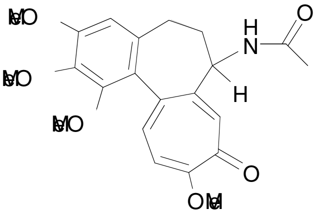
In the previous section, we have shown examples of applications that explore the relation between size and diffusion coefficient primary as a source of information on molecular size. However, this relation can be explored in a different way in order to get information about the strength of intermolecular interactions. The majority of the reports on the application of diffusion NMR to the study of intermolecular interactions deal with the alteration of the diffusion coefficient due to binding phenomena in solution. In fact, when a small molecule binds to a large receptor, its diffusion coefficient may decrease more than one order of magnitude. This means that at least for some time the small molecule will have the diffusion coefficient of the large receptor, and if we consider the fast exchange limit, its observed diffusion coefficient (D_{obs}) is described by:

$$D_{\text{obs}} = f_{\text{free}} D_{\text{free}} + f_{\text{bound}} D_{\text{bound}} \tag{7}$$

where f and D denote the molecular fractions and diffusion coefficients of the free and bound molecule. If the difference in size is large enough, it can be assumed that the diffusion coefficient of the receptor or host (D_{H}) is not greatly modified and that D_{bound} is the same as the D_{H} alone. This relation is the starting point for the majority of the diffusion NMR-related binding studies.

In this field two main lines of application can be identified, one more qualitative, related to the screening of complex mixtures or individual molecules, usually with the aim of identifying potential new drug compounds, and another, more quantitative, concerned with the determination of association constants.

A recent example of the first type of application mentioned above is the binding of cholchicine **10** to α/β tubulines, which is of large interest in cancer-related studies.



10

For this reason, a model peptide containing the 12 C-terminal residues of α-tubulin (VEGEGEEEGEEY) was investigated with respect to the pH dependence of the binding to **10** [40]. Although binding studies on this system have only been computational using docking programs, it was shown in the diffusion studies that the model peptide adopts different conformations depending on the pH, this being reflected by different observed diffusion constants. In this work, NOE data have also been used, but only for determining the conformation of the single peptide.

The determination of association constants (K_a) from NMR data has been recently reviewed by Fielding [9] with a section dedicated to diffusion experiments. The starting point for the determination of the association constant is Equation (7) and the mathematical treatment to get K_a from D_{obs} is exactly the same as for any other NMR observable, such as δ_{obs}. As Fielding points out in his review, the advantage of measuring D_{obs} instead of δ_{obs} is that the diffusion coefficient of the host–guest complex can be assumed to be the same as that of the non-complexed host molecule, thus reducing one unknown in Equation (7). In principle, this allows one to determine K_a within a single experiment and without the need of titrations, as exemplified below. The formation of a host–guest complex of stoichiometry 1:1 is described by:

$$K_a = \frac{[HG]}{[H]\,[G]} \tag{8}$$

$$D_{obs} = f_G D_G + f_{HG} D_{HG} \tag{9}$$

where [HG], [H], and [G] are the equilibrium concentrations of the host–guest complex, host, and guest, respectively and f_G and f_{HG} are the molar fractions of non-complexed guest and complex, respectively. From Equation (9) it follows that:

$$f_{HG} = \frac{D_G - D_{obs}}{D_G - D_{HG}} \tag{10}$$

If, as it was mentioned earlier, D_{HG} is assumed to be the same as the measurable diffusion coefficient of the host (D_H), then f_{HG} can easily be determined. Accounting for mass balance and combining Equations (8) with (10), we arrive to the expression for the association constant:

$$K_a = \frac{f_{HG}}{(1 - f_{HG})([H]_0 - f_{HG}[G]_0)} \tag{11}$$

where $[H]_0$ and $[G]_0$ represent the total concentrations of host and guest, respectively.

The procedure before is straightforward and examples of its application can be found in recent literature related to host–guest chemistry studies [12,41]. Rather than exemplifying the examples in detail here, we prefer to take a closer look at the limitations of the approximation that $D_{HG} = D_H$.

The assumption that $D_{HG} = D_H$ is valid for the majority of studies involving small molecules binding to macromolecules (typically biological), but may not necessarily be true for smaller host molecules usually employed in host–guest chemistry studies. To test the assumption that $D_{HG} = D_H$ for a typical medium-sized host molecule, Cameron *et al.* [10] have studied the β-cyclodextrin **(11)** complexes of cyclohexylacetic acid **(12)** and cholic acid **(13)**. They have shown that caution should be taken when determining the association constant by the single experiment method, and have employed a data treatment which takes into account the diffusion of all species. With this treatment, the ^{1}H NMR chemical shift titration method and the diffusion coefficient method give the same results for K_a.

Simova and Berger presented a comparison of DOSY experiments and chemical shift titrations with respect to the determination of association constants [42]. The authors investigated camphor and cyclodextrins (CD) in D_2O. They showed that precise association constants are more easily determined by chemical shift titration. Diffusion measurements using HR-DOSY allow easy determination of the complex composition at different concentration ratios and an estimation of the binding energy if a viscosity reference, in this case tetramethylammonium bromide, is present. Linear dependence of the diffusion coefficients on the molecular mass of free and associated CD has been observed (see Figure 6). The solution structures of α- and β-CD complexes of camphor in D_2O were deduced from intermolecular cross-relaxation data obtained by using the ROESY sequence. Different preferential orientation in the 2:1 α-CD and 1:1 β–CD species have been derived in contrast to the weak 1:1 complex

with γ-CD. Proton NMR chemical shift values proved to be much more sensitive to diastereomeric complex formation than are diffusion coefficients.

Host–Guest Chemistry

Part I

Solid-State NMR in Host–Guest Chemistry

John A. Ripmeester and Christopher I. Ratcliffe
Steacie Institute for Molecular Sciences, National Research Council Canada, Ottawa, ON, Canada K1A 0R6

Introduction

This contribution will focus on the use of NMR spectroscopy to study host–guest chemistry in the solid state. NMR spectroscopy already is a well-established approach for the study of complex formation in solution, for instance, for measurement of equilibrium constants and stoichiometry. In the solid state, guest–host chemistry is a rather more complex issue, as the materials in question range from molecular receptor–guest complexes that have crystallized, to extended framework materials that have cavities, channels, and interlamellar void space which may or may not be easily accessible to guest species. Examples of the first instance are crown ether and cyclodextrin complexes. For the latter, many diverse organic and metal-organic materials have been constructed using the principles of supramolecular chemistry and crystal engineering to assemble frameworks out of building blocks. On the inorganic side, there are zeolites, clathrate hydrates, clathrasils and zeosils, aluminum phosphates (ALPOs), metal cyanides and oxides, clays, carbons (graphite, nanotubes), and mesoporous materials such as the siliceous MCMs, and related materials. Details on all these different kinds of host–guest materials can be found in the series Comprehensive Supramolecular Chemistry [1]. NMR spectroscopy can contribute a great deal to understanding the structure and properties of such host–guest materials, as also reviewed in a chapter in Vol. 8 of the aforementioned series and references therein [2]. The topic of host–guest materials is a very broad area with an extensive literature, and for this reason and the limited length of this chapter we have chosen to illustrate with examples largely from our own work and to refer the interested reader to more extensive reviews.

In the study of solid-state host–guest chemistry, the problems that stand out are the accurate determination of the host structure, the location and orientation of the guest, and the understanding of specific interactions that lead to molecular recognition and selective adsorption or inclusion. This also includes the understanding of the electronic structure as obtainable from the chemical shift. Applications include gas separation and storage, shape-selective catalysis, molecular sensing, drug delivery, and a variety of systems have been developed that are meant to mimic processes in biology in their entirety or in part, for instance, biocatalysis involving enzymes, ion channels, etc. [1,2].

The Solid-State Spectrum

The main interactions that dominate the NMR lineshape in the solid state include the nuclear dipolar interaction, giving information on the distance between magnetic nuclei (up to ~0.8 nm), chemical shielding, giving information on the electronic structure, and the quadrupolar interaction, which is determined by the interaction of the nuclear electric quadrupole with the electric field gradient at the nucleus [3]. Occasionally J-coupling also has an influence. In many if not most cases, several or all of these interactions are present simultaneously. Since all have a spatial dependence (interactions described by second rank tensors), the solid-state NMR lineshape in powdered materials is broad and complex. Most materials have a number of inequivalent atoms, so the selective elimination of some of the interactions in order to obtain high-resolution spectra was a major focus in the NMR spectroscopy of solids for many years. The most commonly used techniques include high power decoupling (HPDEC), generally to eliminate dipolar couplings to abundant spins such as protons, magic angle spinning (MAS), which can reduce dipolar couplings as well as the anisotropic chemical shift [4], and combinations of pulse schemes and spinning to separate chemical shifts and quadrupolar couplings (MQMAS) [5]. Recently, much effort has been expended into re-introducing dipolar couplings into high-resolution spectra to make use of these to measure a variety of internuclear distances [6].

Unfortunately, the spectroscopy of the ubiquitous ^{1}H is rather difficult, as its chemical shift scale is small and homonuclear dipolar couplings dominate the resonance lines which are often very broad. A number of multiple pulse schemes have been developed to give a measure of high resolution [7], and the more recent developments in fast MAS have proved to be particularly powerful [8]. Especially in soft materials such as polymers and biosolids the use of fast MAS has allowed applications of many of the techniques that are routinely used in solution NMR to derive information on structure in the solid state [9].

© 2008 *Springer.*

As the design of organic and metal-organic guest–host systems is a heavily researched topic today, many applications deal with the use of ^{13}C NMR spectroscopy in the solid state, which is easily accessible to most researchers, and the interpretation of the spectrum is relatively straightforward. The approaches used are similar to those applied to a number of other spin $^{1}/_{2}$ nuclei (^{15}N, ^{31}P, ^{29}Si), as in all of these cases dipolar couplings are mainly heteronuclear, often to ^{1}H, and can be removed by HPDEC. The use of 2D techniques such as HETCOR and WISE are able to provide information on H atoms that are attached to the above spin $^{1}/_{2}$ nuclei with a measure of resolution that can be considerably greater than the ^{1}H spectrum itself.

General Characterization

One of the first things to realize is that some very simple NMR experiments can provide a great deal of information in the characterization of a host–guest material. For example ^{13}C cross-polarization (CP) and MAS are frequently used to determine which guests are taken up by the host and HPDEC/MAS can be used to quantify the relative amounts of host and guest by comparing intensities of distinct lines (This can also be done with CP provided the CP behavior is calibrated for different resonances). Quite often the question with new materials is simply whether the guest is indeed included, and this can be confirmed by CP/MAS since it detects only material in the solid state, even in the presence of excess gaseous or liquid guest, which is sometimes necessarily present to keep the complex stable. The presence of dynamics can also be established using the dipolar dephasing CP/MAS experiment, since, while only quaternary carbons should appear in this spectrum, non-quaternaries will appear with reduced intensity if their C–H dipolar interactions are considerably reduced by dynamics. ^{13}C chemical shifts have been used to determine conformations, e.g. in crown ethers the methylene shifts relate to torsional angles [10]. Chemical shifts can also be used to identify products in "ship-in-a-bottle" type synthesis, e.g. ^{31}P NMR of P_4S_n ($n = 3 - 7$) synthesized inside zeolites [11] and ^{13}C of organics in zeolites, or to show the existence of unusual or unstable species which are stabilized by inclusion, e.g. a novel P_4S_4 isomer in zeolite [11], Na^- and diamagnetic metal clusters in zeolites [12]. The NMR of metal nuclei such as ^{113}Cd and ^{63}Cu has been used to determine local environments and connectivities in metal cyanide host lattices [13,14], e.g. ^{113}Cd shifts reflect the numbers of C and N atoms attached to tetrahedrally coordinated Cd, with CdC_4 to low field ranging to CdN_4 at high field; quadrupolar effects on ^{63}Cu lineshapes indicate whether its environment is strictly tetrahedral (isotropic line), or slightly distorted CuC_4 (2nd order lineshape) or very distorted CuC_3N (too broad to detect); J-couplings can show connectivities, e.g. ^{63}Cu–$^{13}C_4$ or ^{67}Zn–$^{15}N_4$. Chemical shift and quadrupolar lineshapes (and corresponding asymmetry parameters) also reflect the local crystal symmetry, providing another link to structure, e.g. ^{77}Se NMR of H_2Se clathrate hydrate distinguishes between H_2Se in the small spherical cage (isotropic line) and the oblate larger cage (axially anisotropic line), Figure 1 [15]. Chemical shifts can also be sensitive to the presence of other guests in the same or in neighboring cavities, e.g. ^{129}Xe in Dianin's compound [16]. Similarly, quadrupolar nuclei can be particularly sensitive to loss of local crystal symmetry when guests are removed from neighboring cages, e.g. ^{23}Na in the cages of silicon clathrates [17].

Structural Information from Spin $^{1}/_{2}$ Nuclei

Organic and Metal-Organic Hosts

NMR spectroscopy is primarily a local order technique, which makes it a particularly strong ally to X-ray crystallography, which is a technique that depends on the presence of long-range order. However, the ^{13}C spectrum is sensitive not only to the presence of chemical inequivalence, but also to crystallographic inequivalence. For most materials, the ^{13}C NMR spectrum should confirm the asymmetric unit as determined by diffraction. Hence, in many cases ^{13}C NMR spectroscopy provides a rapid way of detecting structural similarities or differences in guest–host materials with a common host lattice: the spectrum gives a quick assessment of the content of the asymmetric unit, a very useful piece of information before attempting a complete structural determination [18]. This is also particularly useful when dealing with issues of polymorphism or pseudo-polymorphism [19].

In the presence of disorder, which may be dynamic, there may be disagreements between diffraction and NMR, usually with more line splittings in the NMR spectrum than one would expect based on the determined asymmetric unit. This means that either locally, or even on a larger scale, the symmetry of the lattice is lower than expected. For instance, in Dianin's compound with *p*-xylene as guest there are many more splittings than one would expect from the X-ray symmetry, from which the cavity where the *p*-xylene resides has three-fold symmetry and an inversion center [20]. However, the *p*-xylene is statically disordered so that each cage has lost its three-fold axis and inversion center. Since the disorder is not correlated throughout the lattice, it is spatially averaged, which gives a high symmetry in X-ray diffraction, and NMR sees the local symmetry, which is far lower. A different situation exists for the compound of calixarene

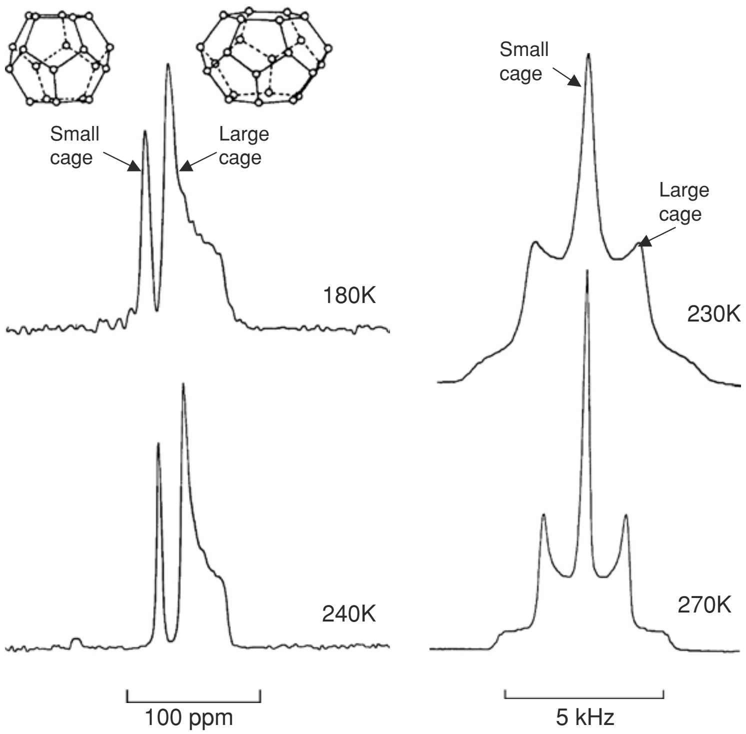

Fig. 1. Symmetry and dynamics in hydrogen selenide structure I clathrate hydrate: ^{77}Se NMR of $H_2Se/7H_2O$ (left) and ^{2}H NMR of $D_2Se/7D_2O$ (right). The spherical small cage gives rise to isotropic lineshapes, whereas the oblate large cage gives axially symmetric ^{77}Se chemical shift anisotropy and ^{2}H quadrupolar lineshapes. The intensities of the two components give the relative cage occupancies. The lines are considerably narrower than the static lineshapes due to rapid reorientation of the guest molecule. The broadening and reduced sharpness of the features, especially of the ^{2}H lineshape, as temperature decreases is due to freezing out of the host–water reorientational motions.

with toluene [21]. NMR spectroscopy shows a symmetry lowering transition to occur at ∼250 K, which is not seen by X-ray diffraction (Cu radiation), Figure 2. However, when shorter wavelength Mo radiation is used, the lower symmetry phase is indeed observed. This can be understood in terms of the volume over which the ordered lattice is coherent. Cu radiation requires a larger volume than Mo, so when using the longer wavelength the spatial averaging inherent in diffraction again shows the lattice to be of higher symmetry than it actually is [22].

As in solution, in the solid state it is possible to use complexation-induced shifts. For instance, guest nuclei that deeply penetrate into the cavity of calix[4]arene are deshielded by ring current effects from four aromatic rings, which can give ^{13}C methyl resonances a high field shift of up to ∼6 ppm [21]. Of course, these may be modified by dynamic processes that involve exchange of methyl groups over different sites. The fact that the toluene methyl has a much larger shift than pentane methyls (with the methyls equivalent) suggests that the pentane molecule can invert itself in the cavity. The X-ray structure shows that there are two positions for the methyl groups of the pentane that are quite different (one in–one out), so that the two methyl groups indeed must exchange between the two positions. This approach has allowed the determination of the order of preference of a variety of moieties for occupancy of the deep cavity in calix[4]arene; generally methyls, methylenes, methines, and hydroxyls are preferred over halogens [23].

Inorganic Hosts

Some of the best-known inorganic host materials are the zeolites. In this case, ^{29}Si NMR spectroscopy has allowed the measurement of the distribution of Si and Al in the lattice, as Si with 0–4 Al nearest neighbors are easily distinguished [24]. Since Al is a quadrupolar nucleus, the Si lines are rather broad, so that further distinctions of inequivalence are not possible. However, on going to an all Si lattice it becomes possible to obtain extremely high resolution spectra, where it is possible to measure through-bond connectivity (COSY), as well as all inter-Si distances less than ∼0.7 nm [25]. A recent example, using a symmetry-based dipolar recoupling scheme has shown that complete three-dimensional structures can be traced out [26].

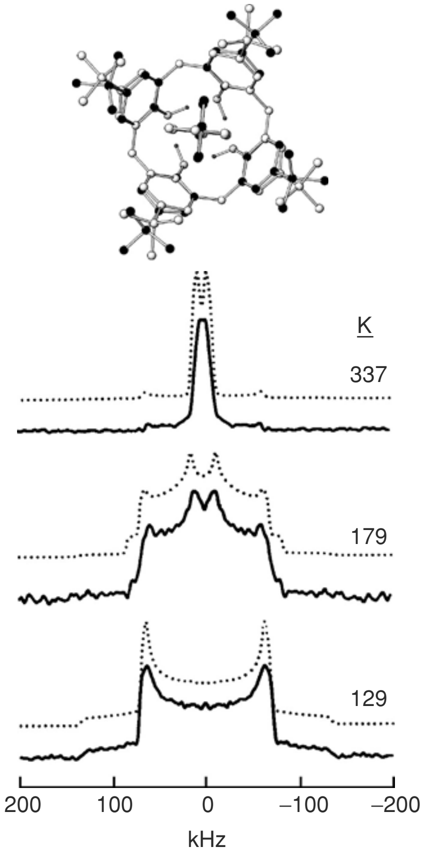

Fig. 2. ^{2}H NMR lineshapes of toluene-d_5 in *t*-butylcalix[4]arene. At 129 K the toluene is static, at 179 K it is undergoing rapid 180° rotations about the molecular axis, and at 337 K it has rapid four-fold reorientation. The weak broader line visible in the 337 K spectrum is from the para-deuteron, which lies along the axis and is largely unaffected by the motion. The switch from two-fold to four-fold motion of the guest is associated with a phase transition at 248 K. In the low temperature phase, the calix host is locked into a two-fold symmetry, but in the higher temperature phase it alternates dynamically between two two-fold structures at 90° to each other.

Distance Measurements

Other methods for measuring distances that give significant information on conformations of the host, or guest–host distances are techniques such as spin-echo double resonance (SEDOR), which is a low-resolution method, and the spinning version, REDOR, which gives high-resolution information. This approach uses the time evolution of the difference in the magnetization for the observed nucleus that arises when it is observed with or without dipolar coupling to one or more nearby heteronuclei. The difference, known as the REDOR fraction, can be modeled in terms of the internuclear distances, e.g. as for the guest–host compound of *p*-*t*-butylcalix[4]arene with Cs [27]. However, an added complication in many guest–host systems would be the presence of molecular motion, giving a distance that is averaged [28]. REAPDOR [29], TRAPDOR, and QUEDOR [30] all are versions related to the SEDOR/REDOR family of experiments but that involve quadrupolar nuclei.

Spin Counting

Spin-counting, a technique that measures the order of the multiple quantum coherence that can be generated, can be used to measure the number of nuclei coupled by dipolar interactions. This can be used to probe the size of clusters of atoms or molecules, which may or may not be bound together, or that fill a cavity in a host material. With increased time, longer distances can be probed, so that intercluster distances can be obtained as well. ^{1}H spin counting in solids was first demonstrated by Munowitz and Pines [31]. One application to host–guest materials was a study of the numbers of protons present in “Si clusters,” and their precursors, formed inside the large cage of Y zeolite [32]. The ^{1}H spin count for the precursor, consisting of Si_2H_6 molecules and Si_2H_5 groups attached to the framework, reaches a plateau at 38 spins corresponding to the number in the cluster held within one cavity, and the final Si-cluster was found to contain 5 H atoms. This evidence helped to show that the clusters must be rather smaller than had been suggested previously.

Probing Pore Spaces

The last two decades have seen the growth of ^{129}Xe NMR [33], and more recently of hyperpolarized (HP) Xe [34,35], as a valuable tool for probing the pore space of host–guest materials. Early work on clathrate hydrates and a number of organic clathrates [36] established a relationship between the size and shape of a closed cavity and the Xe chemical shift and its anisotropy: smaller pores give larger shifts, and anisotropy reflects whether the cavity is spherical (zero anisotropy), oblate (positive anisotropy or skew), prolate (negative anisotropy or skew), or nonaxial. More recently a broad correlation between ^{129}Xe shifts and pore sizes in mesoporous silicas has been determined [37]. The observed Xe lineshape is a dynamic average over all the space accessible to the Xe over the timeframe of the experiment, and in open pore systems this can lead to loading dependent shifts and lineshapes [38]. In some materials incomplete filling leads to signals corresponding to cages with different numbers of Xe [39].

2D EXSY experiments can then be used to follow the exchange of Xe between cages with different occupancies, e.g. in NaA and AgA zeolites [39,40]. Thus Xe can be used to determine the interconnectivity of different pores and the exchange barriers. A recent example is a study of organic aerogels where the hierarchy of exchange between micro and mesopore spaces and the gas phase could be determined [41]. HP Xe is particularly useful due to its enormously enhanced sensitivity. This allows the use of very low Xe concentrations and thus removes the effects caused by Xe–Xe interactions, probing only the Xe–host interaction [42]. Another example is the void space access test, as illustrated in Figure 3 for a low density phase of *p*-*t*-butylcalix[4]arene [42]. HP Xe also makes it possible to follow real time processes, such as the formation/decomposition of gas hydrates [43]. Another important use has been in the study of structural transformations and competitive exchange between Xe and another guest in a metal-organic framework [44]. In recent work on dipeptides, Xe NMR spectroscopy has demonstrated both a new type of material (biozeolites) [45] and experimental and modeling calculations illustrating an application to biomaterials [46]. ^{131}Xe studies have revealed some interesting effects where the quadrupolar interaction probes longer range order/disorder compared to the chemical shift [47].

MRI

While MRI has very broad application in the medical arena, it is finding increasing uses in studies of materials, particularly of porous host–guest systems [48]. This is particularly true of porous host–guest systems where the long T_2 of the guest (as gas or liquid) makes imaging feasible. There has been some use of HP ^{129}Xe as the probe nucleus, but the easiest nucleus is ^{1}H and this is present in many guests, e.g. organic gases or liquids. MRI can be used to study diffusion of a guest into a host, both by direct imaging as a function of time and by MRI spectroscopy [49], and to probe whether the distribution of pore space in a material is homogeneous [41]. HP Xe chemical shift imaging can be used to probe composites of different porous materials [50]. By monitoring the disappearance of the signal from the water as it solidifies into the host framework, ^{1}H MRI was used to establish that growth of gas hydrate from small droplets was not continuous, but had a random component [51].

Dynamics

NMR is the technique par excellence for the detailed study of dynamics in solids (c.f. neutron scattering, dielectric relaxation, and torsional/librational spectroscopy), and dynamics plays a large role in the behavior of host–guest materials [2]: The generally weak interaction between host and guest means that in many instances the guest rotates even at very low temperatures, and is often free to roam about the pore spaces (rotational and translational freedom). This creates problems for structure determination due to dynamic disorder. In many instances the symmetry of the guest does not mesh with the symmetry of the cavity, and the result is an accommodation

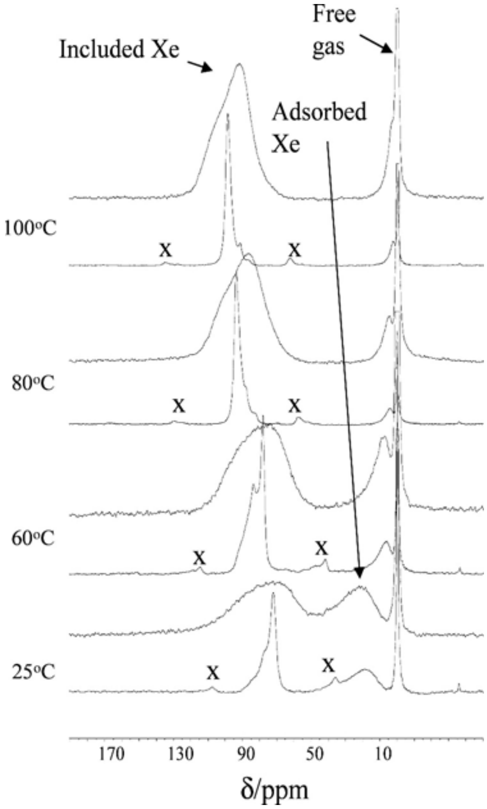

Fig. 3. Void space access test with hyperpolarized ^{129}Xe NMR. The sample, a low density phase of *p*-*t*-butylcalix[4]arene without obvious channels, was exposed to a flow of HP Xe gas at various temperatures in the NMR probe. Static and MAS spectra are shown at each temperature. X marks spinning side bands. At room temperature, the HP Xe signals correspond to adsorbed, or interparticle gas, and included gas. At high temperature much more gas is included, and it has the shape typical of an approximately axial tensor. One can see that the MAS spectrum in intermediate temperature regions consists of two signals. This means that there are two phases, one transforming to the other with increased temperature. The transition is not sharp, as the transition temperature depends on the degree of loading.

with the guest fitting into several possible positions to create a pseudo-symmetry. From the diffraction point of view this disorder can be either static, resulting from spatial averaging over many unit cells, or dynamic, as the molecule hops between the various positions, and NMR can be used to distinguish the two [20,21]. A number of NMR techniques are used to probe dynamics: lineshapes, linewidths, relaxation times, 2D-exchange, dipolar fadeout, etc. The earliest works on host–guest materials used the traditional low field methods of ^{1}H lineshapes, second moments and T_1 vs. temperature to obtain motional models, correlation times and activation energies (E_a), mainly of guests but sometimes of host, as in the case of clathrate hydrates. ^{2}H NMR, however, has perhaps been the greatest tool available for studying reorientational dynamics [52,53] (though it does have the disadvantage of not probing translational motion), and in the process it also sometimes yields geometrical information. As temperature is increased the motion initially distorts the lineshapes which go through a series of changes resulting in a narrowed lineshape in the fast motion limit. The static or fast motion limit lineshapes are readily analyzed to give the three components of the effective quadrupolar coupling tensor, and from these it is usually possible to determine a unique dynamic model. Once a model is determined the lineshapes at different jump rates can be calculated and matched with experiment. A plot of log(rate) vs. temperature then yields an E_a, e.g. 18-crown-6 in its complexes [54]. NMR has shown how surprisingly easy it can sometimes be for rather large molecules, such as 18-crown-6, to reorient in the solid. A guest molecule in cages with different symmetry can have quite different dynamics, resulting in different ^{2}H and chemical shift lineshapes, e.g. H_2Se clathrate hydrate described above [15], and cyclohexane-d_{12} in different metal cyanide frameworks [2]. This sensitivity to symmetry also frequently shows as sudden changes in the dynamic lineshapes of guests at phase transitions [21]. ^{2}H NMR has also been used to study the diffusion of organic molecules as they jump between adsorption sites inside zeolites, e.g. benzene-d_6 in H-SAPO-37 [55]. The analysis of dynamics can lead to a separate determination of the orientation of the guest with respect to crystal axes, and this can help in developing structural models for X-ray refinement, e.g. pyridine-d_5 in *t*-butyl-calix[4]arene [56].

More recently a few cases of dynamics involving non-integer quadrupolar nuclei have come to light, e.g. ^{131}Xe in xenon clathrate hydrate is sensitive to the motion of the framework water molecules [47], and ^{17}O in the water of THF hydrate [57].

NMR and diffraction constitute the two primary tools for the study of structure and dynamics in host–guest materials, and, as will be evident from this brief review, their roles are very much complementary. On the other hand, NMR truly comes into its own when used to provide insight into host–guest materials for which suitable single crystals are not available, or which by their very nature are not crystalline. NMR has a long and bright future in this very diverse and expanding field of chemistry.

Part I

Imaging

Mapping of Flow and Acceleration with NMR Microscopy Techniques

Elke Kossel, Bogdan Buhai, and Rainer Kimmich
Universität Ulm, Albert-Einstein-Allee 11, 89069 Ulm, Germany

Introduction

In this contribution, radio frequency and field gradient pulse sequences for the encoding of position, velocity, and acceleration will be described and explained. The applicability of the techniques will be demonstrated by presenting experimentally obtained velocity and acceleration maps of fluid flow in artificial pore spaces. Porous model objects fabricated on the basis of random percolation clusters are taken as a paradigm for networks in any sort of natural or technical pores or channel complexes. Numerically obtained velocity and acceleration maps will be compared to the experimental data to test the reliability of the methods.

Encoding Principles and Pulse Sequences

Spatial resolution in NMR experiments can be achieved by superimposing a constant field gradient of strength $\hat{G}$ to the external magnetic flux density B_0 during data acquisition. In the presence of the gradient, the Larmor frequency depends linearly on the position of the spins along the axis defined by the gradient. If the gradient is assumed along the x-direction, the resulting Larmor frequencies are given by

$$\omega(x) = \gamma \left(B_0 + \hat{G}_x x\right). \tag{1}$$

As long as the frequency shifts caused by the external field gradient are much larger than chemical shielding or susceptibility-induced shifts, the frequency encoded information of the signal can directly be transformed into spatial information. The "field of view" (FOV) is defined as the spatial window, which can unambiguously be sampled by the pulse sequence:

$$-\frac{\pi}{\gamma \Delta t \hat{G}_x} < x < \frac{\pi}{\gamma \Delta t \hat{G}_x} \tag{2}$$

Here, γ denotes the gyromagnetic ratio of the nuclei and Δt stands for the dwell time of the data acquisition. Contributions from spins outside this window will be folded into the FOV and distort the image. The spatial resolution depends on the FOV and the number of data points N:

$$\Delta x = \frac{2\pi}{\gamma \Delta t \hat{G}_x N} = \frac{x_{\max} - x_{\min}}{N}, \tag{3}$$

where $x_{\max} - x_{\min}$ is the FOV.

Spatial information cannot only be encoded in the frequency of the signal but also in its Larmor precession phase. This can be done by inserting a field gradient pulse of duration τ in the pulse sequence. During the interval τ, the Larmor frequencies along the direction of the gradient, e.g. the y-axis, differ according to Equation (1). After the gradient is switched off, the spins continue to precess with the frequency $\omega = \gamma B_0$, but have gained a position-dependent phase shift given by

$$\varphi(y) = \omega(y)\tau = \int_0^{\tau} \gamma \hat{G}_y y(t) \mathrm{d}t. \tag{4}$$

If the nuclei are displaced by hydrodynamic flow, their positions on the gradient axis become time-dependent:

$$y(t) = y_0 + v_{y_0} t + \frac{1}{2} a_{y_0} t^2 + \cdots. \tag{5}$$

That is, the phase shift depends on the initial position y_0, the initial velocity v_{y_0}, and the initial acceleration a_{y_0}. Higher order terms vanish if the flow field is stationary on the timescale of the NMR experiment (i.e. time-dependent accelerations at a given position do not occur in this case). For a gradient pulse of duration τ and strength $\hat{G}_y$ the total phase shift is consequently

$$\begin{aligned} \varphi &= \gamma \hat{G}_y \left(y_0 \tau + \frac{1}{2} v_{y_0} \tau^2 + \frac{1}{6} a_{y_0} \tau^3 \right) \\ &= \varphi(y_0) + \varphi\left(v_{y_0}\right) + \varphi\left(a_{y_0}\right). \end{aligned} \tag{6}$$

In order to distinguish the three quantities y_0, v_{y_0}, and a_{y_0}, more sophisticated gradient pulse sequences have been designed resulting in phase shifts that essentially depend only on a single parameter or a selection of parameters.

Fig. 1. Gradient pulse trains for (a) position encoding in the absence of flow, (b) position-compensated velocity encoding, (c) position- and velocity-compensated acceleration encoding, (d) position, velocity, and acceleration compensation, (e) velocity-compensated position encoding.

For many systems and flow situations, the position-dependent term dominates the phase shift while the velocity-dependent term is still significantly larger than the acceleration-dependent term. As a direct consequence, terms with a higher order of τ than the term including the parameter to be evaluated may often be neglected while terms with a lower order of τ have to be compensated by the gradient pulse sequence. On the other hand, if the magnitude of higher order terms is comparable to that of the term of interest, the maps are disturbed by motion artifacts. In this case, the pulse sequence has to compensate for contributions of higher order terms too.

Figure 1a–e shows typical gradient lobe trains suitable for the compensation of phase shifts due to any of the above quantities. If an intermittent 180° RF pulse is used (such as in the Hahn echo sequences shown in Figure 2), the gradient lobes after the 180° pulse must be inverted relative to the lobes before the 180° pulse.

If no flow is present or if the phase shifts due to velocity and acceleration can be neglected, a single gradient of duration τ (Figure 1a) can be used for the encoding of *spatial information* on the morphology of the sample. It causes a phase shift $\varphi(y) = \gamma \hat{G}_y y \tau$. The Fourier space (also called reciprocal space or k-space) is sampled by repeating the experiment with different strengths of the gradient $\hat{G}_y$. After performing a Fourier transform of the data, the FOV is given by:

$$-\frac{\pi}{\gamma \tau \Delta \hat{G}_y} < y < \frac{\pi}{\gamma \tau \Delta \hat{G}_y}, \tag{7}$$

where $\Delta \hat{G}_y$ denotes the increment of the gradient between two successive experiments. The resolution can be calculated by dividing the FOV by N, the number of experiments with different gradient strengths:

$$\Delta y = \frac{2\pi}{\gamma \tau \hat{G}_y} = \frac{2\pi}{\gamma \tau \Delta \hat{G}_y N} = \frac{y_{\max} - y_{\min}}{N}, \tag{8}$$

where $y_{\max} - y_{\min}$ is the FOV in the y-direction.

The bipolar gradient pulse in Figure 1b compensates phase shifts due to the position, but produces phase shifts by *velocity* and *acceleration* components along the gradient direction: Two gradient pulses of duration τ and of the same magnitude of the amplitude $\hat{G}_y$ but with opposite sign are applied. The position-dependent term of the phase shift vanishes, whereas the velocity-dependent term provides a finite phase shift proportional to the velocity component:

$$\begin{aligned} \varphi(y_0) = 0;\ \varphi\left(v_{y_0}\right) &= \frac{1}{2}\gamma \hat{G}_y v_{y_0}\left(2\tau^2 - 4\tau^2\right) \\ &= -\gamma \hat{G}_y v_{y_0} \tau^2. \end{aligned} \tag{9}$$

Often, this gradient sequence is modified by a delay $\Delta\tau$ between the two gradient lobes, as indicated in Figure 2b. The position-dependent term is not affected by the additional interval, whereas the velocity-dependent term then results in

$$\varphi\left(v_{y_0}\right) = -\hat{G}_y \gamma \left(\tau^2 + \tau \Delta\tau\right) v_{y_0}. \tag{10}$$

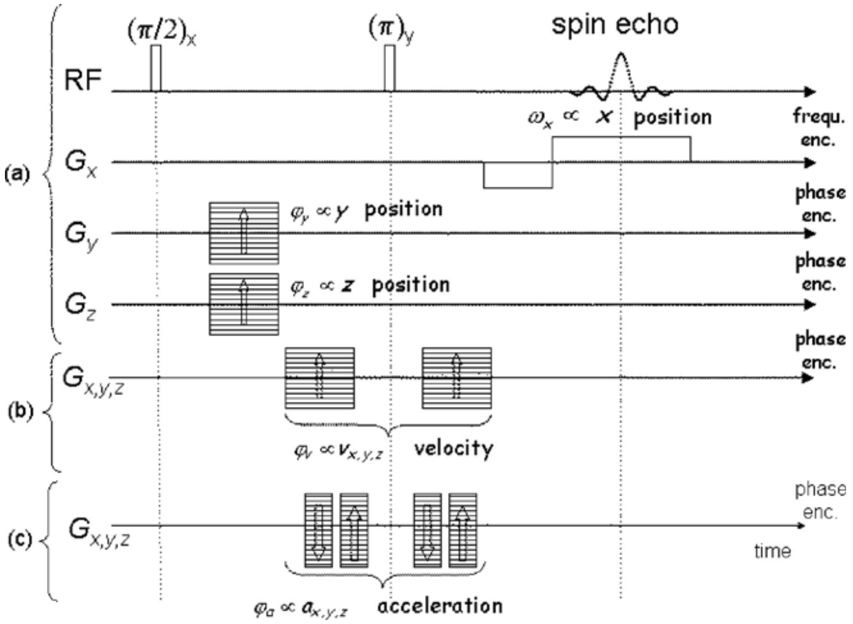

Fig. 2. (a) Complete three-dimensional RF and gradient pulse sequence for spin density mapping, (b) supplement for sequence (a) that allows for velocity mapping, (c) supplement for sequence (a) that allows for acceleration mapping.

Referring to Eq. (9), the velocity "FOV" and the digital resolution are given by

$$-\frac{\pi}{\gamma\tau^2\Delta\hat{G}_y} < v_y < \frac{\pi}{\gamma\tau^2\Delta\hat{G}_y} \tag{11}$$

and

$$\Delta v_y = \frac{\pi}{\gamma\tau^2\hat{G}_y}, \tag{12}$$

respectively.

The gradient pulse variant in Figure 1c compensates phase shifts due to the *position* and to the *velocity* component, but generates phase shifts by the *acceleration* component. The first and the third lobe of this gradient pulse train have the same sign, duration, and amplitude, whereas the second lobe has the same amplitude, an opposite sign, and twice the duration of the first pulse. The induced phase shift can be calculated as

$$\begin{aligned} \varphi(y_0) &= \varphi\left(v_{y_0}\right) = 0; \\ \varphi\left(a_{y_0}\right) &= 2\gamma\hat{G}_y a_{y_0}\tau^3. \end{aligned} \tag{13}$$

The acceleration FOV and the resolution are given by the expressions

$$-\frac{\pi}{2\gamma\tau^3\Delta\hat{G}_y} < a_y < \frac{\pi}{2\gamma\tau^3\Delta\hat{G}_y} \tag{14}$$

and

$$\Delta a_y = \frac{\pi}{2\gamma\tau^3\hat{G}_y}, \tag{15}$$

respectively. The phase shifts caused by gradient pulses, which are separated by time delays (such as shown in Figure 2c) are represented by more complex expressions as published in Ref. [1].

Phase encoding of higher order terms (locally time-dependent accelerations) is feasible in principle according to pulse trains such as the example shown in Figure 1d. However, the relatively long acquisition times of NMR parameter maps conflict with "snapshot" records that would be needed for such maps. Anyway, in Ref. [2], fast imaging techniques are described and discussed that could be employed for moderate versions of "snapshot" experiments.

If an ordinary image or a *spin density map* is to be recorded in the presence of a relatively fast stationary flow with constant velocities, a spatial phase encoding gradient pulse like in Figure 1a should be replaced by the "velocity-compensated" gradient pulse shown in Figure 1e. Otherwise, flow artifacts will arise. This gradient pulse provides spatial phase encoding according to

$$\varphi(y) = \frac{2}{3}\gamma \hat{G}_y \tau y; \quad \varphi\left(v_{y0}\right) = 0, \tag{16}$$

whereas there is no phase shift by the flow velocity.

An appropriate combination of the phase encoding pulse trains given in Figure 1 (modified for an intermittent 180° RF pulse) provides gradient pulse sequences for three-dimensional spin density mapping, as shown in Figure 2a, *velocity component mapping sequences* as given by a combination of Figure 2a and b, or *acceleration component mapping sequences* as given by Figure 2a and c.

In the preceding paragraphs, only the digital resolution of the maps has been discussed. Often, this theoretical resolution cannot be achieved experimentally. Susceptibility differences at material boundaries within the sample, for example, lead to distortions and resolution losses in the frequency encoded spatial direction. These distortions can be avoided by employing phase encoding for all spatial dimensions. But phase encoding, too, may not provide the predicted resolution: High spatial resolution comes along with small voxel sizes and a small number of spins that contribute to the signal that originates from one particular voxel. This small signal is further decreased by diffusion losses in the presence of field gradients and relaxation. In the case of velocity encoding with a bipolar gradient pair like the one shown in Figure 1b, the signal amplitude is decreased due to diffusion by the factor [3]

$$A_{\mathrm{Diff}} = e^{-2/3\gamma^2 \hat{G}^2 D \tau^3},$$

where D is the diffusion coefficient in the liquid.

Pulse sequences that require long gradient pulse trains for parameter encoding suffer substantially from this attenuation. Taking into account the different dependencies of the velocity-induced phase shift ($\propto \tau^2 \hat{G}$) and the diffusive attenuation ($\propto \exp[-(\frac{2}{3})\gamma^2 \hat{G}^2 D \tau^3]$) on the gradient strength and length, it is possible to optimize these two parameters for a given resolution. But especially for experiments with high spatial resolution and a large velocity range to be mapped, this may not be sufficient to retain a satisfactory signal-to-noise ratio. In this case, a number of sub-maps can be recorded and combined to a map that covers the full parameter range but has no equidistant data resolution [4].

Velocity mapping is restricted mainly by two effects: Slow velocities are masked by diffusion and large velocities cause a spin to leave its designated voxel in the time between encoding and signal readout. A flow experiment should be set up in a way that the largest detectable velocity present in the sample is covered by the corresponding velocity FOV. This avoids distortions by back-folding of velocities into the experimental velocity scale. But the larger the FOV is, the longer and stronger gradients are required to maintain the required resolution and the larger is the attenuation by diffusion. Therefore, instead of performing one experiment with a large number of gradient steps, the entire range should better be covered by at least two experiments with a significantly smaller number of gradient steps ('two-step strategy').

The first experiment has a velocity FOV that covers the entire velocity range in a small number of steps. The velocity map is not distorted but small velocities are identified as "zero" due to the coarse resolution.

The second experiment covers the velocity range between the minimum measurable velocity and the minimum velocity detected by the first experiment. It is distorted because of back-folding of high velocities into the spectrum, but it properly shows the small velocities. All voxels from the first map, which show zero velocity can now be compared to the corresponding voxels of the second map. If those show a finite velocity, the value can be transferred to the first map. The combination of the two maps is then a map, which covers the full velocity range and includes small velocities, but has a fine resolution at low velocities and a coarse resolution at high velocities. With this technique, a substantial decrease of the diffusive attenuation of the signal can be achieved.

Experiments

Figures 3 and 4 represent velocity and acceleration mapping experiments carried out in percolation model objects and the corresponding numerical simulations. The template used for the fabrication of the model objects was computer generated based on a two-dimensional site percolation model [5–7] and is shown in Figure 4a. Patterns of this sort were either mechanically milled into polystyrene sheets (photograph in Figure 3a) [8]or etched into 1 mm thick PMMA sheets by Deep X-ray Lithography (photograph in Figure 4b) [9,10].

Experimental results comparing velocity and acceleration maps are shown in Figure 3. The data were measured with the $10 \times 10\ \mathrm{cm}^2$ sample (smallest pore size 400 μm) shown in Figure 3a. Velocity mapping and acceleration mapping experiments were carried out with a Bruker 4.7 T magnet with a 40 cm horizontal bore. The maximum applied field gradient was 50 mT/m. A detailed discussion of the effect of gradient ramps on the phase encoding and of the four pulse gradient sequence (Figure 2c) that was used for acceleration encoding can be found in Ref. [1].

Figures 3b and c show numerically obtained acceleration and velocity maps, whereas the experimental results are presented in Figure 3d and e. The simulations were done with the FLUENT 5.5 (FLUENT Inc., Lebanon, NH, USA) finite-element software package. The positions

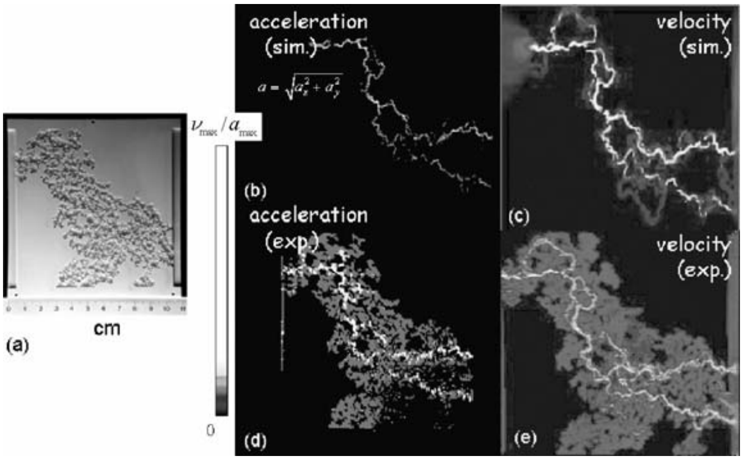

Fig. 3. (a) Photograph of a 10 × 10 cm^2 percolation model object milled into a polystyrene sheet with a depth of 2 mm. (b) Simulated acceleration magnitude map. (c) Simulated velocity magnitude map. (d) Experimental acceleration magnitude map. (e) Experimental velocity magnitude map. (See also Plate 10 on page XXI in the Color Plate Section.)

where the acceleration is finite (i.e. above the experimental resolution) are obviously localized spots in contrast to the more continuous flow patterns visible in the velocity map. That is, acceleration maps specifically reveal the distribution of flow bottlenecks and changes of the flow resistance. Note, that experimentally obtainable velocity maps are too crude to deliver an acceleration map by derivation of the flow field. A distinct method for the direct measurement of acceleration is therefore essential.

Figure 4 refers to the much smaller lithography objects. Three different realizations of the structure are shown in the photographs Figure 4b. Their sizes are 15 × 15, 18 × 18, and 24 × 24 mm^2. The smallest pore sizes within the samples are 50, 60, and 80 μm, respectively. In Figure 4c, a part of a numerically achieved map of the flow velocities (left hand side) is compared to the same part of an experimentally obtained map of flow velocities of $CuSO_4$-doped water (right hand side) [4]. The velocity FOV of the two experiments was chosen to be $\pm{-9.6}$ mm/s for the first experiment and $\pm{-2.4}$ mm/s for the second. Each single measurement had as few as six velocity encoding gradient steps. Zero-filling to 16 steps was applied afterward. The digital spatial resolution was 26.3 × 36.7 μm, whereas the smallest pore size within the sample was 60 × 60 μm^2. The spectrometer used was a BRUKER DSX 400 spectrometer with a microimaging gradient unit. Gradients of up to 0.8 T/m were used for the experiment.

Concluding Remarks

The NMR velocity and acceleration mapping methods described above are suitable to gain insight into flow distributions and flow properties. Since we are dealing with non-invasive and non-optical techniques, any opaque or transparent, non-metallic system can be examined on this basis in the velocity and acceleration fields of view outlined above and with some restriction with respect to the time resolution.

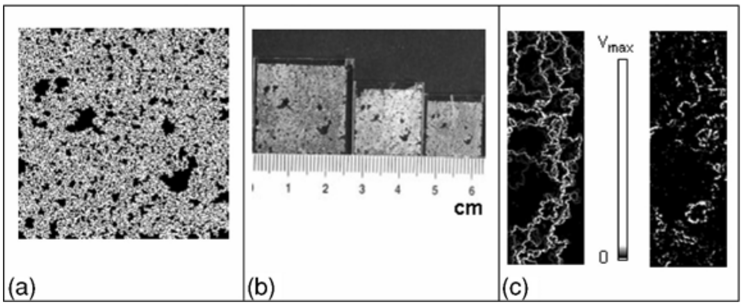

Fig. 4. (a) Computer generated pore space structure that served as template for sample fabrication and as matrix for numerical simulations. (b) Photograph of model objects etched 1 mm deep into PMMA sheets with X-ray lithography. (c) Cut-outs of flow velocity magnitude maps. Left hand side: numerically derived map; right hand side: experimentally obtained map. The size of the displayed section is 6 × 18 mm^2, which is 1/3 of the total sample size.

As a well-defined paradigm for complex pore spaces we have considered random-site percolation clusters that were generated on a computer. Fabricating model objects on this basis provides samples the pore space structures of which are known quantitatively in all details. This in turn permits finite-element or finite-volume computational fluid dynamics studies which in combination with the experimental NMR results provide an unsurpassed conclusiveness concerning the relationship of the pore space structure and the transport properties.

Fundamental investigations with "known" porous media are suitable to reveal the laws needed to understand transport on microscopic length scales. Knowledge elaborated on this basis is expected to trigger studies also of interest for chemical engineering and microsystem technology applications.

Finally, it should be mentioned that hydrodynamic flow is not the only transport phenomenon that can be studied by magnetic resonance microscopy techniques. There are other, more specialized transport quantities that can be examined on this basis as well. Examples are electric current, diffusion, and heat. Corresponding applications to the same sort of percolation model objects reported in this chapter can be found in Refs. [11–13].

Industrial Application of *In situ* NMR Imaging Experiments to Steel-Making Process

Koji Saito
Nippon Steel Corporation, Advanced Technology Research Laboratories, 20-1 Shintomi Futtsu City, Chiba 293-8511, Japan

The biggest advantage of NMR is that is non-destructive. This means that *in situ* experiments are not difficult, when several conditions are established in the experimental scheme and probe. There are many applications of *in situ* NMR which strongly contribute to the solution of industrial problems and clarify complicated phenomena in the science and technology fields. For example, catalysis reactions, chemical reactions, ion or gas or liquid flow, phase transition, etc. In this chapter, I would like to explain mainly two results [1,2] of *in situ* NMR experiments which are very helpful and useful to solve real problems in industries.

NMR imaging is a powerful tool that is widely and successfully used in medical applications. At the same time, its potential to solve materials science problems has been recognized only more recently. NMR imaging of solids is still a challenge despite significant achievements in this field [3]. NMR microscopy allows one to study the macroscopic transport of liquids in materials by monitoring the transformation of the spatial distribution of liquid content in time [4]. Another important process that involves mass transport in materials is drying [5–9]. The conventional approach utilizes the evaluation of the total amount of losses of liquid vs. time (drying curves), e.g. by sample weighing, while its distribution within the porous object is determined using a gravimetric method based on sample sectioning.

It is well known that the presence of water and water transport play key roles in determining the pore structure and long term durability of cementitious mortar materials. In real life, some problems, e.g. hydrogen-explosion, can occur because of poor drying conditions. To date, however, a severely limiting factor has been that resonance line widths in cements are very broad. Consequently, only the most mobile water in the largest capillaries, cracks, and voids has been observed. Only more recently have STRAFI imaging techniques [10] been examined. Surface relaxivity has been exploited by McDonald and Newling [11] using the complementary technique of magnetic resonance relaxometry. These authors show that the initial ^{1}H spin–spin relaxation time (T_2) of water in a dried 0.5 water to cement (w/c) ratio mortar paste varies according to water content, indicating that the rapid exchange model of relaxation can be applied to determine the pore surface area to volume ratio. This paper presents the results of a STRAFI imaging study of the hydration and drying of mortar pastes and of subsequent water transport in dried material. This process may also be performed in underwater environments, and such cases were also studied. The objective is to correlate the bulk relaxation analysis of samples sealed during cure, which are assumed to be spatially uniform, with the structure of the paste based on traditional understanding. Quantitative STRAFI imaging is then used to observe deviations from this model in the case of samples dried open or underwater where spatial heterogeneity is expected. Also, knowledge of the mechanism of the drying of these refractory mortars will permit the optimization of the drying using modern solid state NMR techniques [^{27}Al M(3 and 5)QMAS and ^{1}H–^{27}Al CP/3QMAS in Ref. 12] in the real steel-making process.

Typical refractory mortar samples are prepared as sample 1 (sample 3 + surface active agents) and sample 3(Al_2O_3: 92%, MgO: 7%, CaO: 1%). For most of the studies, mortar samples were cast in glass pots and NMR tubes from real industrial materials using a food processor to mix the water and mortar powder and a vibration table to remove incorporated air. The tubes and pots were sealed. For the measurements made during the cure, the samples were examined *in situ* (50 °C).

Representative STRAFI echo train profiles recorded at 50 °C every 40 min from samples 1 and 3 of drying refractory mortar are shown in Figure 1. In the case of sample 3, a drying time of around 18.3 h is required, whilst sample 1 requires less than half this drying time (8 h) due to the effect of the surface active agent. The STRAFI *in situ* experiments produced a large number of water content profiles. The details of the front shape are distorted by the finite time required to record the profile. Details of the front shape are better determined in a time of flight experiment in which the signal intensity is recorded at a fixed location as the front passes. Because data acquisition is considerably more rapid, the distortion is much less. The analysis discussed below uses a combination of time of flight and profile data. The drying of the sample proceeds from the surface, so that close to the surface the free water ratio decreases with proximity to the surface. However,

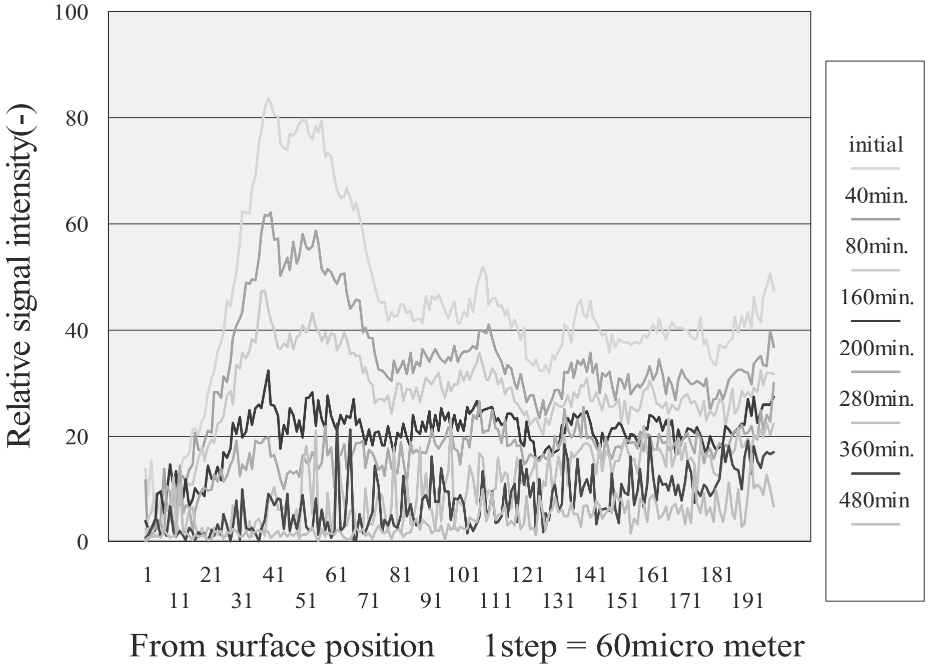

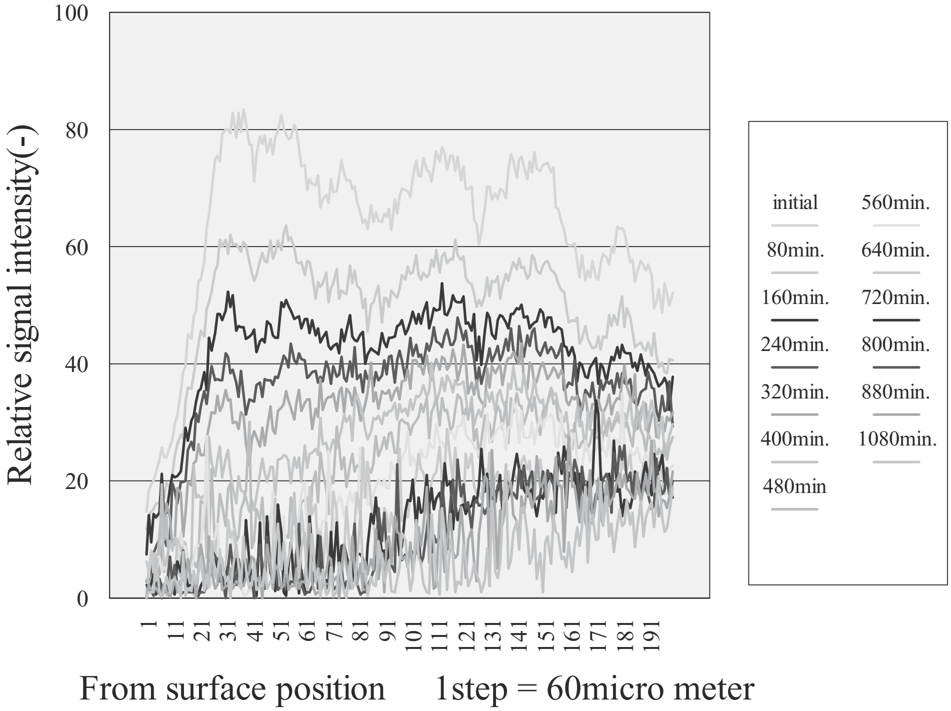

Fig. 1. The typical results of STRAFI experiments of sample 1 (upper) and sample 3 (bottom). (See also Plate 11 on page XXII in the Color Plate Section.)

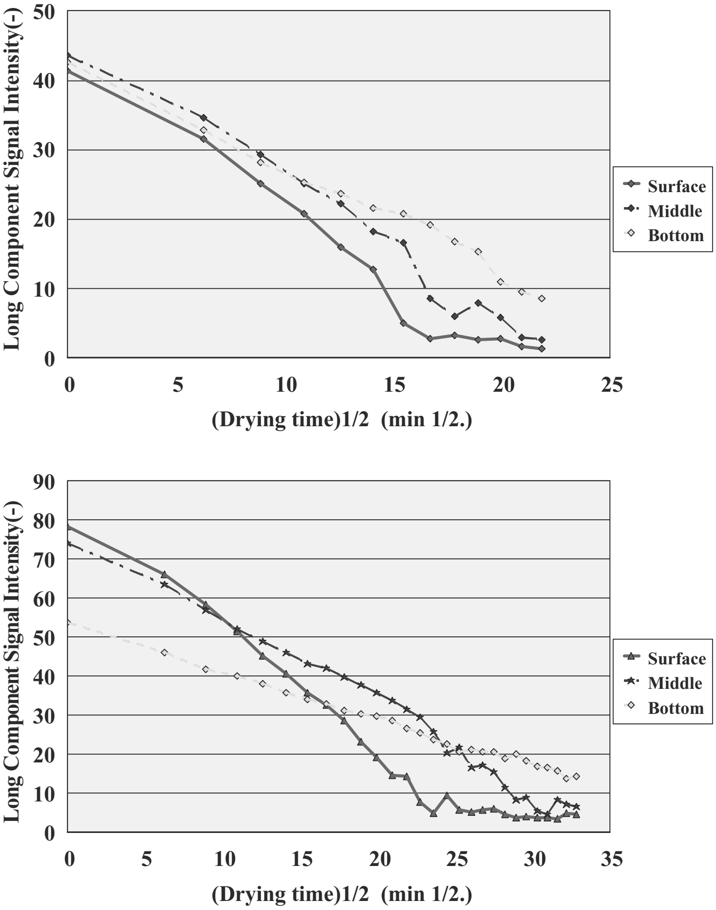

Fig. 2. At the each three position long component of signal intensities as a function of root *t* for a selection of typical drying experiments in the case of sample 1 (upper) and sample 3 (bottom).

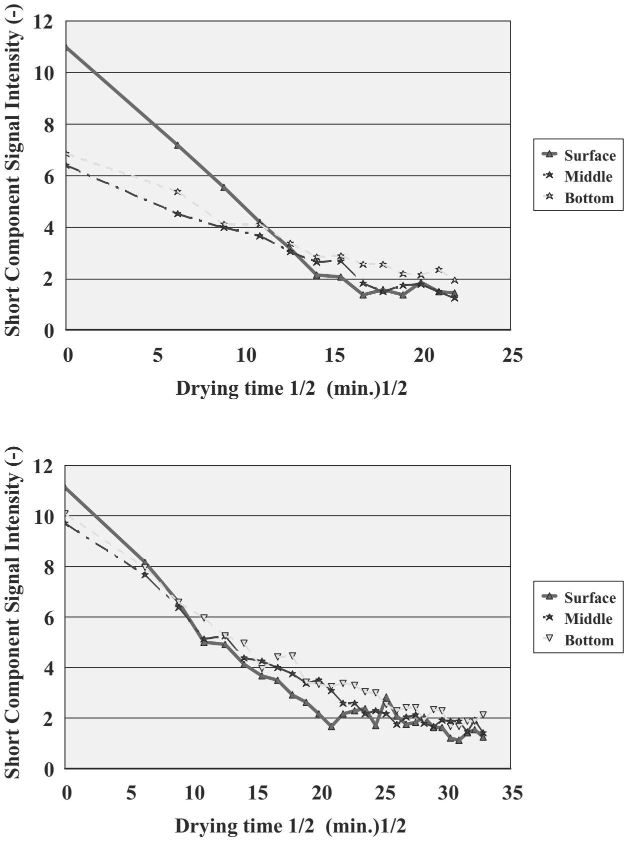
behind this initial region the ratio is maintained constant throughout the remaining sample as water diffuses more rapidly from the lower regions. In order to test whether or not the observed STRAFI profiles are due to Fickian diffusion, we plot the diffusing front position as a function of root time, where t is the time. In the case of Fickian diffusion, such a plot will appear linear so long as the front does not approach the far end of the sample. We define the front position as the position where the front reaches half the maximum concentration. The front position is measured relative to the original sample surface whose position is established from a profile measured before the drying.

Figure 2 shows the three positions (surface, middle, bottom) from the surface front as a function of root t for a selection of typical drying experiments for sample 3 and sample 1, respectively. The data in the case of capillary water are all well approximated with linear fits, indicating that Fickian diffusion is taking place. In addition the slopes of all positions are almost identical for sample 1, indicating that the drying is homogeneous. On the other hand, the slope at the bottom position in the case of sample 3 is different from the others. It is likely that inhomogeneous drying is going on. We can obtain a "characteristic" diffusion coefficient D, from these plots since we know that the characteristic diffusion length is given by $(D_{\text{av}}\ t)^{1/2}$ which can be equated to the front position. D_{av} is simply the slope of the front position vs. the $t^{1/2}$ plot. This measure will be used frequently in the subsequent discussion since it is a robust and straightforward way of parametrizing the profile position data and is related to the magnitude of the mutual diffusion coefficient.

The average diffusion coefficient of free water for the drying of sample 3 at 50 °C was found to be $6.1–8.7 \times 10^{-5}$ cm^2/s. For instance, moisture diffusivity in brick and clay is in the range $10^{-5} - 10^{-3}$ cm^2/s for various moisture

Fig. 3. At the each three position short component of signal intensities as a function of root *t* for a selection of typical drying experiments in the case of sample 1 (upper) and sample 3 (bottom).



contents in the materials, while the self-diffusion coefficient for water is only 2.1 × 10^{-5} cm^2/s. In the case of sample 1, the average diffusion coefficient for the drying at 50 °C was found to be 9.7 × 10^{-5} cm^2/s. Although the total drying time was quite different between sample 3 (1080 min) and sample 1 (480 min), it is surprising that the average diffusion coefficient of free water is almost the same for both samples.

On the other hand, what about bounded water behavior? Stray-field imaging is a very powerful tool to monitor all capillary water (long T_2, component) and bounded water (short T_2, component). It is found that the recorded quadrature echoes, which in the case of combined water reflect a degree of line narrowing and in the case of mobile water are strongly diffusion attenuated, can be well represented by two-component exponential decays, with the relative amplitudes of the components corresponding to the proportions of capillary water and chemically combined water, respectively. Figure 3 shows profiles of bound water for samples 1 and 3, respectively. A feature of generalized Fickian diffusion is that the water front should advance as $t^{1/2}$. We note that this is the case in the experiments reported here. While it is possible that this is due to the additional drying damaging the delicate gel structure of the mortar, we believe that the result is significant and reflects the different uptake characteristics of refractory mortar to capillary and to bounded water. Based on the fits, the diffusion coefficient for bounded water of sample 1 is calculated to be $D(\text{c}) = (3.4 - 6.2) \times 10^{-5}$ cm^2/s except for the surface position. On the other hand, the diffusion coefficient for combined capillary water of sample 3 is difficult to confirm as Fickian diffusion because of bad linearity of Figure 4. Thus it appears that Case II type diffusion is occurring in the case of bounded water for sample 3.

To clarify chemical reasons we have carried out the measurements of ^{27}Al M(3 and 5)QMAS. Figure 4 shows ^{27}Al 5QMAS spectra for the before drying and after drying of sample 1, respectively. ^{27}Al 5QMAS shows there are mainly four chemical structures (two 4-coordinate type and two 6-coordinate type). Table 1 shows the quantitative analysis of these chemical structures for samples 1

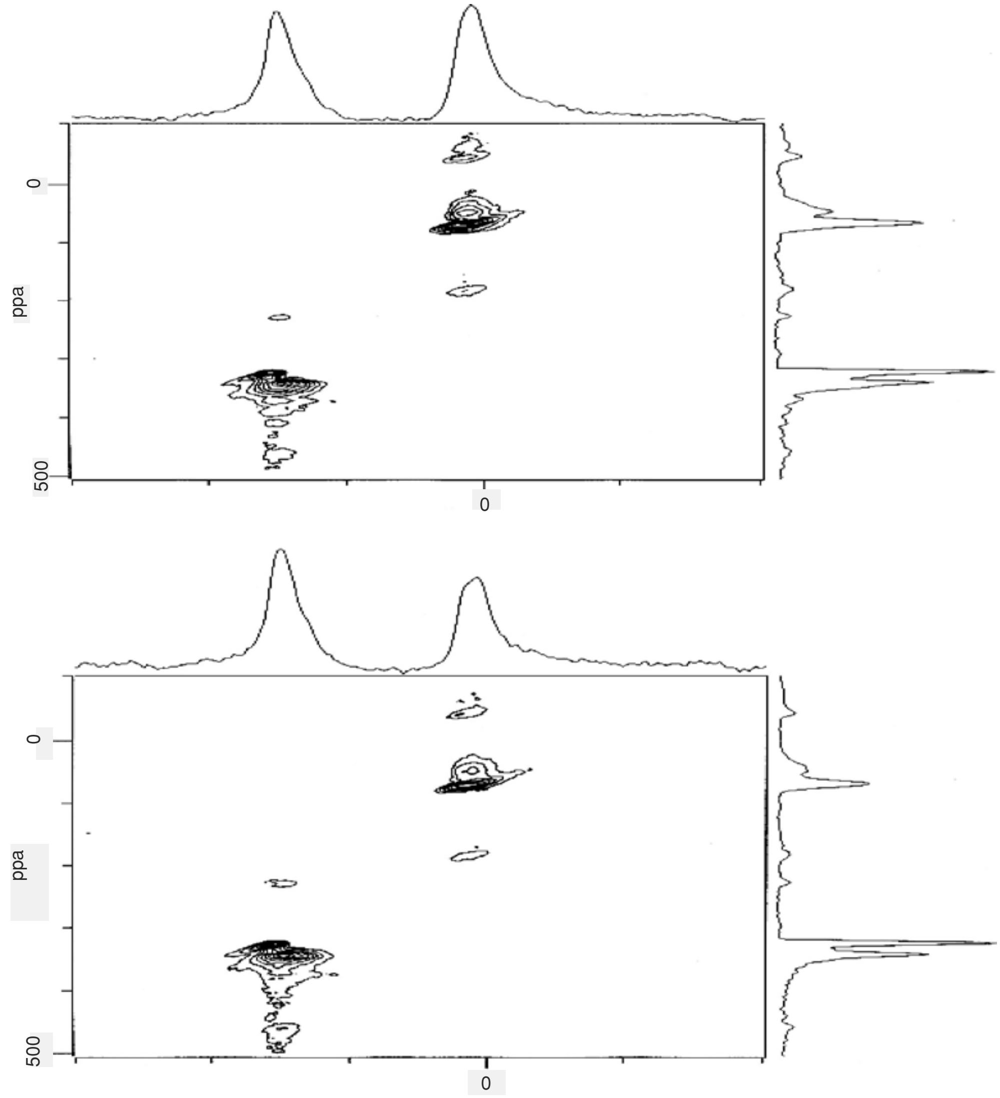


Fig. 4. ^{27}Al 5QMAS spectra for the before drying (upper) and after drying (bottom) of sample 1.

and 3 after drying. It is clear that sample 3 has $Al(OH)_3$ and a 6-coordinate type structure as compared to sample 1, since sample 1 has the surface active agent. On drying, the 6-coordinate type structures change to 4-coordinate type structures because of water loss. It is very difficult to precisely determine the chemical structure because of the high complexity of the mixture, but the effect of quite different proportions of these chemical structures are one of the reasons for the difference of relaxation profiles between samples 1 and 3. These results show the surface active agent is very effective and helpful in optimizing the drying condition for refractory mortar in the real process.

It has been shown that the amplitudes of a simple two-component T_2 analysis of mortar pastes correlate well with the expected fractional volumes of chemically combined and capillary water. It has further been shown that stray-field imaging can quantify all the water. The techniques allow a detailed quantitative study of the effects of drying regimes that result in non-uniform drying and the effects of surface active agents in the water. Differences

†Integrated signal of the sum of two 6-coordinate is 100 (standard).

between the uptake of capillary water and that of combined capillary water have been observed and quantified. In addition, solid state NMR [^{1}H-CRAMPS and ^{27}Al M(3 and 5)QMAS] studies were performed to clarify the change of chemical structure by drying treatment. It is clear that imaging and solid state NMR give useful information to enable the optimization of the drying conditions. These results are very useful to optimize the drying conditions in the real steel-making process.

Coal [13] is considered to be a heterogeneous organic rock and is typically black, although, deposits can range in color from brown to brownish red. At the same time, it is no doubt that energy 13 is an important commodity because it affects our lives in many ways. Coal is playing a very important role in energy fields. Because total world resources of coal are 1×10^{12} tons; total world production is estimated to be 4.0×10^9 tons/year. The importance of the resource is that, despite having greater problems with production, transportation and utilization compared with oil and gas, it represents a vast resource to meet energy demands well into the future (for more than 1000 years). From the viewpoint of energy resources, coal is a very important material for human and also NMR techniques have many advantage points compared to other methods in order to analyze coal structures.

Thermally induced changes in coals are interesting from the standpoints of both fundamental and applied research for the steel-making process. Furthermore, for very inhomogeneous coals, there is a fascination in the study of the influence of thermal dynamical changes. To monitor the dynamic changes in coals with temperature, an *in situ* method must be used, because it is well-known that the properties of coals change dramatically in high temperature ranges (from 350 to 550 °C) [14–19]. However, the main problem with standard empirical tests, such as the Gieseler plastometer and Audibert-Arnu dilatometer to study the properties of coal changes, is that they have no relationship with the actually occurring structural changes. High temperature ^{1}H-NMR is a powerful technique for the *in situ* investigation of molecular motions in coals during carbonization. The ^{1}H-NMR spectra obtained for coals basically comprise contributions from a mobile and an immobile (rigid) component. The technique was shown by Sanada and coworkers [20] in the late 1970s to clarify fluid materials from coal during early carbonization stages. However, the *in situ* ^{1}H-NMR spectroscopy investigations are limited to the average data for heterogeneous coals which lack information about the distribution of the mobile component and its variations in the specimen due to chemical change by the heating process. We have carried out the first systematic *in situ* variable temperature NMR microimaging study of coals between 25 and 600 °C with our newly developed high temperature microimaging probe and systems in order to clarify the behavior of the mobile component at high temperature in heterogeneous coal specimens. The main specifications of our developed probe are

1. maximum sample temperature is 600 °C,
2. maximum field gradient strength is 250 G/cm,
3. maximum current is 50 A

These specifications can be completely achieved by adopting a rectangular enameled wire for the coil producing the field gradient, using a cooling system by water and alcohol mixture, a coil molding technique, and a very efficient heating system in the probe. The rectangular wire has an extremely high space-factor (over 95% is available), so it is possible to get a high total current density, and it has also good heat dissipation. A Founer–Bessel expansion method [21] was used for optimal coil design. Following this design, the coil was wound as stand alone type coils. Moreover these coils are cooled by a closed circulation cooling system. These coils and cooling pipes are molded by resin for heat dissipation and for preventing coil vibration. Figure 5 shows our variable temperature probe. It has very long spiral heating wire, and the path of the heated N_2 gas is a very close to this heating wire, so that high efficiency of heat exchange is achieved. We have tried the SPI and SPRITE methods at 500 °C using this probe. Both of those two methods are very tolerant of gradient-switching time. For example we applied large pulsed field gradients up to 250 G/cm to this probe, which made the gradient-switching time as long as 150 µs. But the fixed phase-encoding time tp can be shorten as short as 64 µs (method: SPI, FOV: 5 mm, points). So, the combination of high temperature and the SPI or SPRITE method is very effective for coal science. The 2D-SPI sequence for *in situ* experiments was applied in order to observe the distribution of the mobile component in coals using a variable encoding time, because T_2^* of the mobile component for coals is changeable from 100 µs 1 ms with increasing

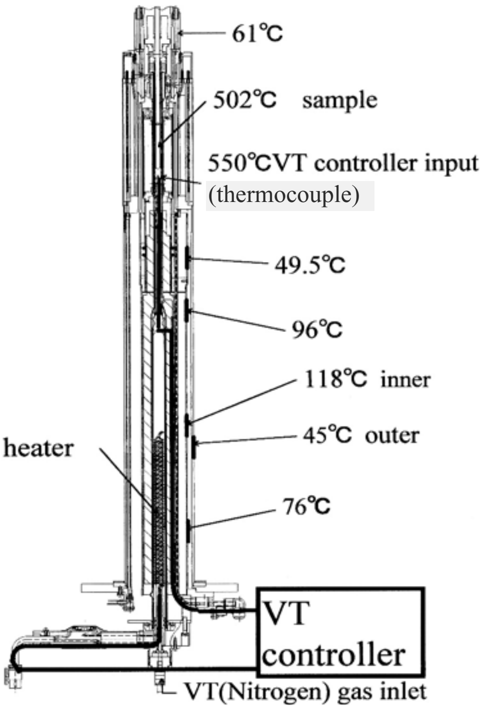

Fig. 5. The developed high temperature imaging probe.

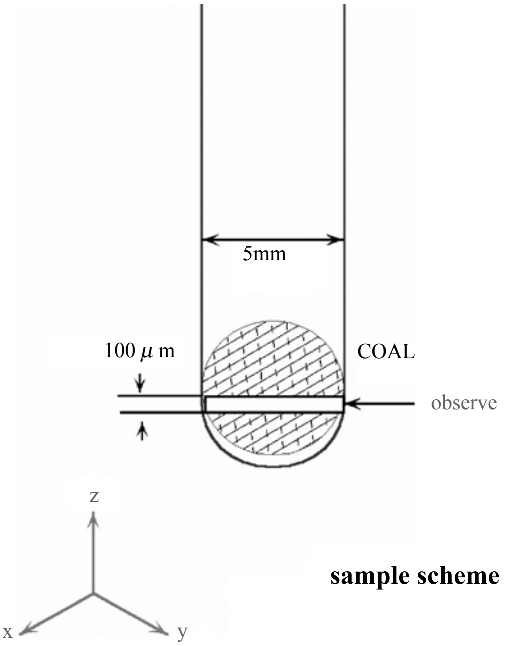

Fig. 6. Experimental sample scheme.

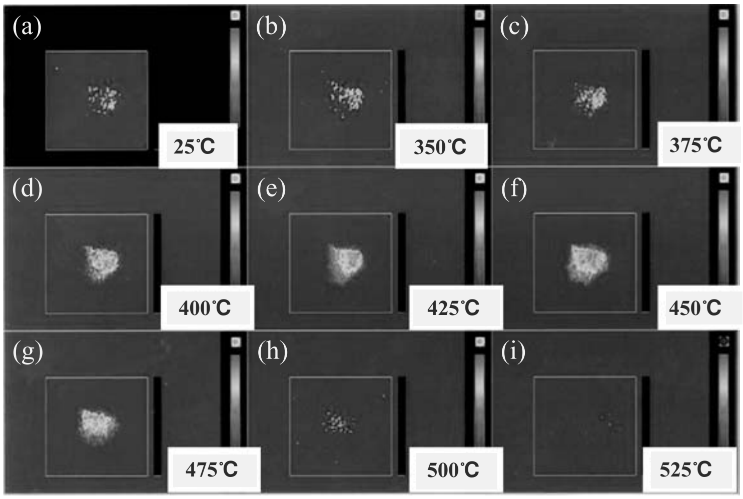
temperature. To avoid the contribution of an immobile component, a variable encoding time at each temperature was optimized. The data matrix size was 128 × 128 (the digital resolution: 50 μm), and the number of signals accumulated was 16. The data acquisition required about 8 min. The experimental sample scheme is shown in Figure 6. The rate of heating was 3 °C /min. which is the same as that of the industrial coking process. This means that the sample temperature was increased by about 24 °C (8 min × 3 °C/min.) during the NMR microimaging measurements.

According to the properties of both coals, the data of Goonyella obtained from Gieselar plastometer and Ro (vitrinite refraction rate %) which are common methods for estimating the properties of coals is better than those of Witbank for coking. It is well-known that coals start to soften and melt at about 400 °C and then, to cake and carbonize at more than 450 °C. The solid echo pulse sequence with a refocusing of 4 μs was used to minimize the loss of signal due to the dead time of the NMR coil. Figure 7A shows NMR image of Goonyella coal at 25 °C and it was found that the distribution of the mobile component was very heterogeneous like the distribution of *macerals* about the coal which was cut with a thickness of 100 μm. As the temperature became higher, the mobile component increased but remained heterogeneity (Figure 7B and C). The images of Figure 7D–F shows that the distribution of the mobile component became more homogeneous. This means that the coal starts to soften and melt, and then the existent rate of the mobile component increases dramatically. It is likely that these areas which are easy to soften and melt are fixed initially, because there are rich areas of the mobile component on the right side of Figure 7A at 25 °C. It is very interesting that the softening and melting areas are moving from the right side to the left side in these images slightly like diffusion phenomena. According to the half-width of the mobile component at 400 °C (where 400 °C means average data from 400 to 425 °C during the measurement, as the temperature increases at the rate of 3 °C/min), compared to other materials measured at the same frequency, the mobility of the mobile component indicates a similarity to gels, rather than liquids. Therefore, it is likely that the stretching of the mobile component occurs since an immobile component can change to a mobile component by heating. At the same time some mobile component parts which have good fluidity initially can melt at first and move with slow diffusion to other areas. As the optimized variable encoding time at each temperature was used in order to avoid the contribution of immobile components in these experiments, it is noted that all results show the behavior of a mobile component only. When the temperature was

Fig. 7. (A) NMR image of Goonyella coal at 25 °C, (B) at 350 °C, (C) at 375 °C, (D) at 400 °C, (e) at 425 °C, (F) at 450 °C, (G) at 475 °C, and (H) at 500 °C. (See also Plate 12 on page XXIII in the Color Plate Section.)



over 450 °C, he resolidification starts and then the mobile component decreased (Figure 7G) and at last, there are a few mobile parts at 500 °C (Figure 7H), because of resolidification this means that a mobile component converts to an immobile component and the carbonization means that the number of protons in coal decreases extremely. On the other hand, Figure 8 shows the image of Witbank coal at 425 °C which indicates the maximum mobility. It is surprising that it shows low mobility areas and retains an unsoftened area, corresponding to an inert area, in spite of the maximum mobility for Witbank. It is likely that low rank coals for coking like Witbank has an inert area which is difficult to soften and melt at its maximum mobility temperature and to move to other areas with diffusion.

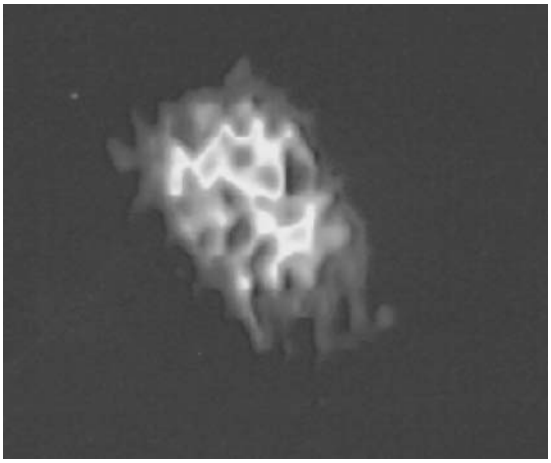


Fig. 8. The image of Witbank coal at 425 °C. (See also Plate 13 on page XXIII in the Color Plate Section.)

Thermally induced changes in coals are interesting from the standpoints of both fundamental and applied research for the iron-making process. Furthermore, for very inhomogeneous coals, there is a fascination in the study about the influence of thermal dynamic changes. To monitor the dynamic changes in coals with temperature, an *in situ* method must be used, because it is well-known that the properties of coals change dramatically in the high temperature range (from 350 to 550 °C). Therefore, we have carried out the first systematic *in situ* high temperature NMR microimaging study of coals between 25 and 550 °C with our newly developed high temperature microimaging probe with systems to clarify the behavior of the mobile component at high temperature in coal specimens. Finally, we have demonstrated the application of recent NMR techniques to new coking process development in the 21st century [22]. It is clear that coal is very inhomogeneous and complex, and at the same time, from the viewpoint of energy coal is very important. But we believe NMR is very powerful, effective and the best tool in order to not only characterize coal structures and clarify the behavior at high temperature but also develop new processes.

Biomedical NMR Spectroscopy and Imaging

Toshiro Inubushi and Sigehiro Morikawa
Biomedical MR Science Center, Shiga University of Medical Science, Seta, Otsu, Shiga 520-2192, Japan

Introduction

An application of NMR spectroscopy for biomedical area is most clearly embodied as MRI, a diagnostic imaging tool, where the information obtained by NMR is presented in a visualized image. Signal intensity, more often, T_1 and T_2, of H_2O signal in ^1H NMR is utilized for the construction of image in 2-dimensional space, as the so-called slice. To acquire data along the direction of chemical shift, it requires further elaborated time in addition to the measurement of MRI data. This is the major reason why the MR spectroscopic imaging is not widely accepted in clinical situation. Furthermore, MR images are sometimes obscured with overlapping images generated by separated signals, so-called "chemical shift artifact." In order to circumvent this bias, it is necessary to employ a technique to enhance the sensitivity of the detection of NMR signal and also to shorten the measurement time by a fast scan technique in MRI. In this section a unique, however, an important area of NMR application, which will lead to the future NMR technology, the so called, molecular imaging (MI) in the near future is discussed.

Tracking of Metabolites: *In Vivo* ^{13}C NMR Images with H-1 Detection

Among many nuclei utilized *in vivo* NMR spectroscopy, a ^{13}C tracer has been widely used for investigating the mechanisms of chemical reactions occurring in biological systems. Despite the difficulties inherent in directly observing ^{13}C NMR signals *in vivo* [1,2], a number of applications have been used ^{13}C tracers to analyze the metabolic pathway in rats [3–5] and humans [6,7].

Various innovative methods have been devised so far, such as hetero nuclear decoupling [8] and cross polarization [9,10], for efficient detection of low sensitive nuclei *in vivo*. One successful method was hetero nuclear editing to select protons coupled with ^{13}C nuclei, which has been extensively applied to studies of ^{13}C-labeled metabolites in animals by Shulman and his colleagues [11,12]. Another approach utilizes the selection of multiple quantum coherence (HMQC) created by the interaction between ^1H and other nuclei having low gyromagnetic ratios, such as ^{13}C and ^{15}N. In the environment of biological NMR, selecting the coherence has been further advanced by employing field gradient pulses (GE-HMQC) [13–16], which can relieve the burden on the NMR instrument by eliminating complicated and eventually time-consuming phase cycling of the RF pulses. Another advantage that accompanies this technique is the removal of unwanted solvent peaks, typically that of H_2O in *in vivo* ^1H NMR spectra, which is forced to diffuse out by the applied field gradient pulses to select the coherence, if the gradient pulses are strong enough. Therefore, it is not necessary to apply a strong RF power on the solvent signal to suppress it. This is particularly beneficial in working with living tissues, in which the ^1H NMR spectrum is dominated by a large H_2O signal. In addition to this, echo planar spectroscopic imaging (EPSI) method was combined to HMQC, which remarkably improved the temporal resolution of spectroscopic imaging [17]. Here the combined technique to observe ^{13}C NMR tracers by ^1H is applied to investigate the metabolic process of 1-^{13}C-glucose in the animal brain [18].

1-^{13}C-glucose data sets were consecutively observed every 35 min. Representative ^{13}C glucose images and the extracted spectra from 10 × 12 voxels of 32 × 32, corresponding to the brain region, are shown in Figure 1A. The glucose images were constructed by summing up the doublet ^1H peaks split by $J^{13}C$-^1H coupling at 1-^{13}C -glucose. These signals were obtained with the ^{13}C frequency selective pulses which excite only the ^{13}C signal at the l-C position of glucose.

Representative serial ^{13}C metabolite images and the extracted spectra in one rat are shown in Figure 1. First, baseline data of 1-^{13}C-glucose and 3/4-^{13}C-Glu/Gln were collected by applying frequency-selective pulses onto 1-^{13}C-glucose and 3/4-^{13}C -Glu/Gln, respectively. Subsequently, 1-^{13}C-glucose infusion was commenced, and acquisition of glucose data was started immediately. After one data set of glucose was collected, the ^{13}C frequency was switched to that of 3/4-Glu/Gln (30 ppm). Thereafter, the data collections of Glu/Gln were repeated.

High ^{13}C-glucose signals in the brain region were detected in the first data set after ^{13}C-glucose infusion, however, then disappeared rapidly. Next, 3/4-^{13}C-Glu/Gln data sets were consecutively observed (Figure 1). The 3/4-Glu/Gln images were constructed from either peak 1 or 2 of the 3/4-^{13}C-Glu/Gln spectra separately, because

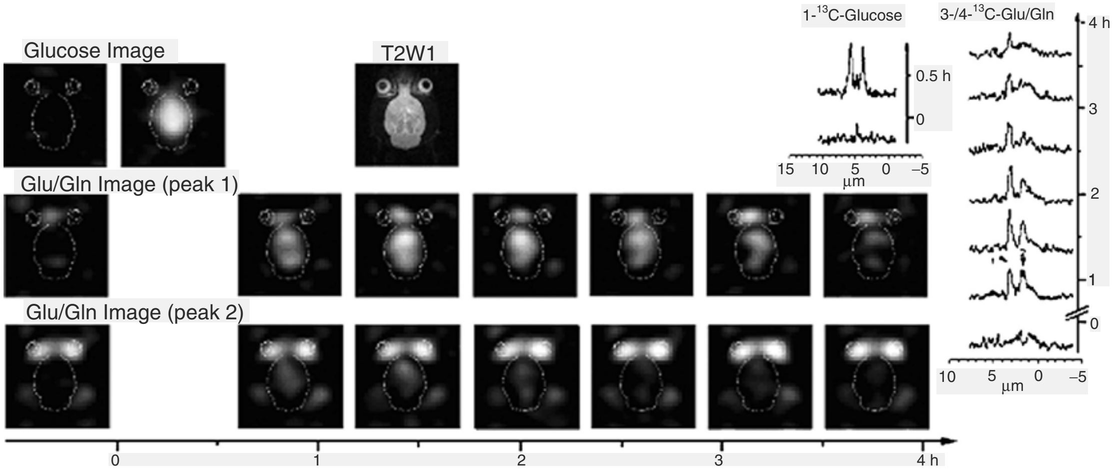

Fig. 1. ^{1}H-detected C-13 Metabolic map of rat brain derived from 1-^{13}C-Glucose. The ^{13}C NMR signals were indirectly detected *via* ^{1}H signals coupled with ^{13}C. The inserted spectra were extracted from 10 × 12 voxels of 32 × 32 CSI data. The images for 1-^{13}C-glucose and for 3-/4-^{13}C glutamate/glutamine were superimposed onto regular ^{1}H images. A measurement of the metabolic map took approximately 20 min. The peak 1 and peak 2 for 3-/4-^{13}C glutamate/glutamine were split by J-coupling with ^{1}H, which were combined to construct the Glu/Gln images.

prominent natural abundant fat CH_2 signals in the orbita also appeared on the peak 2 image. The 3/4-^{13}C-Glu/Gln signals in the brain were minimal in the first data set after ^{13}C-glucose infusion. These signals were maximal in the second and then gradually decreased therefore.

GE-HMQC method possesses several advantages. The GE-HMQC method, in principle, does not require phase cycling, which makes it less sensitive to errors caused by movement of the animal or by hardware instability during high-speed gradient switching. The prominent water signal can be dephased only by the gradient pulses for HMQC selection without water suppression pulses, which enabled us to detect the glucose signal in the brain. The clinically applicable lower magnetic field strength, less expensive tracer, tolerance to movement or hardware performance, and the detection of glucose uptake into the brain might be beneficial for human studies in the future. Thus, the combination of the signal enhancement technique with a rapid acquisition technique enables to obtain chemical shift selective images for living systems.

Physiological Properties: pH

Phosphorus-31 NMR spectroscopy enables the evaluation of the relative concentrations of phosphoenergetic constituents and measurement of intra-cellular pH *in vivo*. The measurement of pH in the living tissues is important to analyze the viability of tissue, since pH change depends upon the oxygen stress. This is clearly demonstrated in an exercised skeletal muscle described below.

The three parameters (height, width, and center frequency) of Pi and PCr peaks in the NMR spectra of 32 × 32 voxels were extracted by specifying the region of each peak with an automatic line-fitting routine to a Lorenzian line shape. Referring to the chemical shift imaging constructed by Pi, we determined the threshold level of Pi signal intensity for pH calculation. The data from the voxels in which the signal intensities of Pi were below that threshold were discarded. Then the pH values in the selected voxels were calculated from the difference (Δ) between the chemical shifts of the two peaks according to the following equation [19].

$$\mathrm{pH} = 6.75 + \log(\Delta - 3.27/5.69 - \Delta) \qquad (1)$$

The calculated pH data were converted to image size 32 × 32 and superimposed onto MRI and/or CSI data [20].

The pH images of human calf muscle after ischemic exercise [21] are shown in Figure 2. Immediately after exercise, ischemic acidosis was severe in the peroneus muscles, moderate in the tibialis anterior muscle and minimal in the triceps muscle of the calf. The severity of acidosis showed good correlation to that of the decrease in phosphoenergetic level. These heterogeneous changes should be caused by the applied workload and heterogenous muscle fiber components. Ten minutes after exercise, the acidosis in either region did not progress further although

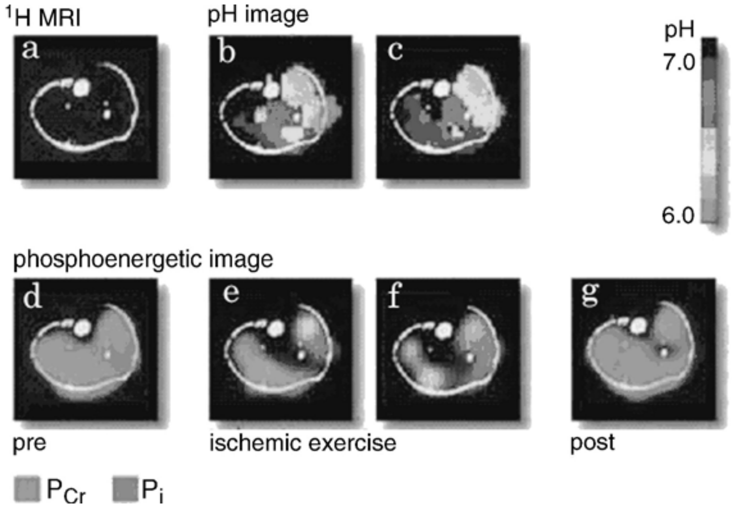

Fig. 2. Metabolic and pH changes in human calf muscle by exercise. ^{1}H MRI image (a) and ^{31}P chemical shift image (d) of human calf muscle in the resting state. A pH image (b) and a chemical shift image (e) during 4 min exercise. (c) and (f) were taken immediately after the exercise. (g) is a chemical shift image obtained 10 min after the exercise. All data were obtained by a clinical MR scanner at 1.5 T. (See also Plate 14 on page XXIII in the Color Plate Section.)

the phosphoenergetic level further decreased during this period. These results suggest that the acidosis is mainly caused not by the ischemia without workload, but by the lactate formed during exercise.

Heterogeneous phosphoenergetic and pH changes in each human calf muscle caused by ischemic exercise are demonstrated as 2D metabolic images using an 1.5 T standard clinical NMR machine and a custom-built volume coil. The spatial and temporal resolution of the images was satisfactory. This non-invasive procedure should be useful in the fields of sports medicine and clinical medicine for peripheral vascular diseases.

Temperature Image and Navigation Surgery Under MRI Guidance

Temperature is also an important parameter to monitor the activity of the living system. Especially in a clinical field, an accurate measurement of the therapeutic area in thermotherapy is essential to carry out appropriate treatment. The use of a thermo coupler or of glass fiber based probe penetrated into the vicinity of the lesion is the only method to monitor the temperature in the treatment. This requires further invasion into a patient other than the surgical invasion. Since there is no reliable method to detect body temperature especially for deeply berried organs in human body at the present time, the temperature image by MRI is the only useful information for the therapeutic response. Temperature image by MRI is based on the temperature dependence of MRI parameters, such as relaxation time T_1, the diffusion coefficient (D) and the hydrogen-bonding shift of tissue water.

Of these parameters, the ^{1}H chemical shift of water has been practically used for temperature mapping. In MRI, chemical shift is calculated from the phase in gradient-echo images

$$\Phi(T) = \gamma\sigma(T)T_\mathrm{E}B_0 \tag{2}$$

where Φ is the phase, γ is the gyromagnetic ratio of the observed nucleus (^{1}H), σ is chemical shift, and T_E is the echo time. In practical, phase shift is measured at given temperature as compared with the phase at reference temperature, and the temperature difference is given as

$$\Delta T = T - T_\mathrm{ref} = [\Phi(T) - \Phi(T_\mathrm{ref})]/\alpha\gamma T_\mathrm{E}B_0 \tag{3}$$

where α is a constant for the temperature dependence of water chemical shift in ppm/°C. Since the constant α is very small at particularly low field and the phase is susceptible to subtle distortion of magnetic field due to body movement of patient, it is important to maintain a stable environment to measure temperature with MRI.

Particularly MRI is advantageous in guiding thermotherapy, since MRI allows not only temperature mapping but can be also used as for target delineation and immediate judgment of therapeutic efficacy during the surgical procedure. We have incorporated the temperature monitoring procedure into intra-operative MRI system introduced at Shiga University of Medical Science.

Temperature monitoring with MRI is undoubtedly a potential tool for the real-time evaluation of the therapeutic effects of thermal ablation. From the viewpoint of electromagnetic interference in the MR images, usage of 2.45 GHz microwave band for ablation is more favorable than the radiofrequency of 500 KHz band for regular ablation. In fact, with radiofrequency ablation, a switching circuit for time sharing is required to reduce the noise in the

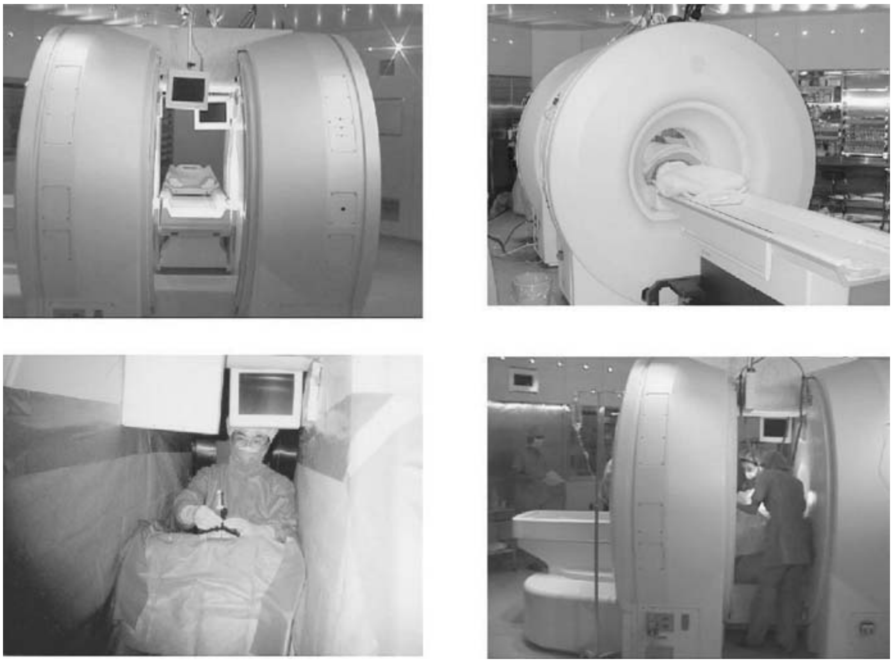

Fig. 3. Photographs of 0.5 Tesla intra-operative MRI instrument (ioMRI). Front (top left) and side (top right) view of the uniquely shaped superconducting magnet having 54 cm vertical gap. Bottom left photo shows that a physician carries out operation over a patient in the MRI magnet, referring to the real time MR images displayed on the monitor placed in the magnet. Supporting staffs also penetrate into the strong magnetic field for patient care (bottom right). (See also Plate 15 on page XXIV in the Color Plate Section.)

MR images [22]. Therefore, we incorporated microwave ablation into MR guidance surgery [23]. Actually, good and reasonable results could be obtained with phantoms or excised tissues. In clinical cases with liver tumors (Figure 4), however, many difficulties should be overcome when using MR temperature monitoring (Figure 5). Because temperature changes are calculated by very small sifts of the water proton resonance frequency form baseline conditions, this technique is highly susceptible to the movement of the liver. This is mainly due to the low-static magnetic field of clinical MR system. Movement of the surgeons and surgical instruments even affects the static magnetic field around the target and results in enormous errors in calculated temperature. From the technical aspect with this MR system, the complicated process and required time for the parameter setting of temperature monitoring were also problems when applying this technique to clinical cases. The improvement of easy and quick parameter setting with our new application was an important step in using temperature monitoring as a useful clinical tool for the evaluation of the therapeutic effects.

The interventional microwave thermocoagulation therapy has regularly been carried out under the guidance of ultrasonography. Actually, ultrasonograpy is an easy, handy, and cost-effective instrument, however, it has serious limitations. The ribs and air space disturb the visibility of ultrasonography and the possible puncture routes are limited. It is sometimes difficult to detect the lesions in the deep parts of the liver. Microbubbles formed by the ablations also perturb the visibility and hampers repeated ablations. The use of MR guidance should be especially beneficial for cases in which ablation therapy is difficult to perform under the guidance of ultrasonography.

Cellular Tracking

Molecular imaging is a newly emerging field of biomedical imaging in which the modern tools of molecular and cellular biology are merged to state-of-art technology for non-invasive imaging. The ultimate goal of this field is to develop technology to investigate molecular and cellular events in living systems. This approach is hoped to lead to better methods for understanding biological processes as well as diagnosing diseases. NMR is one of the key technologies, among positron emission tomography (PET), optical imaging and CT, since NMR is naturally endowed with the ability to operate non-invasive manner.

A technique that can continuously and non-invasively monitor grafted cells in the living system is crucial to

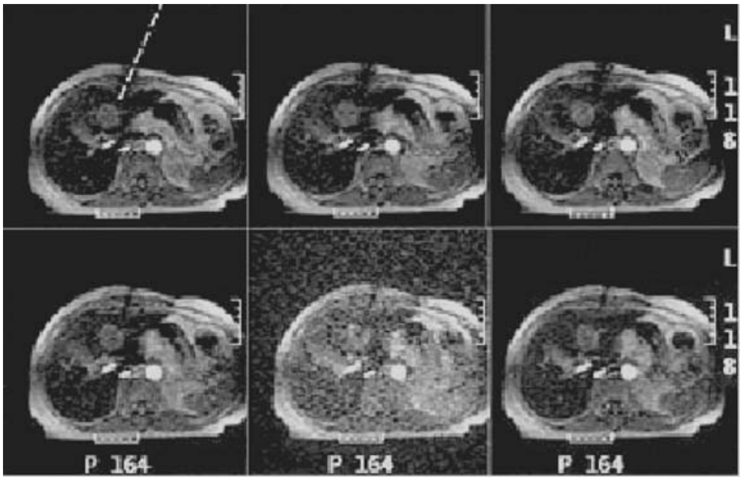

Fig. 4. Microwave ablation therapy for liver tumor under MRI guidance. A surgeon advances a needle to a targeted tumor under the guidance (A) of real time ^{1}H NMR images displayed on a monitor placed inside a magnet. The image for needle was observed as a dark line (B, C). Once the guide needle reached the target, the needle is replace with a microwave antenna (D) and ablation is started (E). During thermal ablation some noises are intruded into a real-time MRI (E). However, the treated area is not distinguished in a regular MRI (F). Therefore, a temperature image is essential for this procedure.

guide further advances in cell transplantation therapy, especially in regenerative medicine using stem cells. So far, various methods have been reported employing available techniques. However, most of these studies have utilized histological techniques, including cytochemistry and imunocytochemistry. These are *ex vivo* techniques, which are limited to apply on postmortem samples and to require corroborative image evidence in order to correlate with *in vivo* data. Recently optical tracking has been developed using luminescent proteins, such as GFP and luciferase. Although these optical methods are operative *in vivo*, a resolution of image is limited and remains difficulty to investigate on a deeply buried organ inside animal body.

Recently, a commercial available MR contrast reagent, dextran-coated superparamagnetic iron oxide (SPIO), was found to be deliverable into several cells, such as, lymphocyte, oligodendrocyte, and HeLa cells with the use of regular lipofection agent, superFect (QIAGEN GmbH, Hilden, Germany) [24]. These magnetically labeled cells on cultured medium showed signal reduction in MRI. More recently ultra small SPIO (USPIO) was incorporated into embryonic stem (ES) cells with lipofection agent, FuGENE (Roche Diagnostics, a division of F. Hoffmann-La Roche Ltd, Basel, Switzerland) and the labeled ES cells were traced by MRI after grafted into rat brain [25]. We have developed a novel method to deliver magnetic labels into cells with an aid of hemagglutinating virus of Japan (HVJ) liposome vehicle, an effective gene transfer vector [26], and also serves as a drag delivery system.

This cell-labeling technique is applicable for many categories of cells, ES cells, neuronal progenitor cells, astrocytes, and PC12 cells. PC12 cells were established from rat adrenal pheochromocytoma, which are described to synthesize catecholamines, such as dopamine and norepinephrine, in response to nerve growth factor. Figure 6 shows the MRI of rat brain received the tagged PC12 cells. MRIs were measured at point to point after the surgical transplantation of the tagged cells up to 2 months. In this period, the implanted cells were well distinguished against the background images in rat brain. The areas of the contrast induced by the grafted cells were observed as long as 2 months, however, they were gradually decreased toward the end of the period, without changing the position.

The efficacy of endosomal labeling of cells and the ability of tracking of the labeled cells is the key factor for

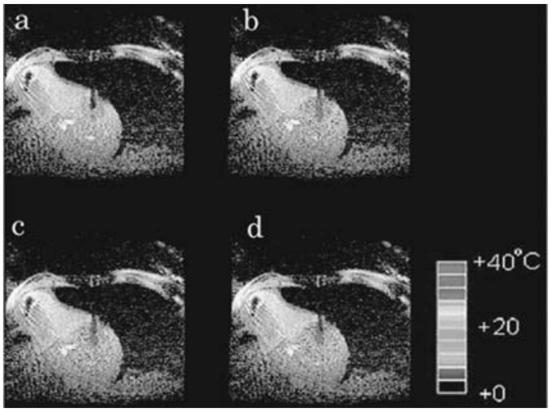

Fig. 5. NMR temperature images obtained during thermotherapy applied for human liver tumor. These figures show that the temperature rises by the microwave ablation. A regular ^{1}H NMR image (A) is superimposed with MR temperature images to display the region treated the thermotherapy. Repetition of ablation brings gradual increase of temperature in the order of (B), (C), and (D) and expands the area reached to the highest temperature. The images (B), (C), and (D) are the display presented to a surgeon during the therapy. (See also Plate 16 on page XXIV in the Color Plate Section.)

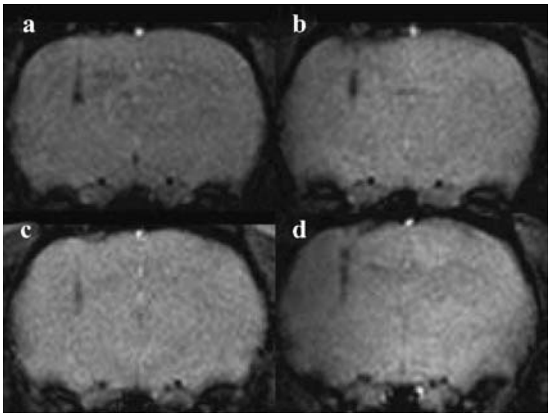

Fig. 6. Coronal views of T_2*-weighted MRI for rat brains received magnetically labeled PC-12 cells. (a) MR image obtained for the rat brain received approximately 2500 labeled cells at day 4 after the transplantation surgery and (b) at day 11 for the same rat as in (a). (c) MR image obtained for the rat brain received approximately 1250 labeled cells at day 4 and (d) at day 11 for the same rat as in (c). Note that the hypo-intensity areas indicating the location of the labeled PC12 cells. The reduction of signal intensity is due to the strong susceptibility effect by the SPIO-based contrast agent Feridex incorporated into the PC12 cells.

the monitoring in cell treatment. The above approach may offer convenient method for studying the distribution and migration of grafted cells in the living system. We expect that MRI tracking of transplanted cells may become a valuable tool for understanding the cellular functions that are key to successful utilization of differentiated stem cells in cell therapy.

Concluding Remarks

Molecular imaging in the future will not merely report on the success or failure of therapy several months after it has been initiated but will play a crucial role in detecting lesions based upon their molecular signatures, will characterize lesions *in situ* to aid in treatment decisions, and will help define successful therapeutic drug levels on an individual basis. The chemical aspect of NMR imaging technology reviewed here shows examples of physiological probes and some example clinical-use paradigms for their implementation into practice. Treatment and screening approaches of number of cancers may benefit in the near future from these tools. In combination with newly emerged bioluminescence and fluorescence imaging techniques targeting specific molecule, an NMR technique, in no doubt, continues to serve as a diagnostic imaging tool in biomedical field.

Electron Spin Resonance Imaging in Polymer Research

Shulamith Schlick

Department of Chemistry and Biochemistry, University of Detroit Mercy, Detroit, Michigan 48221-3038, USA

Introduction

In 1973 Paul Lauterbur proposed the use of magnetic field gradients in order to "tell exactly where an NMR signal came from" [1]. The name he coined for the technique, *zeutmatography*, is derived from the Greek word for "joining together": to join the magnetic field gradient and the corresponding radiofrequency in a nuclear magnetic resonance (NMR) experiment. This connection allowed the encoding of spatial information in NMR spectra. The use of magnetic field gradients to separate the resonant frequencies corresponding to different spatial slices led to the development of NMR imaging (NMRI) or, in current language, magnetic resonance imaging (MRI). In the last 25 years, NMRI has blossomed into an essential diagnostic procedure in medicine that provides clear images of previously hidden anatomic parts. Applications of NMRI to Materials Science and other important disciplines, although not as dramatic as the medical applications, are steadily developing [2]. The wonderful story on the discovery of NMRI has been told recently [3].

Imaging based on magnetic field gradients has also been applied to imaging of unpaired electron spins via electron spin resonance (ESR) spectroscopy. The advantages of ESR imaging (ESRI) are the specificity for the detection of paramagnetic species, and the high sensitivity. Papers describing the feasibility of ESRI started to appear in the late 1970s and continue to this day. Early instrumentation, software, and applications of ESRI have been described in a 1991 monograph [4]. Numerous challenges stand in the application of the Lauterbur method to ESRI: First, higher gradients are needed compared to NMRI, usually 100–1000 times larger. Second, ESR spectra are often complex and contain hyperfine splittings that complicate the ESRI experiments. Third, most systems do not contain stable paramagnetic species on which imaging is based; contrast in ESRI is usually provided by radicals produced by irradiation, paramagnetic transition metal ions, or stable nitroxide radicals as dopants.

As seen in the 1991 monograph, the early efforts laid the foundation for the hardware necessary for ESRI and the software necessary for image reconstruction in 1D (spatial) and 2D (spectral-spatial and spatial-spatial). These studies also investigated the feasibility of ESRI experiments in a variety of "phantom" samples, and discussed and estimated the spatial resolution. Typical resolution in ESRI experiments is of the order of 50–80 μm, but can vary widely, depending on the ESR line shapes and line widths.

Information on the spatial distribution of paramagnetic molecules deduced from ESRI experiments has been used successfully for measuring translational diffusion. Diffusion coefficients of paramagnetic diffusants can be deduced from an analysis of the time dependence of concentration profiles along the diffusion direction. Determination of diffusion coefficients for spin probes in liquid crystals and model membranes, and the effect of polymer and probe polydispersity, have been described in a series of papers by Freed and coworkers [5]. These papers represented an effort to move beyond phantoms, and to extract quantitative information from ESRI experiments.

The ability to perform ESRI is restricted to a small number of groups worldwide. While most groups study biological applications of ESRI [6–8], a small number of studies on polymeric materials have appeared: Diffusion coefficients of guests in ion-containing polymers, polymer solutions, crosslinked polymers swollen by solvents, and in self-assembled polymeric surfactants have been determined by 1D ESRI [9–12]. Lucarini *et al.* have determined by 1D ESRI the distribution of the nitroxide radicals in UV-irradiated polypropylene (PP) containing a hindered amine stabilizer (HAS) [13,14]. Ahn *et al.* have deduced the concentration profile of heat-induced radicals in a polyimide resin [15]. *In vitro* degradation of poly(ortho esters) containing 30 mol% lactic acid has been studied by 1D and 2D spectral-spatial ESRI, based on pH-sensitive nitroxide spin probes [16]. Spatially resolved degradation in heterophasic polymer systems, such as poly(acrylonitrile-butadiene-styrene) (ABS) and heterophasic ethylene-propylene copolymers (HPEC), has been described in a series of recent papers [17–25]; details on some of these studies will be described in Section 3 of this Chapter.

ESR Spectra in the Presence of Field Gradients

ESR spectroscopy can be transformed into an imaging method for samples containing unpaired electron spins, if ESR spectra are measured in the presence of magnetic field gradients. In an ESRI experiment the microwave

Graham A. Webb (ed.), Modern Magnetic Resonance, 179–185.

© 2008 *Springer.*

power is absorbed by the unpaired electrons located at coordinate x when the resonance condition, Equation (1), is fulfilled.

$$\nu = (g\beta_e/h)(H_{\text{res}} + xG_x) \qquad (1)$$

In Equation (1) G_x is the linear magnetic field gradient (in G/cm) at x. As in NMRI, the field gradients produce a correspondence between the location x and the resonant magnetic field H_{res}. For a sample consisting of two capillary tubes, the distance between the tubes along the gradient direction can be deduced if the field gradient is known [14b].

The spatial resolution, Δx, is an important parameter in imaging, and can de defined in various ways, as discussed recently [26];the resolution depends on the line width and line shape. Most commonly Δx is expressed as the ratio of the line width to the field gradient, $\Delta H/G_x$; this definition implies that two signals separated by one line width due to the field gradient can be resolved.

An ESRI system can be built with small modifications of commercial spectrometers: gradient coils fixed on the poles of the spectrometer magnet, regulated DC power supplies, and required computer connections. In most systems the software for image reconstruction in 1D and 2D ESRI experiments must be developed on site. Bruker Biospin Inc. has recently commercialized X- and L-band ESR imagers.

Intensity Profiling from 1D ESRI

In the general case, the sample contains a distribution of paramagnetic centers along a given direction, for example x. The ESR spectrum in the presence of the magnetic field gradient is a superposition of signals from paramagnetic centers located at different positions. In 1D ESRI experiments, the intensity profile is obtained from two ESR spectra: $F_0(H)$ measured in the absence of magnetic field gradient, and $F(H)$ measured in the presence of the gradient (the "1D image"). Figure 1 presents the ESR spectrum at 340 K of a nitroxide radical in a HPEC plaque of thickness ≈3 mm: in the absence (top) and in the presence (bottom) of a magnetic field gradient. The intensity (concentration) profile is then determined by deconvolution, as described below.

Mathematically, $F(H)$ is a convolution of $F_0(H)$ with the distribution function of the paramagnetic centers [4,24], Equation (2),

$$F(H) = \int_{-\infty}^{\infty} F_0(H - H^*)\,C(H^*)\,\mathrm{d}H^*, \qquad (2)$$

where $H^* = H_0 - xG$, $H_0 = \mathrm{h}\nu/g\beta_e$, and $C(H^*)$ is the intensity distribution (profile) of the paramagnetic centers along the gradient direction. The convolution expressed in Equation (2) is correct only if the ESR line shape *has no spatial dependence.* This requirement has dictated the conditions for data acquisition in the 1D ESRI study of degradation processes described in Section 3 [17–22].

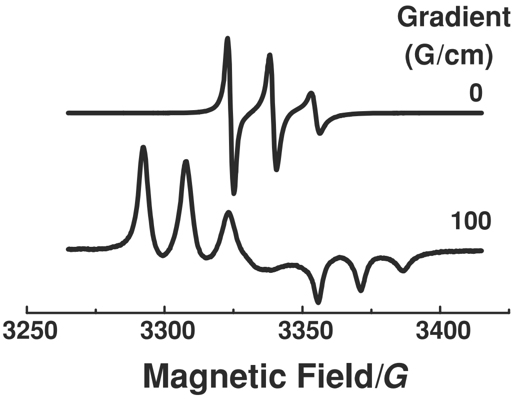

Fig. 1. X-band ESR spectrum at 340 K of HAS-derived nitroxide radicals in a HPEC plaque of thickness ≈3 mm: in the absence (top) and in the presence (bottom) of a magnetic field gradient.

Various optimization methods are viable alternatives to deconvolution. The process starts by assuming an initial distribution, which can be described by a set of parameters. In diffusion studies, for example, the initial distribution is calculated as a function of the diffusion coefficient, diffusion time, and other parameters that define sample configuration [9–12]. Optimization methods use the convolution of this initial distribution function with the experimental spectrum in the absence of magnetic field gradient in order to calculate the spectrum in the presence of the gradient. The deviation between the calculated and the experimental spectra is then minimized by an optimization procedure. In our initial ESRI studies, the concentration profiles of the radicals were deduced by Fourier transform followed by optimization with the Monte Carlo (MC) procedure [13,14,17–20]. The disadvantage of this method is the high-frequency noise present in the optimized profiles. In following publications, the intensity profile was fitted by analytical functions and convoluted with the ESR spectrum measured in the absence of the field gradient in order to simulate the 1D image. The best fit was obtained by variation of the type and parameters of the analytical functions chosen (Gauss or Boltzmann, for example) in order to obtain good agreement with the 1D image, and selected by visual inspection [21,22,24]. Lately the genetic algorithm (GA) for minimization of the difference between simulated and experimental 1D images was implemented; this procedure allowed the best fit to be chosen automatically [23,25]. A typical GA consists of creation of the initial population, calculation of the fit to experimental data, selection of the couples, crossover (reproduction) and mutation. The approach and terminology are adopted from biology and resemble fundamental steps in evolution.

Line Shape Profiling from 2D Spectral-Spatial ESRI

Each 2D image is reconstructed from a complete set of projections, collected as a function of the magnetic field gradient, using a convoluted back-projection algorithm [24]. The number of points for each projection (usually 1024) is kept constant. The maximum experimentally accessible projection angle, $\alpha_{\max}$, depends on the maximum gradient $G_{\max}$ according to $\tan\alpha_{\max} = (L/\Delta H)\, G_{\max}$, where L is the sample length, and ΔH is the spectral width. The maximum sweep width is $\mathrm{SW}_{\max} = \sqrt{2\Delta H/\cos\alpha_{\max}}$. For a width $\Delta H \approx 65$ G (which is typical for the slow-motional component of a nitroxide radical), a sample depth of 3–4 mm, and a maximum field gradient of 250 G/cm along the vertical axis, $\alpha_{\max} = 57^{\circ}$ and $\mathrm{SW}_{\max} = 169$ G. A complete set of data for one image consists of 64–128 projections, taken for gradients corresponding to equally spaced increments of α in the range -90–$+90^{\circ}$; of these projections, typically 41 or 43 (out of 64) are experimentally accessible projections and the rest are projections at missing angles (for α in the intervals 60–90°, and -60° to -90°). The projections at the missing angles can be assumed to be the same as those at the maximum experimentally accessible angle $\alpha_{\max}$, or determined by the projection slice algorithm (PSA) with several iterations [4,17–26].

Spatially-Resolved Degradation from ESRI Experiments

Oxidative degradation of polymeric materials can be viewed on the molecular level as a cascade of events triggered by chemically reactive molecules such as free radicals (R, RO,·and ROO·), and hydroperoxides (ROOH). Modification of polymer properties due to exposure to environmental factors is both on the molecular and macroscopic levels: change of the chemical structure (double bonds formation, chain scission, and crosslinking), and deterioration of mechanical properties. Accelerated degradation is often performed in the laboratory, and the results are interpreted in terms of polymer lifetimes in actual applications [27,28].

Recent advances in the understanding of degradation processes are anchored on the finding that polymer degradation is often spatially heterogeneous. When the rate of oxygen diffusion is not sufficient to supply all the oxygen that can be consumed, only outside layers in contact with oxygen are degraded, whereas the sample interior is protected: this is the diffusion-limited oxidation (DLO) regime [29]. The DLO concept implies that in order to understand degradation and predict lifetimes of polymeric materials in different environments, it is necessary to develop spatially resolved methods for the study of the extent of degradation within sample depth.

Recent studies of photo- and thermal degradation in ABS (Chart 1) and HPEC have demonstrated that one-dimensional (1D) and two-dimensional (2D)

Chart 1

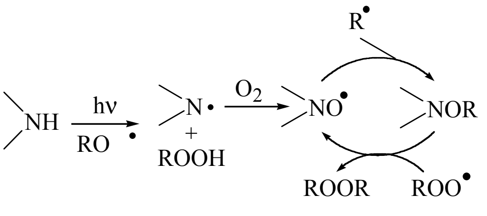
spectral-spatial ESRI can provide details on the extent of degradation as a function of depth and in different morphological domains [14b,17–25]. This approach will be illustrated here for thermally treated ABS [21,22].

ABS polymers are complex, multiphase materials consisting of a butadiene (B) core to which a copolymer of styrene (S) and acrylonitrile (AN) has been grafted [30,31]. The SAN-rich phase is normally continuous, and the size of the B-rich ("rubber") domains is ≤ 1 μm in emulsion polymerization, and 0.5–5 μm in mass polymerization. The ESRI approach was applied to ABS because it represents a polymer that is exceptionally important in technological applications, yet is also vulnerable to thermal and photodegradation, and can be used only in the presence of protecting additives. Hindered amine stabilizers (HAS), for instance bis(2,2,6,6-tetramethyl-4-piperidinyl) sebacate (Tinuvin 770, Chart 1), are added for stabilization of polymeric materials [32,33]. The HAS-derived nitroxides are thermally stable, but can react with free radicals (as scavengers) to yield diamagnetic species; the hydroxylamines can regenerate the original amine, thus resulting in an efficient protective effect. Scheme 1 presents some of the chemical processes involving HAS during exposure to radiation and oxygen.

The HAS-derived nitroxides in the ABS and in the HPEC studied by ESRI perform, however, a triple role. First, they provide the contrast necessary in imaging experiments; second, they probe the morphology of the system, in terms of glass transition characteristics and dynamics; and third, they reflect the degradation process. Once ESRI data are collected and transformed into intensity profile (from 1D ESRI) and spectra as a function of sample depth (from 2D ESRI), the remaining challenge is to translate information extracted from ESRI into details on degradation kinetics and mechanism. Nitroxide radicals reflect not only the spatial extent of degradation, but also events that occur in different morphological domains: In recent studies of ABS polymers, 1D and 2D spectral-spatial ESRI images have enabled the visualization of the selective damage, along the sample depth, in B-rich domains, compared to acrylonitrile/styrene (SAN)-rich domains. Most ESRI experiments were performed on ABS containing ≈10 %B (Magnum 342 EZ, from Dow Chemical Company), doped with 2% wt Tinuvin 770 (Chart 1).



Scheme 1. The Chemistry of Hindered amine stabilizer.

The notation is ABS2H. After treatment, cylindrical samples 3–4 mm in diameter were cut from the plaques; the samples were placed vertically in the ESR resonator, with the symmetry axis along the field gradient.

Typical X-band ESR spectrum at 300 K of HAS-NO in ABS thermally treated at 393 K is presented in Figure 2, and consists of a superposition of two components, from nitroxide radicals differing in their mobility: a "fast" component (F, width ≈32 G), and a "slow" component (S, width ≈64 G). These spectra indicated the presence of HAS-NO radicals in two different environments, and were assigned to nitroxides located respectively in low-T_g domains dominated by B sequences ($T_g \approx 200$ K), and in high-T_g domains dominated by S ($T_g \approx 370$ K) or AN sequences ($T_g \approx 360$ K). By simulation of the fast component and subtraction from the composite spectrum it was possible to reproduce all composite spectra and to determine the relative concentration of the F and S components. The decrease of the relative intensity of F with irradiation or heating time was explained by the consumption of the HAS-derived nitroxide radicals located in B-rich domains of the polymer, which are more vulnerable to degradation [17–20].

The presence of the two spectral components, F and S, is due to the heterophasic nature of ABS. The variation of the F/S ratio with treatment time is, however, due to chemical reactions; in this way a connection was established between the concentration and ESR line shapes of the nitroxides, and the degradation process.

The concentration profiles for the indicated time of thermal treatment at 393 K are shown in Figure 3; the profiles were deduced by simulation of 1D ESR images measured at 240 K. All profiles on the right side are presented with the same maximum height; the profiles on the left are given for one side of the samples (because of symmetry), and normalized by the nitroxide concentration measured

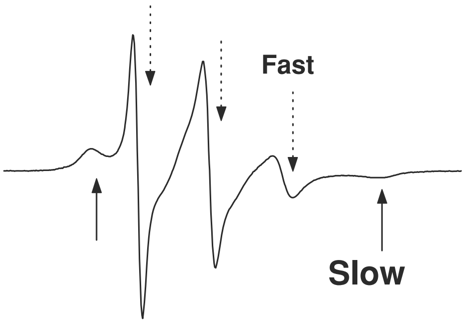


Fig. 2. X-band ESR spectrum at 300 K of HAS-derived nitroxide radicals in heterophasic ABS. Fast and slow components are indicated (see text). The extreme separation of the S component is ≈64 G.

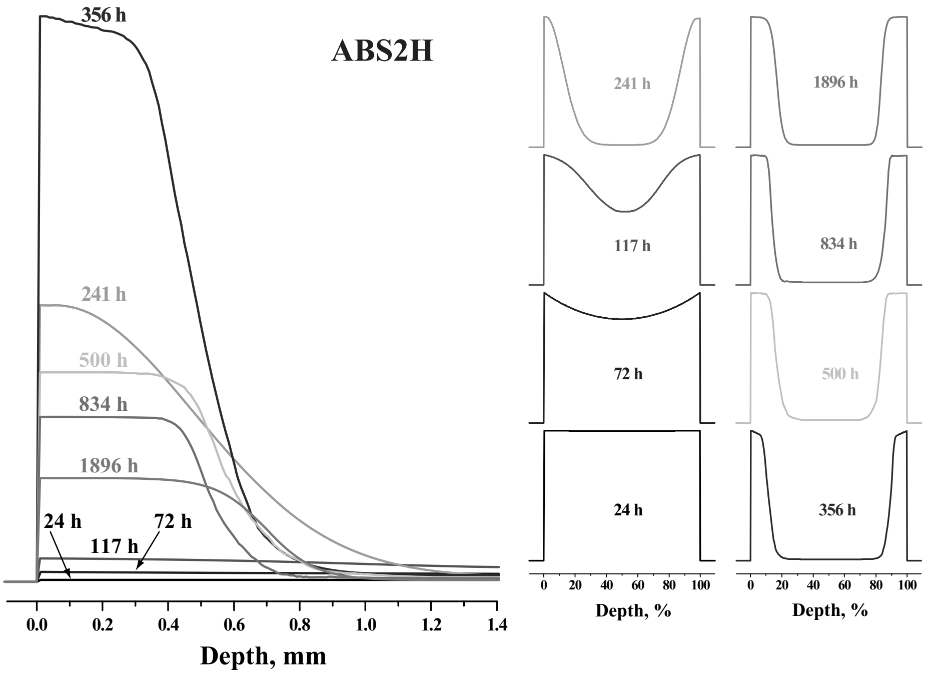

Fig. 3. Right: 1D concentration profiles in ABS2H for the indicated treatment time at 393 K. Left: 1D concentration profiles normalized to the measured total nitroxide concentration; only one side of each (symmetrical) profile is shown (see text).

in whole samples. The evolution from flat profiles in the initial stages of thermal ageing to spatially heterogeneous profiles due to DLO is clearly seen in Figure 3. The 1D profiles indicate that the HAS-derived nitroxides are located at the two sample extremities, in regions of widths is 500–600 μm in ABS2H.

Figure 4 presents 2D spectral-spatial perspective and contour images of nitroxide radicals in ABS2H that has been thermally treated at 393 K for 241 h (left) and 834 h (right). The ESR intensity is presented in absorption mode. Corresponding "virtual" spectral slices obtained nondestructively allowed the determination of the F component (in the B-rich phase) at different depths of the sample: the spectral profile. Figure 5 presents spectral profiles deduced from 2D spectral-spatial ESRI. The evolution of %F along the sample depth is shown as a function of treatment time ($t = 72$, 241 and 834 h), and reflects the nitroxide radicals located in the B-rich domains. The profiles presented in Figure 5 can also be considered as *elastomer profiles*: a look into spatial changes in the elastomeric properties of ABS as degradation progresses. Conclusions from the ESRI experiments were substantiated by attenuated total reflectance (ATR) FTIR spectroscopy of microtomed samples of the polymer [34].

In conclusion, results from ESR imaging, together with the determination of the nitroxide concentration, allowed the mapping of the temporal and spatial variation of the nitroxides, depending on the time and temperature of the treatment. Moreover, the nondestructive ESRI method is sensitive to early stages in the degradation process, and is expected to be complementary to existing profiling methods, for instance FTIR, which are normally applied to more advanced stages of degradation. Finally, the ESRI is of special interest for the study of polymers with phase-separated morphologies. In ABS and HPEC systems, ESRI studies have demonstrated a hierarchical variation of the HAS-derived nitroxide concentration: within the sample depth on the scale of mm, and within morphological domains on the scale of a few μm.

NMR Imaging: Monitoring of Swelling of Environmental Sensitive Hydrogels

Hydrogels

Cross-linked hydrophilic polymers immersed in water can uptake the water. They swell and form hydrogels. The improved performance of hydrogels in biological systems is strongly associated with the water content in the polymeric system. The swelling process is critical to technology areas such as chemical industry (separation matrices), medicine and medical care (gels for cell culture, soft contact lenses, and drug delivery), sanitary products (superabsorbent gels), farming and agriculture (superabsorbend polymer—mixed soil), electric and electronic industries (electrolyte gel), and sensors (fixation of enzymes onto gel) [1]. The kinetic of swelling determines time-constants of the processes using the uptake or loss of swelling agent. The water transport mechanism into the polymer is particularly important for assessing the suitability of hydrogels as drug delivery and drug release systems, as the amount of released drug is dependent on the rate and the transport mechanism of water diffusing into the gel.

Environmental sensitive or "smart" hydrogels are able to change their volume by more than one magnitude in response to different sensitivities such as temperature, pH value, light, ion, and substance concentrations. Therefore, an enormous importance for many technological and scientific applications was expected [2]. The swelling/shrinking of an environmental (or stimuli) sensitive hydrogel starts, if conditions for a volume phase transition, e.g. volume phase transition temperature, mixing ratio of water with a hydrophobic agent like organic solvents, are fulfilled. The swelling/shrinking is connected with a strange change in mobility of the net chains.

Swelling Process

The kinetics of diffusion in polymers ranges from simple Fickian diffusion to high-order diffusion. As proposed by Alfrey *et al*. [3], three models based on the relative rates of penetrant diffusion and relaxation of polymer chain can describe it. In the Fickian (or case I) diffusion, the diffusion is significantly slower than the rate of relaxation of the polymer chains. If the rate of penetrant diffusion is higher than the relaxation rate of the polymer chains a case II diffusion occurs. In a case III or anomalous diffusion, the rates of penetrant diffusion and chain relaxation are comparable.

A variety of techniques to monitor the swelling/shrinking process are known. The easiest and most utilized are based on the determination of the degree of swelling in dependence of time. A partial differential equation describes the swelling for a given geometry [4]. D_{coop}, an apparent cooperative diffusion coefficient associated with long-range diffusion processes involving the cooperative motion of several solute molecules, determines the swelling time. By dynamic light scattering on a swollen gel, it is possible to measure D_{coop} directly [5]. However, since such measurements were performed at a macroscopic level, only little information has been obtained relating to properties of solvent inside the polymeric matrix and the mechanisms of the processes that control the diffusion. Mostly, a network shows varied types of non-regular structures, e.g. distribution of cross-linking density, which influence swelling degree and swell kinetic.

Advantages of NMR Imaging and Application on Network Characterization

NMR methods are a powerful tool for investigation of structure and dynamic in polymer gels [6,7]. NMR relaxation, esp. the dipolar relaxation in fluctuating fields of neighboring spin moments, and model calculations give information about cross-linking density and net chain mobility [8]. NMR spectroscopy and NMR relaxation can be performed as imaging measurements (NMR imaging, NMR microscopy).

This allows a lot of further possibilities, like visualization of non-homogeneities, anisotropy effects, and surface and interface effects [9]. The application of NMR imaging techniques to solid materials have been most rapid in the field of elastomers because of their high chain mobility at moderate temperatures (see review [10]). In the past years, a lot of research work was done concerning the application of NMR imaging on swollen polymers. It can be used to monitor the transport of solvent into

Graham A. Webb (ed.), Modern Magnetic Resonance, 187–193.
© 2008 *Springer.*

solid systems in real time [11], e.g. the shrinking of a poly(methacrylic acid) (PMAA) gel under the application of a d.c. field [12]. It provides information relating to the nature of the diffusion process into a gel on a spatially resolved level with a lateral resolution of about 10–100 μm. An instantaneous diffusion coefficient can be calculated from a single image taken at a specific time. The spatial distributions of low molecular weight components throughout the gel, e.g. profiles of water concentration within different cross-linked hydrogels [13], e.g. distributions of water molecules in PMAA gel under an a.c. field [14], are measurable.

The swelling degree is strongly connected with the cross-linking density. Non-homogeneity in cross-linking density is detectable by measuring a spatial resolved swelling degree within a gel. Some of the water swellable polymers have a low glass transition temperature T_g. By sorption of a solvent, in this case the solvent acts as a plasticizer, T_g decreases. This gives the possibility to monitor the transport of a solvent during swelling by following the change in mobility of the net chain at different places inside the sample.

Combining of NMR imaging with NMR spectroscopic techniques allows both, a quantitative description of the kinetics and mechanism of swelling process and also an insight into the nature of water–polymer interaction. The last could be of great interest in case of application of hydrogels as drug release and drug delivery systems. Fundamental research on hydrogels by means of NMR techniques has been reviewed in reference [15]. Summarizing, NMR imaging gives possibilities to follow time and space resolved a change in concentration of diffused species and, therefore, to collect data to calculate diffusion coefficients, to measure influences on the net chain mobility, and to detect changes in chemical composition due to transport processes. NMR techniques are powerful means of studying dynamics of complicated systems with mobile components such as smart gels and their response process by an application of environmental stimulus.

Experimental

An image delivering MR-measurement consists of two steps in principle: At first the desired effect or contrast (e.g. self-diffusion or relaxation) will be prepared. In a second step, the frequency axis (Larmor frequency) is converted into the space axis by application of an additional gradient field G in direction of the desired profile. For a three dimensional spatial resolution, it can be done in each local dimension x, y, and z:

$$\omega_{\mathrm{L}x(y,z)} = \gamma(B_0 + G_{x(y,z)}) \tag{1}$$

where B_0 is the static magnetic field, γ is the gyromagnetic ratio, and $\omega_{\mathrm{L}x}$ is the resonance frequency of the spin at place x [16].

The spatial resolution Δr depends on the gradient power and the width of the NMR resonance line $\Delta\omega$ of the observed system:

$$\Delta r = \frac{\Delta\omega}{\gamma\,|G_x|} \tag{2}$$

Cross-linked macromolecules show line widths of 0.1–2.0 kHz in dependence on the degree of swelling, solvent molecules of only a few Hz. At a gradient power of 500 mT/m this gives a resolution of about 50 μm, in the case of restricted diffusion of a few μm.

The self-diffusion can be prepared by the Stejskal–Tanner experiment [17]. During the echo time (T_E) of a spin echo two additional magnetic field gradients of strength g and duration δ are switched on at t and $t + \Delta$. Besides the spin-lattice relaxation the displacements of molecules caused by diffusion (D) during Δ lead to an incomplete refocusing of the magnetization of the observed nuclei and an attenuation of the echo S (for details see Figure 1)

$$S(g, \Delta, D) = S_0 \exp\{-\gamma^2 g^2 \delta^2 (\Delta - \delta/3) D\} \tag{3}$$

Higher rates of diffusion strongly weaken the signals. So it is possible to investigate diffusion indirectly by a multiple measurement of echoes influenced by a series of growing/decreasing field gradients.

A further example of the imaging effect is the T_2-contrast of swelling experiments, which can be encoded by a series of spin-echoes with different echo times (Figure 2). The contrast roughly scales the microscopic molecular mobility [18].

Not in any case the echo decay is an (one-) exponential decay. Very often a non-exponential part at the beginning of the relaxation curve can be observed, providing important information on the material, like the anisotropy of molecular motion, which can be a measure for the cross-linking density of a polymer [8].

The spatial information is detected in the second part of the imaging experiment by using a field gradient additionally to the static field B_0. The item “second part” does not mean that the spatial resolution is detected after the contrast preparation in any case. In practice, very often the pulse sequences detect the contrast and the local features during the same echo cycle.

Three-dimensional spatial resolution is done by using three orthogonal gradients, a 2D or 1D (profile imaging) by two or one gradient(s), respectively.

Two basic principles of sampling the spatial information are used:

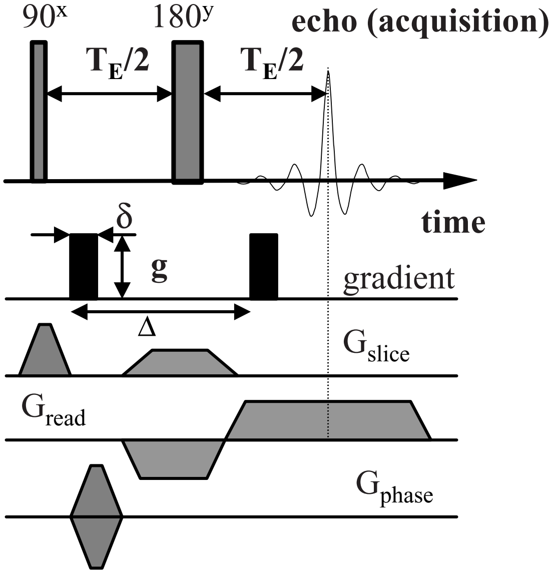

Fig. 1. NMR sequence for diffusion weighted imaging. The upper part agrees with the pulsed experiment of Stejskal and Tanner. The amplitude of the signal is coded in dependence on the diffusion coefficient by two gradients (δ, g) in a time difference Δ because only stationary spins refocus with the original echo amplitude. The lower part shows the magnetic field gradients for coding the coordinates in space (Fourier imaging). $G_{(\mathrm{index})}$ are different field gradients. The read out-, phase-, and slice-gradients normally match the x-, y-, and z-direction of the object.

- Fourier imaging (FI) with a Cartesian sampling of the k-space ($k = 2\pi/\lambda$) and
- (filtered) Back Projection (fBP) with a spherical sampling of the k-space.

The advantage of the FI is the simple calculation of the images by Fourier-transformation. The disadvantage may show up in the higher demands on the technical realization, including gradient rising times of only 1–3 μs, which are needed for the measurement of systems with very short relaxation times, typical of more solid like systems like strongly cross-linked macromolecules.

In opposite to the FI, the gradients of fBP-sequence stay constant during the whole echo pulse sequence until the next projection angle. However, fBP-sequences have more difficulties in the image calculation. The filtering process and the transformation from spherical to Cartesian coordinates are very sensitive to artifacts.

All discussed experiments were done with a VARIAN unity 200 MHz (wide bore) equipped with a homemade imaging probe of following features:

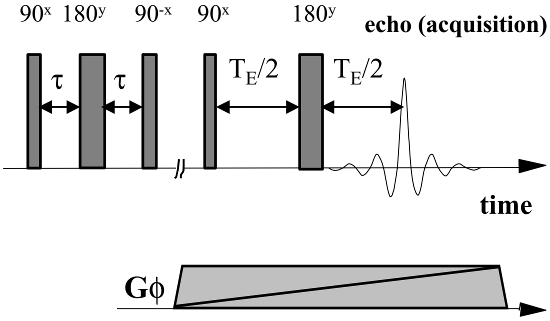

Fig. 2. Spin echo sequence with variable echo time τ for determination of T_2 relaxation curve. The angle of the field-gradient direction with respect to the x-axis is given by $\phi = \arctan(G_y/G_x)$ and is stepped within $0 < \phi < 180°$.

Active shielded design, gradient power up to 50 A (giving a maximum gradient of 5 mT/cm), inner diameter 30 mm, temperature control between 0° and 120°C. Rf-part: resonance frequency 200 MHz (protons) or 67 MHz (deuterium), saddle coil or solenoid (different inner diameters: 5 mm, 7 mm, and 26 mm for the deuterium coil). In case of moderate cross-linked elastomers and gels the resolution is better than 50 μm for ^{1}H-imaging.

The experimental set-up for measurements of concentration profiles along a swelling gel (1D-measurements) are shown in Figure 3a and c. In this case the experiments were done without slice selection, giving a high signal-to-noise ratio in a very short time (<1 min). 2D-measurements with a slice thickness of less than 1 mm

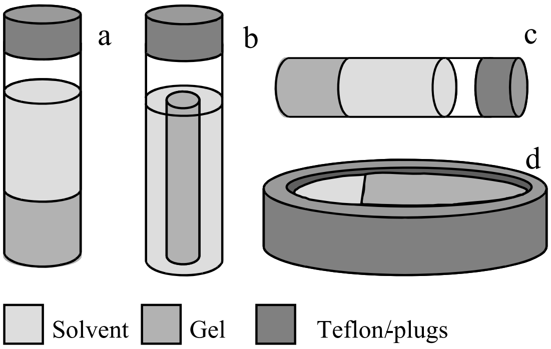

Fig. 3. Experimental set-up for swelling and diffusion experiments on gels. a: vertical arrangement, restricted solvent contact (^{1}H; saddle coil; inner diameter: 7 mm), b: vertical arrangement (^{1}H; saddle coil; inner diameter: 7 mm), c: horizontal arrangement (^{1}H; solenoid; inner diameter: 5 mm), d: vertical arrangement, restricted solvent contact (^{2}D; saddle coil; outer diameter: 30 mm).

are made by an arrangement of the slices perpendicular to the symmetry axis of the coil.

Volume Phase Transition, Net Chain Mobility, and T-Stimulus

An often-investigated T-sensitive polymer is poly(*N*-isopropylacrylamide) (PNIPA). A PNIPA gel undergoes a volume phase transition during heating at about 33 °C, the volume phase transition temperature T_{vpt}. A two-step mechanism is discussed for this transition (isochore conditions). At T_{vpt} the net chains in the swollen gel tend to collapse. They form a macro-network, i.e. bundles of aggregated and stretched polymer chains very fast. A following of this is the reduced mobility of the net chains. Figure 4 shows the 2D Fourier images of PNIPA swollen in D_2O during heating. The signals result from the protons of the net chain. The processes at T_{vpt} causes a reduced T_2 relaxation time and therefore a signal reduction (the color represents the chain mobility), even at a high content of water.

The swelling degree in the first step of the transition process is constant. In a second step the de-swelling starts. The time-constant τ_{swell} to reach the new equilibrium degree of swelling depends on the cooperative diffusion coefficient ($D_{\text{coop}} \approx 10^{-7}$ cm^2/s) and the square of a dimension characterizing the geometry of the gel d^2 (in case of homogeneous gels their macroscopic dimension), $\tau_{\text{swell}} \sim d^2/D_{\text{coop}}$. To follow the whole process of volume phase transition, we investigated the PNIPA gel swollen in H_2O (Figure 5). At $T < T_{\text{vpt}}$ the image contrast represents the T_2-weighted spin density of ^{1}H of the net chains and the self-diffusion and T_2-weighted spin density of ^{1}H of H_2O. At $T > T_{\text{vpt}}$ it represents only the signals of H_2O inside and outside the gel.

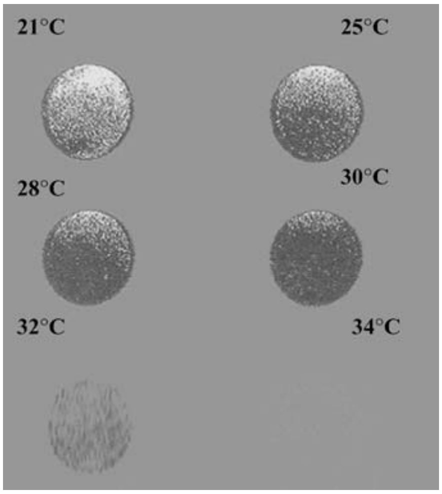

Fig. 4. 2D-^{1}H-Fourier images of PNIPA gel swollen in D_2O at different temperatures. Cross-sections of cylindrical samples (experimental set-up: Figure 3b), contrast from the protons of polymer matrix (T_2-weighted), resolution ca. (30 μm)^2. (See also Plate 19 on page XXV in the Color Plate Section.)

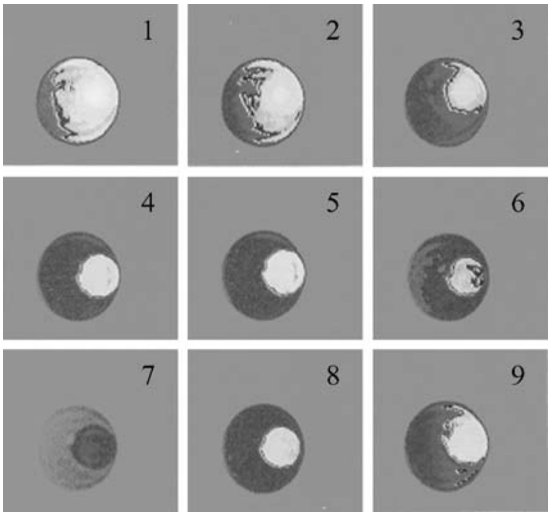

Fig. 5. 2D-^{1}H-Fourier images of PNIPA gel swollen in H_2O at different temperatures and times. 1: 22 °C/0 min, 2: 25 °C/6 min, 3: 30 °C/13 min, 4: 32 °C/16 min, 5: 34 °C/20 min, 6: 40 °C/25 min, 7: 50 °C/50 min, 8: 40 °C/57 min, 9: 30 °C/67 min. The pictures show cross-sections (experimental set-up: Figure 3b) of the immobilized water (contrast mainly from the water protons) inside the polymer matrix (clearly seen as yellow circles in 4, 5, and 8) and of the surrounding free water. 1–4: The signals outside the gel attenuate due to convection during heating. 5: The macro-network formation at T_{vpt} does not influence the signals (as it does at D_2O measurements!). 6: At higher *T* and at longer times structural changes yield to signal attenuation (shortening of T_2, interactions between polymer matrix and water). 7: Polymer matrix is homogeneous. 8,9: Cooling the sample. (See also Plate 20 on page XXV in the Color Plate Section.)

Diffusion of Low Molecular Weight Compounds

Different diffusion processes can occur in a swollen gel. An exchange of the swelling agent inside and outside of the gel is possible. Figure 6 shows the transport of D_2O into a water swollen PNIPA gel ($T < T_{\text{vpt}}$). The signal represents the concentration of D_2O inside the gel in dependence on time.

Under isothermal conditions, the volume phase transition can be achieved by adding an organic solvent to the swelling agent in the surrounding of the gel. The

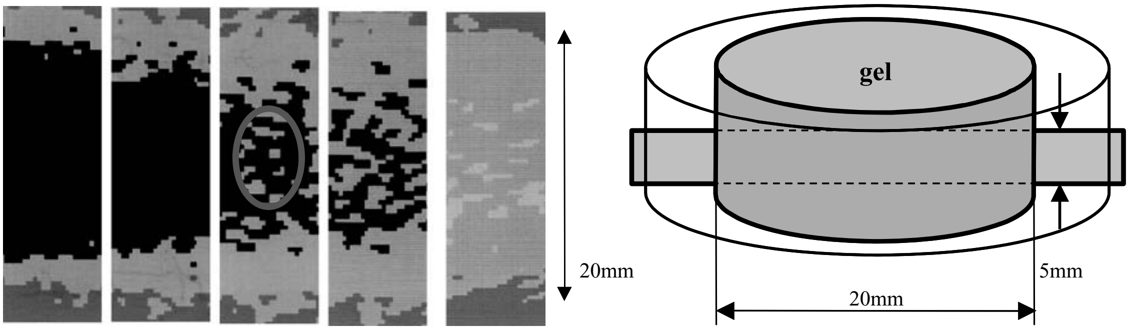

Fig. 6. Diffusion of D_2O into a water swollen PNIPA gel cylinder. Deuterium flash imaging at 20 °C of a thin vertical (5 mm) layer (right); the cylindrical gel (15.5 mm high) is immersed in D_2O. The gel was cross-linked with a high concentration of cross-linker. This results in a non-homogeneous (porous) gel structure, notice the diffusion channels (red ellipse). Time after immersion into D_2O (from left): 2 min, 82 min, 162 min, 212 min, 24 h. (See also Plate 21 on page XXV in the Color Plate Section.)

organic solvent (here methanol) diffuses into the gel. The volume phase transition appears at a given concentration of methanol in the gel (for PNIPA: 20 vol% of methanol in water). The shrinking, which is determined by the cooperative diffusion, starts. The diffusion of partially deuterated methanol (CH_3OD) into the D_2O swollen gel is followed by measuring the change of magnetization in a layer inside the gel of 60 μm thickness at a given distance to the surface [19]. From the time lag between starting the diffusion to the increase of signal due to the raise of CH_3OD D_{MeOD} can be calculated (1D experiment, exp. set-up: Figure 3a). Under the used experimental conditions $D_{MeOD} = (1.8-3.9)\ 10^{-5}$ cm^2/s in dependence of CH_3OD concentration was determined. The same experiment can be performed with H_2O. In this case the self-diffusion coefficient of water inside the gel can be measured ($D_{\text{self}} = 2.3\ 10^{-5}$ cm^2/s).

Distribution of Water Inside the Gel

NMR techniques enable us not only to follow transport processes, but also to visualize the distribution of components inside a gel. Figure 7 gives an example of measuring the distribution of swelling agent, here a mixture of water and partially deuterated methanol, in a gel. The water-swollen gel was immersed in a D_2O/CH_3OD-mixture with such a methanol content (40 vol%) that the volume phase transition occurs. Because the condition for volume phase transition is fulfilled the net chains collapse. A dense layer on the gel surface is formed. This happens at either temperature or solvent induced transitions. In case of a homogeneous gel the layer is thin (skin effect, Figure 7a) and further diffusion is not hindered. But in case of a porous gel a thicker layer of collapsed net chains is formed. It acts as a barrier and prevent shrinking processes (shrinkage barrier [19]). The skin formation is a time-distance problem of different diffusion processes that happen simultaneously: D_{coop} and the typical dimension of the gel determine the time constant for de-swelling. In case of a homogeneous structure, the typical dimension is given by the geometry of the gel. The dimension determining the diffusion in a sponge-like gel (Figure 7c) depends on the geometry of the pores. Now, the shrinking process is faster in comparison with the diffusion of the low molecular weight component.

The shrinkage barrier separates the inner part of the gel from the outer part and prevents a further de-swelling (Figure 7b).

Diffusion Coefficients Inside the Gel—Structure of Non-homogeneous Networks

The diffusion of the swelling agent is influenced by the structure of the gel matrix. An image of the diffusion coefficients inside the gel gives information about the homogeneity of the gel. The Tanner-Stejskal sequence (Figure 1) with different echo-times yields to a series of diffusion weighted images (Figure 8, left shows one image). Using of Equation (3), a reciprocal diffusion coefficient for each pixel can be calculated (Figure 8, right). The signals of the surrounded water are influenced by thermal fluctuation and do not represent a diffusion coefficient.

The temperature-sensitive poly(vinyl methyl ether) (PVME) can be cross-linked by high-energy radiation. A non-homogeneous network is formed at e-beam irradiation of high concentrated aqueous solution [20,21]. Due to absorption of energy the aqueous polymer solution is heated, the volume phase separation occurs and the phase-separated structure is fixed by cross-linking. The gels are sponge-like and show a high response on heating/cooling (the same situation is given, if PNIPA is cross-linked with

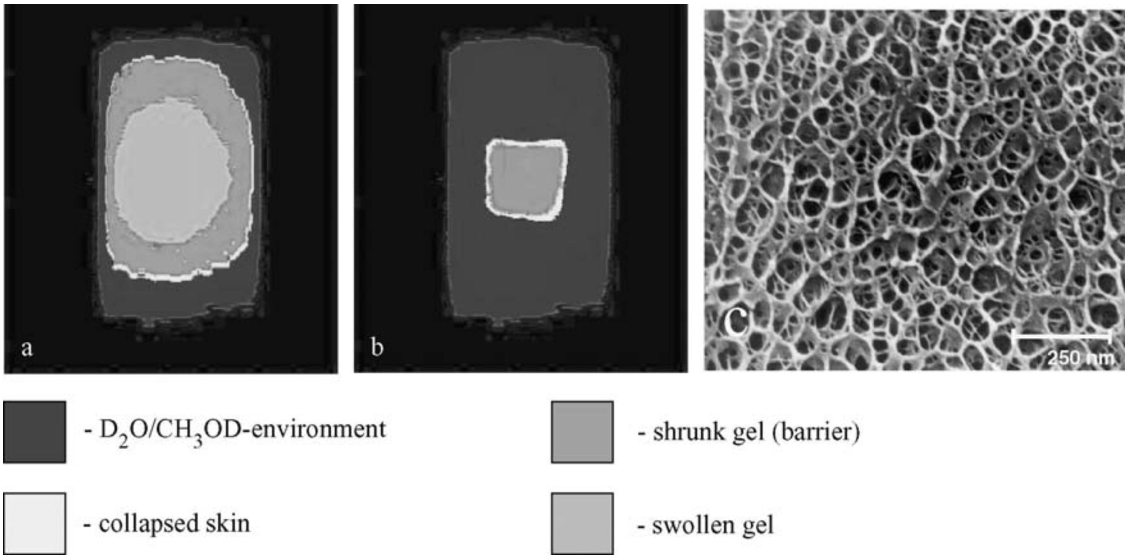

Fig. 7. Distribution of water in collapsed PNIPA gel, de-swelling induced by methanol. Fourier images (slice selection, T_2-weighted) of a vertical plane of PNIPA gels. (a) sponge-like gel after 3 days in D_2O/CH_3OD; (b) homogeneous gel; (c) The FESEM micrograph shows the sponge-like structure of gel b (scale bar: 250 nm). (See also Plate 22 on page XXVI in the Color Plate Section.)

a high concentration of cross-linker, sample Figure 7b). A characterization of such networks with rheological methods is difficult because of its porosity.

The diffusion coefficient of the swelling agent is influenced by the structure of the surrounded gel matrix. The distribution of D (here water) can act as an indirect measure for structural non-homogeneities. Figure 9 shows diffusion images of different PVME gels. The brightness is correlated with a fit parameter d ($\sim 1/D$). The figures illustrate changes in a distribution of d ($\sim 1/D$) with the radiation dose.

With increasing dose the cross-linking density increases and the D decreases. At a dose of 100 kGy the D shows a minimum (Table 1). As mentioned above, at

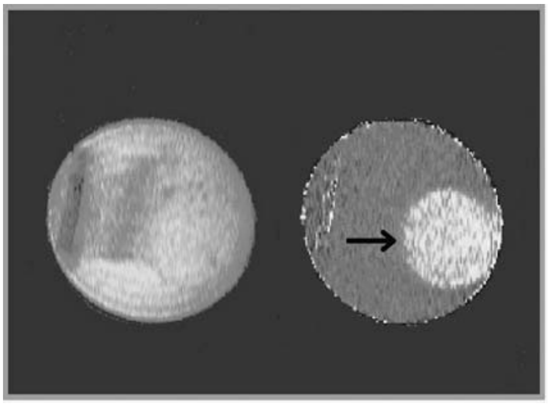

Fig. 8. Determination of diffusion coefficient of water inside a gel. Cross sections of a glass tube (7 mm diameter) containing the cylindrical PNIPA gel (3 mm diameter). Besides the dark strip on the left side (which arises from a piece of Teflon used to fix the gel) no further details can be seen in the diffusion weighted image (left). In the diffusion image (right), the hindered diffusion of water in the gel gives a good contrast to the water outside. Notice, the diffusion is depicted with inverse intensity giving brighter pixels to the gel. A surface layer of stronger diffusion (~0.5 mm) can be observed also (arrow). (See also Plate 23 on page XXVI in the Color Plate Section.)

Table 1: Water diffusion coefficient inside PVME gels with different cross-linking densities (irradiation doses). A calibration of the signal (Figure 9) is necessary to calculate absolute values of D. This was done by means of measurements with pure water at different temperatures

Dose (kGy)	50	75	100	150
$D(H_2O)$ (10^{-5} cm^2/s)	2.1	1.7	1.25	1.65

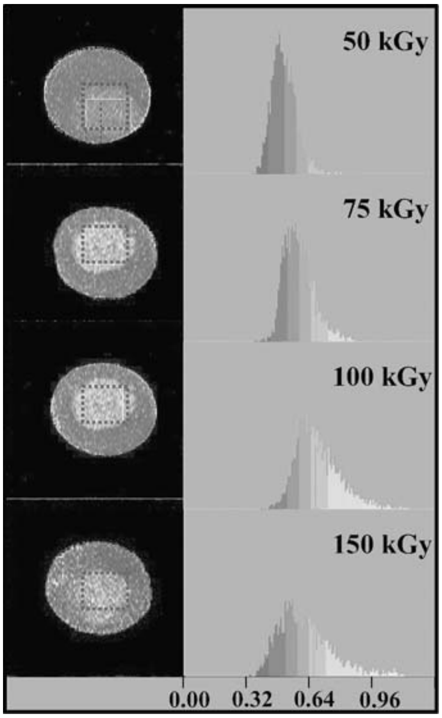

Fig. 9. Influence of cross-linking on D of water and its distribution. Diffusion images (left) of e-beam cross-linked (different doses in kGy) PVME swollen to equilibrium in water at room temperature. To match the Stejskal–Tanner equation (Equation (3)) an one-exponential fit, $I = I_0 \exp(-g^2/d)$, of each data point from at least six diffusion-weighted images of different gradient strength g was performed. The figures show the fit-parameter d. $1/d = \gamma^2\delta^2\left(\Delta - \delta/3\right)D$ (See also Plate 24 on page XXVI in the Color Plate Section.)

higher values of dose due to energy absorption the gels get a sponge-like structure. This results in an increase of *D* and a broader distribution of *D*.

Inorganic Materials and Catalysis

Exploiting $^1H\longrightarrow{}^{29}Si$ Cross-Polarization Features for Structural Characterization of Inorganic Materials

Piotr Tekely
UMR CNRS 7565, Université Henri Poincaré, Nancy I, Vandoeuvre-lès-Nancy, France

Introduction

High-resolution solid state ^{29}Si NMR spectroscopy was frequently used during the last 25 years in structural studies of inorganic materials including zeolites [1–3], minerals [1–3], glasses [3], and cement-based systems [4]. Its important place in structure determination of these materials relies on the fact that ^{29}Si NMR spectra permit a precise determination of the ^{29}Si isotropic chemical shift in different silicon environments of powdered samples. Indeed, for materials with silicon in tetrahedral coordination, the isotropic position of resonance signal provides immediately the degree of condensation of SiO_4 terahedra ($Q^{(n)}$, with $n = 0, 1, 2, 3, 4$) and informs about Si–O–Si bond angles and Si–O bond lengths [1–3]. Although the easiest way to record the quantitative ^{29}Si NMR spectrum is a direct excitation by a single pulse, this cannot be reasonably applied in most cases due to extremely long ^{29}Si longitudinal relaxation times. To avoid this inconvenience, one can take advantage of magnetization transfer from protons to ^{29}Si spins.

In spite of the fact, that when using cross-polarization (CP) procedure, the quantitative proportions of chemically or crystallographically inequivalent sites cannot be reached as with single pulse excitation, an extremely valuable structural and dynamic information can be obtained in this manner. However, to access such information, some basic precautions have to be taken. Indeed, when recording the CP spectra under MAS at spinning frequencies of the same order of magnitude as the dipolar coupling interaction involved in polarization transfer, two complications immediately arise. First, the Hartmann–Hahn (H–H) matching condition is split into several sideband-matching positions (Figure 1a–d).

Consequently, $^1H\rightarrow{}^{29}Si$ CP occurs effectively only when the generalized H–H matching condition $\omega_{1\mathrm{H}} = n\omega_r + \omega_{1\mathrm{Si}}$ with $n = 1, 2, \ldots$ is satisfied. As it is difficult to achieve stable and reproducible results using mismatched H–H CP, because even very small (<0.1%) instability of rf fields may lead to an important loss of intensity of the NMR signal, it may be necessary to render the CP less sensitive to exact matching of the applied radio-frequency field strengths, especially upon higher spinning speeds. The matching condition can be indeed substantially broadened by 180° phase shifts (Figure 1e) or variable-amplitude rf field CP transfer (Figure 1f) and can even trim down the burden of finding and maintaining an exact CP match (Figure 1g). This may be very useful in any experiment involving $^1H\rightarrow{}^{29}Si$ polarization transfer even at modest spinning speed of a few kHz.

Second complication arises from the fact that the CP transfer time may be quite long and even longer than the relaxation time in the rotating frame of protons. This fact must be clearly recognized to avoid a false structural image of investigated materials. In the following, we will first show how one can check the actual CP regime and how the CP dynamics can be exploited to provide subtle structural details including the geometry of strongly hydrogen-bonded silanols.

$^1H\longrightarrow{}^{29}$ Si CP Dynamics: Basic Features and Pitfalls

The CP transfer of magnetization between the abundant I and the rare S spins can be described by the simplified thermodynamic model [5,6] when the average I–I homonuclear dipolar interaction is larger than the I–S heteronuclear dipolar interaction. Assuming that there is no relaxation of the S spins, the NMR signal of these spins, as a function of contact time t_{CP}, can be described by the well-known relationship [6]

$$M_{\mathrm{S}}\left(t_{\mathrm{CP}}\right) = M_{\mathrm{S}}^{\infty}\alpha\frac{\gamma_{\mathrm{I}}}{\gamma_{\mathrm{S}}}\frac{1}{1-\dfrac{T^{\mathrm{IS}}}{T_{1\rho}^{\mathrm{I}}}} \times\left(\exp\left(-\frac{t_{\mathrm{CP}}}{T_{1\rho}^{\mathrm{I}}}\right)-\exp\left(-\frac{t_{\mathrm{CP}}}{T^{\mathrm{IS}}}\right)\right) \quad (1)$$

where M_{S}^{∞} is the equilibrium magnetization of spins S; $\alpha = \omega_{1\mathrm{I}}/\omega_{1\mathrm{S}} = (\gamma_{\mathrm{I}}H_{1\mathrm{I}})/(\gamma_{\mathrm{S}}H_{1\mathrm{S}})$ is the ratio of the radio-frequency fields at the I and S frequencies (the Hartman–Hahn mismatch parameter); $1/T^{\mathrm{IS}}$ is the CP rate, which increases dramatically with the strength of the

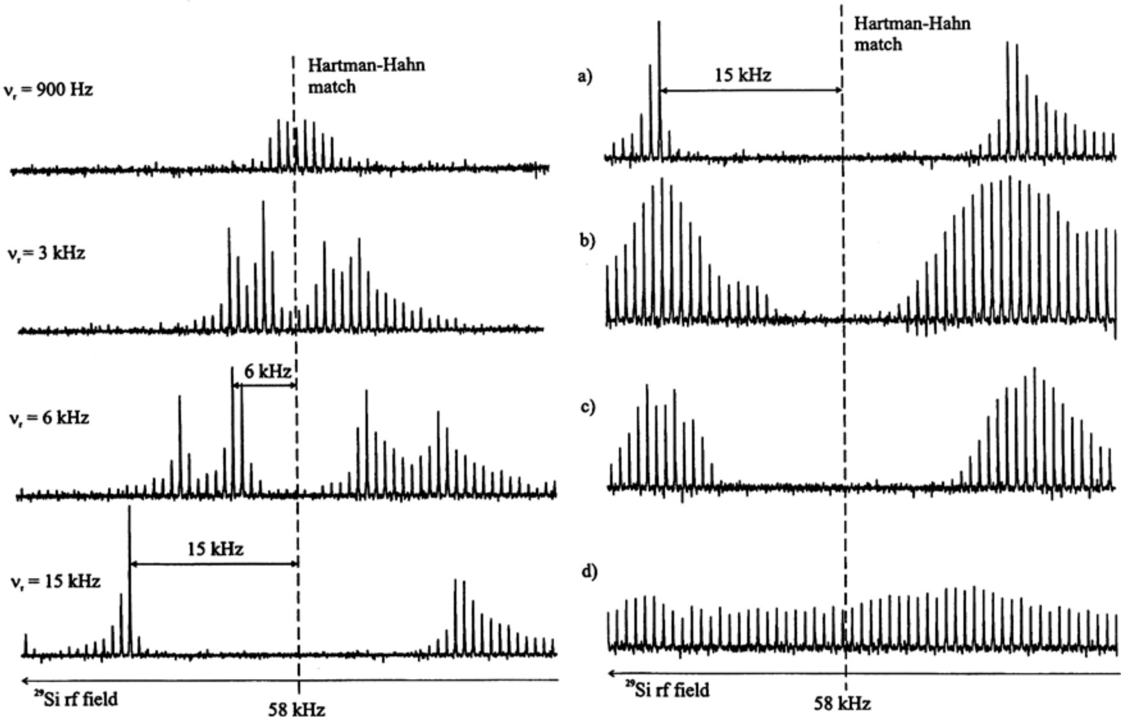

Fig. 1. Hartmann–Hahn (H–H) matching curves for $Q^{(3)}$ site in a layered hydrous silicate at different spinning speeds (left) and at 15 kHz (right). (a) standard CP transfer; (b) phase-inverted (π phase shift every rotor period) ^{29}Si rf irradiation during CP; (c, d) variable-amplitude CP using 15 amplitudes of ^{29} Si rf field increased in steps changing in the range 0.9–1.0 and 0.58–1.0, respectively. The total contact time period was 1 ms in each case.

heteronuclear I–S dipolar interaction but also depends in a complex way on the strength of the homonuclear I–I dipolar interaction, on the correlation time of molecular motions and on the experimental parameters; $T_{1\rho}^{\mathrm{I}}$ is the relaxation time in the rotating frame of the I spins. According to Equation (1), the CP build-up curves are inherently sensitive to internuclear distances via T^{IS} and the presence of mid-kHz motions via $T_{1\rho}^{\mathrm{I}}$, this makes that the dynamics of CP transfer still remain one of the most attractive NMR tools for structural and motional investigation of solids.

As has been pointed out recently [7], the expression (1) is valid not only when $T^{\mathrm{IS}} < T_{1\rho}^{\mathrm{I}}$, the usual condition (fast CP regime), but also holds whatever the ratio $T^{\mathrm{IS}}/T_{1\rho}^{\mathrm{I}}$. NMR CP measurements are usually analyzed assuming that the CP time T^{IS} of magnetization transfer is shorter than the relaxation time $T_{1\rho}^{\mathrm{I}}$. However, the reverse situation (i.e. $T^{\mathrm{IS}} > T_{1\rho}^{\mathrm{I}}$, slow CP regime) can be frequently encountered, especially in inorganic solids where protons are more remote from rare nuclei than in organic systems. In this case, the S spin magnetization will as well begin to rise but this increase cannot proceed further when the I spin system is rapidly depleted by the $T_{1\rho}^{\mathrm{I}}$ relaxation. Consequently, the transfer of magnetization is stopped at a time close to $T_{1\rho}^{\mathrm{I}}$ and there is a reverse flow from the S to I spin system which remains depleted by the faster $T_{1\rho}^{\mathrm{I}}$ relaxation. This reverse flow from the S to the I reservoir occurs, as does the forward one, at the CP rate $1/T^{\mathrm{IS}}$. In such a situation, when analyzing the experimental data under the usual fast CP assumption, an interpretation of both dynamic parameters will be strongly in error. In fact, it is impossible to know from the CP curve alone, whether $T^{\mathrm{IS}} < T_{1\rho}^{\mathrm{I}}$, or $T^{\mathrm{IS}} > T_{1\rho}^{\mathrm{I}}$. This is the consequence of the fact that apart from the intensity factor, Equation (1) is fully symmetrical with respect to the interchange of T^{IS} and $T_{1\rho}^{\mathrm{I}}$.

Contrary to the standard variable-contact CP experiment, a direct visualization of the ratio $T^{\mathrm{IS}}/T_{1\rho}^{\mathrm{I}}$ is easily accessible by using the TORQUE experiment [8]. This experiment has been originally designed with the aim of quenching the I spin $T_{1\rho}^{\mathrm{I}}$ dependence (**T** **O**ne **R**ho **QUE**nching) when studying polarization transfer in solids with $T^{\mathrm{IS}} < T_{1\rho}^{\mathrm{I}}$. It uses a spin lock period on spin I of duration t_{SL} followed by the CP transfer of variable duration t_{CP}, the total time $T_{TORQUE} = t_{CP} + t_{SL}$ being kept constant. The TORQUE signal grows as a function of t_{CP} according to

$$M_S^{TORQUE}(t_{CP}) = \exp\left(-T_{TORQUE}/T^{I}_{1\rho}\right) \times \left(\frac{1 - \exp\left(-(1-\lambda)(t_{CP}/T^{IS})\right)}{(1-\lambda)}\right) \quad (2)$$

with $\lambda = T^{IS}/T^{I}_{1\rho}$. Figure 2 shows the simulations of the temporal evolution of S spin magnetization in a standard CP experiment and in the TORQUE experiment, both in three different situations: (i) $T^{IS} < T^{I}_{1\rho}$; (ii) $T^{IS} > T^{I}_{1\rho}$; (iii) a simple combination of (i) and (ii) cases.

As expected, in the standard CP experiment, beside the differences in the absolute intensity, very similar temporal evolution of magnetization is observed in each case. However, dramatic differences in the curvature of the TORQUE temporal evolution are visible. This allows an unambiguous recognition of the $T^{IS}/T^{I}_{1\rho}$ ratio and assures the proper analysis of dynamic CP parameters in terms of structural and/or motional features. A couple of illustrative examples of such analysis in silica gels and layered hydrous sodium silicates are shown below.

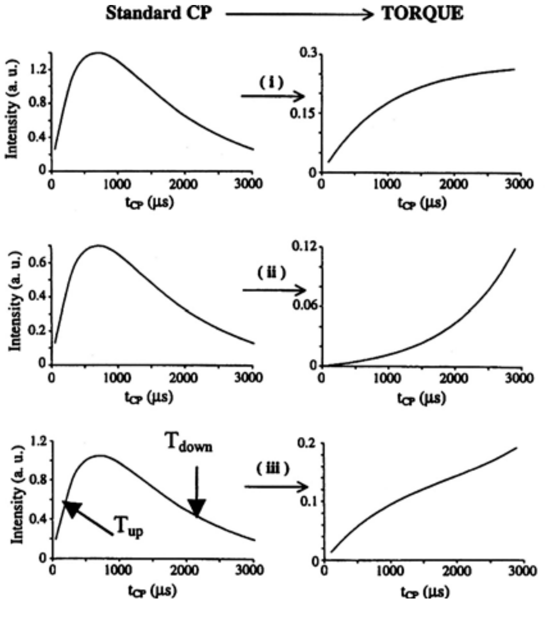

Fig. 2. Magnetization transfer time dependence in standard CP (left) and TORQUE (right) experiments calculated using Equations (1) and (2) with (i) $T^{IS} = 0.5$ ms, $T^{I}_{1\rho} = 1.0$ ms; (ii) $T^{IS} = 1.0$ ms, $T^{I}_{1\rho} = 0.5$ ms; (iii) equally weighted (i) plus (ii) conditions.

Silica Gels

Silica gels are highly porous materials which play an important role in numerous applications such as catalysis or chromatographic separation and have been the subject of much NMR investigations for several years [9]. The high-resolution solid state ^{29}Si CP/MAS NMR spectra of silica gel show three peaks at −91.5, −101, and −110 ppm assigned, respectively, to three $Q^{(2)}$, $Q^{(3)}$, and $Q^{(4)}$ types of silicon environments. The results from the CP, and TORQUE experiments on a Fisher S-157 silica gel sample are presented in Figure 3.

Assuming a simple monoexponential polarization transfer, the results of a fit of three CP curves using Equation (1) are T_{UP} = [2.3, 2.6, 10.3] ms and T_{DOWN} = [10.3, 13.4, 30] ms, for [$Q^{(2)}$, $Q^{(3)}$, $Q^{(4)}$] silicons, respectively. It is also observed that the $T_{1\rho}(^1H)$ relaxation curves are

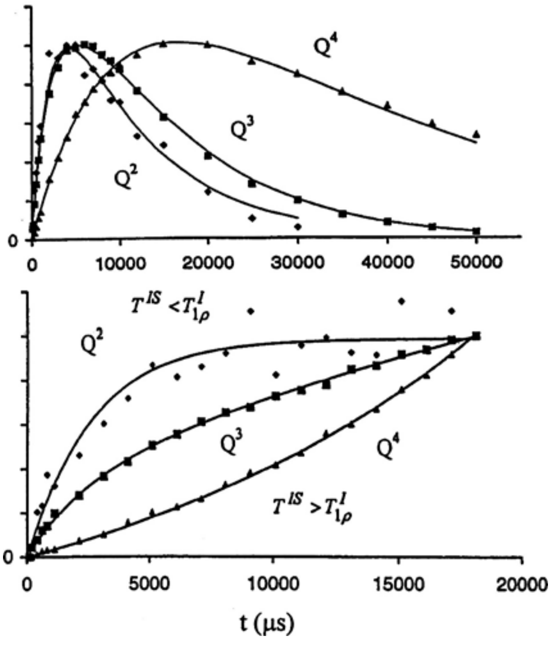

Fig. 3. Time dependence of ^{29}Si magnetization for Q^2 (◆), Q^3 (■), and Q^4 (s) sites of silica gel in the (A) indirect $T_{1\rho}(^1H)$ measurements; (B) TORQUE experiment with a total constant time of 20 ms; (c) standard cross-polarization $^1H \rightarrow ^{29}Si$ experiment. Insert: ^{29}Si CP/MAS spectrum of a silica gel sample (Fisher S-157) showing three peaks assigned to three types of silicon environment.

identical for protons involved in the CP process and give the unique value $T_{1\rho}(^1H) = 10.3 \pm 0.5$ ms. This clearly indicates that the differences observed in the decreasing part of the CP curves do not correspond to different $T_{1\rho}$ of protons involved in the CP transfer on different sites. The value of 10.3 ms is equal to T_{DOWN} for $Q^{(2)}$ and to T_{UP} for $Q^{(4)}$. This suggests that $T^{IS} < T^{I}_{1\rho}$ for $Q^{(2)}$ whereas $T^{IS} > T^{I}_{1\rho}$ holds for $Q^{(4)}$. For $Q^{(2)}$ and $Q^{(4)}$ silicons, these two diametrically opposite situations are visualized immediately by the opposite curvatures of the TORQUE temporal dependence. For $Q^{(3)}$ site, the shape of the TORQUE curve proves the existence of at least two different $Q^{(3)}$ species, first one having $T^{IS} < T^{I}_{1\rho}$, the second one with $T^{IS} > T^{I}_{1\rho}$.

Layered Sodium Hydrous Silicates

This class of materials, available only in microcrystalline form, has a two-dimensional layered structure, the negative charge of the silicate layer being compensated by sodium ions that are coordinated by the oxygen atoms of the intercalated water molecules. Hydrated sodium silicates are of rapidly growing industrial interest due to their high ion- or proton-exchange properties and new applications in catalysis and in the synthesis of composite mesoporous materials. Magadiite, the most frequently researched, has the idealized formula $Na_2Si_{14}O_{29} \cdot nH_2O$ ($n = 8$–10). ^{29}Si MAS NMR studies show the presence of $Q^{(3)}$ and $Q^{(4)}$ silicons in its basic layer structure. The experimental build-up curves obtained from standard CP and TORQUE experiments for $Q^{(3)}$ and Na^+ are shown in Figure 4.

Assuming as usual that $T^{IS} < T^{I}_{1\rho}$, the standard CP curves can be fitted according to Equation (1), each of them being described by two pairs of time constants T_{up} and T_{down} for their rising and decreasing parts, respectively. A simple model for which each site is characterized by a single set of T_{up} and T_{down} values was found to be inadequate. However, the observed curvature in the TORQUE temporal dependence makes it immediately evident that it is essentially the $T^{IS} > T^{I}_{1\rho}$ situation which takes place for $Q^{(3)}$ sites. For Na^+ ions, the situation is even more complex, the TORQUE curve exhibits a pronounced S-shape form which means that both the fast and the slow CP regime are equally relevant for this CP dynamics. From the independent measurements of relaxation in the rotating frames two distinct $T^{I}_{1\rho}$ values have been obtained for protons appearing at 3.8 and 15.2 ppm, respectively. It turns out that these two relaxation times are equal neither to T_{down} nor to T_{up} found in the fitting procedure of CP build-up curves when assuming $T^{IS} < T^{I}_{1\rho}$. As the $T^{I}_{1\rho}$ values reflect two different proton environments existing in magadiite, a realistic model should include both relaxation parameters and assume at least two types of $Q^{(3)}$ as well as sodium sites being differently coupled to hydrogen species. Consequently, the CP and TORQUE build-up curves are each the weighted sums of two different contributions, each one given by Equations (1) and (2) for CP and TORQUE, respectively. A good agreement between experimental and calculated CP and TORQUE temporal dependencies is indeed observed for both species under such assumptions. The fitted T^{IS} and corresponding proportions are given and discussed in structural terms elsewhere [10].

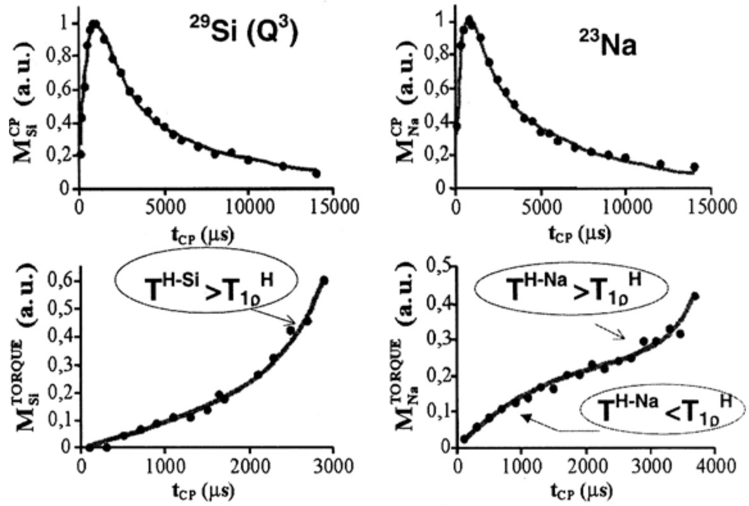

Fig. 4. Temporal evolution of ^{29}Si (left) and ^{23}Na (right) magnetization in the standard CP (top) and TORQUE (bottom) experiments for $Q^{(3)}$ and Na^+ sites of magadiite spinning at 3 kHz. Solid lines correspond to the fitted curves.

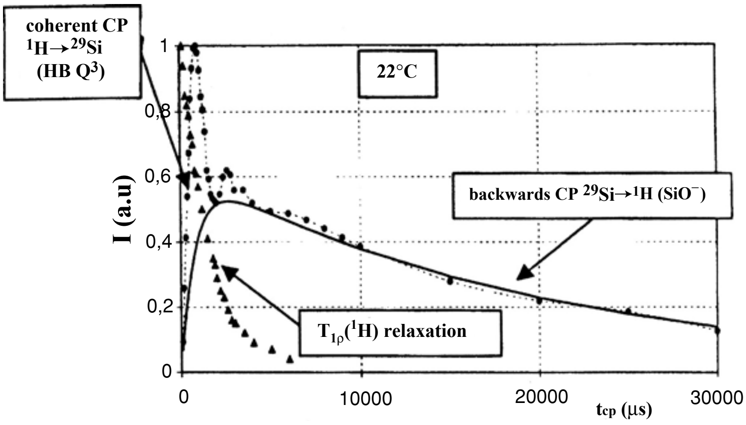

Fig. 5. Temporal evolution of ^{29}Si magnetization for the $Q^{(3)}$ signal during CP and $T_{1\rho}(^1H)$ experiments. All experiments were run with $\omega_{1S} = \omega_{1H} - \omega_r$ Hartmann–Hahn condition and at a spinning frequency of 2.5 kHz. The proton rf power was 62.5 kHz and its carrier frequency was exactly that of hydrogen-bonded protons at 15.98 ppm, though the proton offset corresponding to the water resonance at 3.8 ppm does not lead to any changes in CP dynamics of the nonoscillating component.

The ensemble of fitted dynamic parameters brings evidence that the long time decays of magnetization in the standard CP experiments result from the back flow of magnetization to the proton system.

Very similar situation occurs in the case of layered sodium hydrated octosilicate [11] with the idealized formula $Na_8\{Si_{32}O_{64}(OH)_8\}\cdot 32H_2O$. The experimental CP and indirect $T_{1\rho}(^1H)$ curves of $Q^{(3)}$-type resonance peak are shown in Figure 5.

In this case, an initial CP rapid growth, with an oscillating behavior is followed by long time decay. However, the independent $T_{1\rho}(^1H)$ measurements show a rate of magnetization decay at least one order higher than the observed long time decay. This clearly indicates once again that the observed long time decrease of CP curves is not due to $T^{I}_{1\rho}$ relaxation. Although a single, isotropic $Q^{(3)}$ resonance signal is observed, it is obvious that the CP curves must be interpreted as composed principally of two types of contributions, an oscillating and a nonoscillating component, the first one cross-polarizing under fast CP regime (i.e. $T^{IS} < T^{I}_{1\rho}$), the second evolving under the slow CP regime (i.e. $T^{IS} > T^{I}_{1\rho}$. This implies that, in analogy to magadiite, octosilicate contains two types of structurally different $Q^{(3)}$ silicones present in hydrogen-bonded –Si–O—-H···O–Si– and –Si–O$^-$– type sites having dramatically different abilities to cross-polarize and being sensitive to different mobilities of neighboring hydrous species. In fact, the direct proton $T_{1\rho}$ measurements show that the oscillating component relaxes with the rate of proton signal representing hydrogen-bonded silanols, while the nonoscillating component is mainly influenced by much more rapidly relaxing water molecules. Consequently, the final decrease of the CP curves in Figure 5 can only result from the backwards $^{29}Si \rightarrow ^1H$ flow of the magnetization to the proton reservoir. Unambiguous experimental proof of this is provided by the TORQUE experiment (Figure 6).

Indeed, the TORQUE curve exhibits a clear S-shaped character which according to the discussion above makes it immediately evident that some of $Q^{(3)}$ silicons are coupled to one species of protons under $T^{IS} < T^{I}_{1\rho}$, the others to a second type of protons under $T^{IS} > T^{I}_{1\rho}$. This proves that hydrogen-bonded –Si–O—H···O–Si– and –Si–O$^-$– type sites evolve, respectively, under fast and slow CP regimes.

Finally, it is also worth pointing out that a single set of CSA principal values characterizes both types of $Q^{(3)}$ sites. This means that the ^{29}Si shielding tensor is mainly related to the Si–O bond character (including the lengths and interbond angle differences between terminal and bridging oxygens) in the SiO_4 tetrahedron and is rather insensitive to the presence of protons in the second sphere of coordination.

Probing the Geometry of Strongly Hydrogen-Bonded Silanols

Hydrogen bonds are the most important of all directional intermolecular interactions and play a central role in determining molecular conformation and aggregation, as well as the function and dynamics of a great number of systems ranging from inorganic to biological chemistry. In order to understand the physical and chemical properties of layered microporous materials as well as the role of hydrogen bonds in the aggregation and ordering of silicate layers, the correlation of such contacts with the spectroscopic response is highly desired. In sodium hydrous silicates, the nature of strong hydrogen bonding having an O···O distance of less than 2.60 Å and present at room or higher temperature remains indeed the subject of considerable controversy. Both inter- and intralayer hydrogen bonding involving the silanol or water protons have been proposed. As the intercalation of polar molecules in

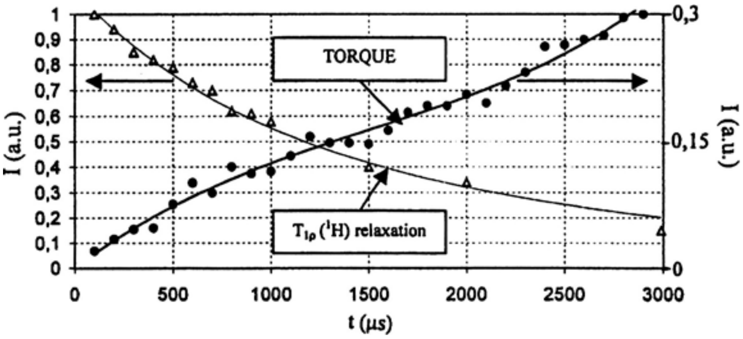

Fig. 6. Experimental time dependence of ^{29}Si magnetization for the $Q^{(3)}$ signal during TORQUE and $T_{1\rho}(^1\text{H})$ experiments. Solid lines correspond to the fitted curves with two components (i) and (ii) having following time constants: for the TORQUE experiment: (i) $T^{\text{IS}} = 0.7$ ms, $T^{\text{I}}_{1\rho} = 2.54$ ms; (ii) $T^{\text{SI}} = 20.0$ ms, $T^{\text{I}}_{1\rho} = 0.8$ ms; for the $T_{1\rho}$ experiment: (i) $T^{\text{I}}_{1\rho} = 0.8$ ms; (ii) $T^{\text{I}}_{1\rho} = 2.54$ ms.

layered materials can be dramatically controlled by the existence of interlayer hydrogen bonds, the appropriate recognition of the extent and the nature of hydrogen bonding present in these materials is of prime importance. To get this local geometric information, one can determine the internuclear Si···H distances and the orientation of the ^{29}Si chemical shift tensor in the hydrogen-bonded $Q^{(3)}$-type units by exploiting a simple experiment based on the CP inversion of the ^{29}Si spin magnetization used as a modulation of the slow magic-angle spinning chemical shift spectrum [12]. The experiment starts with the classical CP procedure followed by a period during which the contact between protons and silicons is maintained but the phase of proton spin-locking irradiation is inverted. As shown in Figure 7, this leads to non-uniform dipolar modulation of the ^{29}Si CSA spinning sidebands recorded under high power proton decoupling.

Such an effect gives evidence for largely coherent magnetization transfer within the silanol groups having a pronounced inhomogeneous character of the dipolar

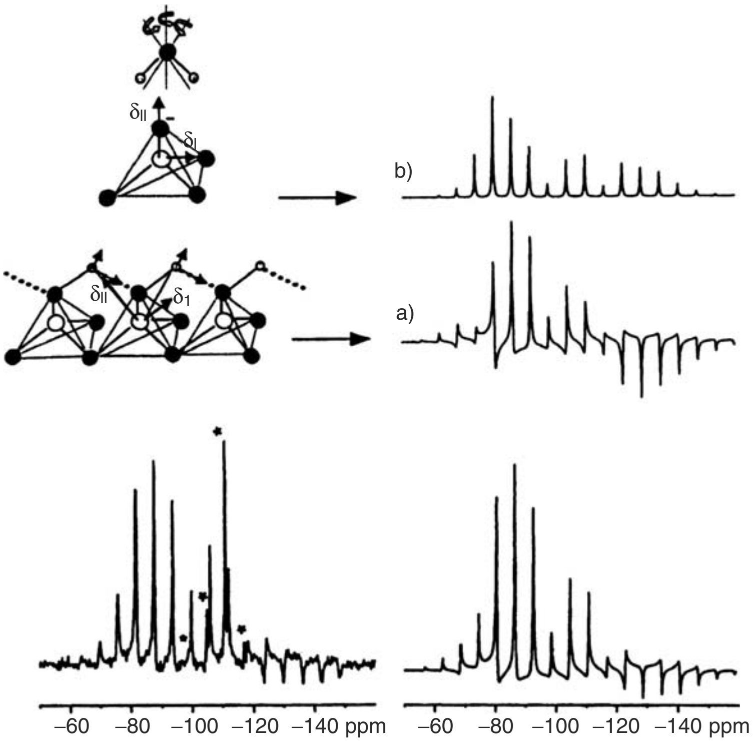

Fig. 7. Dipolar modulated ($t_1 = 400$ μs), natural abundance ^{29}Si NMR spectrum of slowly magic-angle spinning ($\nu_r = 357$ Hz) octosilicate (left bottom). Asterisks indicate the spinning sidebands of $Q^{(4)}$ sites. Fitted spectrum of $Q^{(3)}$ sites along with its individual components (right bottom). Dipolar modulated subspectrum (a) represents as indicated the hydrogen-bonded $Q^{(3)}$ sites, the subspectrum (b) comes from Si–O$^-$ $Q^{(3)}$ type sites cross-polarizing from the water molecules.

system, the observed difference in the dipolar oscillation frequency of different spinning sidebands resulting from variation of the orientation-dependent dipolar coupling. More interesting in the context of this work, the dipolar modulated spinning sidebands contain all the desired information on the hereronuclear distance as well as the magnitude and orientation of the principal elements of the chemical shielding tensor in the molecular frame.

In order to reproduce the observed dipolar modulated envelope of $Q^{(3)}$ spinning sidebands in Figure 6, the presence of two different components representing two types of $Q^{(3)}$ sites has to be assumed. Indeed, as discussed above, although a single isotropic $Q^{(3)}$ resonance signal is observed, two types of $Q^{(3)}$ tetrahedra, hydrogen-bonded silanols and $Si–O^-$ type sites need to be distinguished by their different abilities to cross-polarize. As can be seen in Figure 7, the calculated spectrum is in excellent agreement with the experimental envelope and phase features of the $Q^{(3)}$ family of spinning sidebands. The simulations show that dipolar modulated envelope of spinning sidebands is very sensitive to small changes of $r_{Si...H}$ distances and of their polar coordinates in the chemical shielding principal axis frame [11]. The results clearly support the intralayer character of strongly hydrogen-bonded silanol groups in a bridging albeit not symmetric position between neighboring tetrahedra.

Conclusions

The CP measurements are usually analyzed assuming that the CP time T^{IS} of magnetization transfer from the abundant I spins to the rare S spins is shorter than the relaxation time $T_{1\rho}$ in the rotating frame of the I spins (fast CP regime). Here, it was shown that the reverse situation ($T^{IS} >> T^{I}_{1\rho}$, slow CP regime) frequently occurs for the $^{1}H \rightarrow ^{29}Si$ transfer in commonly encountered inorganic materials. This fact must be clearly recognized to avoid a false structural image of investigated materials. The efficiency of the TORQUE experiment in visualizing the real CP regime or its possible mixed character has been underlined.

The proper exploitation of the proton–silicon polarization transfer spin dynamics in fast and slow magic-angle spinning experiments permits a deeper insight into structural and motional features of silicon-containing materials. The analysis of the dipolar modulated ^{29}Si CSA spectrum yields straightforward geometric information on the hydrogen-bonded silanols, including the orientation of ^{29}Si CSA tensor in the molecular frame. The CP methods employed to obtain such information take advantage of a weakly dipolar coupled proton–proton network, largely disconnected from the heteronuclear dipolar couplings within the silanol groups. This leads to significant truncation of weak dipolar couplings from neighboring protons by the largely dominant flip-flop coupling term of the heteronuclear spin pairs. This in turn makes it possible to exploit the coherent magnetization exchange without applying homonuclear decoupling which itself eliminates any uncertainty about the heteronuclear scaling factor inherently connected with homonuclear decoupling. The presented strategy may be useful to obtain structural information in the related layered alkali metal silicates, silica gels, calcium silicate hydrates as well as in other classes of microporous materials.

Solid State NMR Characterization of Solid Surface of Heterogeneous Catalysts

Feng Deng, Jun Yang, and Chaohui Ye
State Key Laboratory of Magnetic Resonance and Atomic and Molecular Physics,
Wuhan Institute of Physics and Mathematics, the Chinese Academy of Science, Wuhan 430071, P. R. China

Solid state NMR spectroscopy has become a powerful tool for investigation of the solid surface of various heterogeneous catalysts [1–4], such as zeolite, metal oxide, and solid heteropoly acid, which are widely used in petrochemical industry. Identification and characterization of the active centers, reaction intermediates, and products are essential for understanding reaction mechanisms occurring on the surface of heterogeneous catalysts. Compared to X-ray diffraction (XRD) which is determined by long-range orderings and periodicities, solid state NMR is more sensitive to local orderings and geometries, thus providing a more detailed description of the local structure, especially for powder samples. Multinuclear magic angle spinning (MAS) NMR, especially ^{1}H MAS NMR, probe molecule techniques, double-resonance techniques as well as two dimension correlation techniques have been employed to reveal the detailed structure of the active sites on heterogeneous catalysts. In addition, *in situ* MAS NMR technique [3,4] has been developed as an indispensable tool for investigation of the heterogeneous catalytic reaction mechanisms. Although many surface properties of heterogeneous catalysts can be investigated by solid state NMR spectroscopy, two main topics will be discussed in this section: surface acidity and catalytic reaction of heterogeneous catalysts.

Surface Acidity of Heterogeneous Catalysts

The surface acidity is described by the following three properties: (1) the type of acid sites (Brönsted or Lewis site); (2) the acid strength, which can be defined, for a Brönsted site, as the ability of the surface hydroxyl groups to protonate an adsorbed molecule; (3) the concentration of acid sites accessible to probe molecules. ^{1}H MAS NMR can resolve various hydroxyl groups that may acts as proton donators (Brönsted acid sites) on the surface of heterogeneous catalysts. In the case of zeolites [1,2], ^{1}H MAS NMR signals consist of non-acidic SiOH groups at chemical shifts of $\delta = 1.2$–2.2 ppm, extra-framework AlOH groups at $\delta \approx 3$ ppm, acidic bridging SiOHAl groups at $\delta = 3.6$–5.2 ppm, and residual ammonium ions at $\delta = 6.5$–7.0 ppm. For an ammonium-free zeolite, adsorption of a small amount of water molecules on Lewis acid site also gives rise to a ^{1}H signal at ca. 7.0 ppm. Hydrogen bonds of the surface OH groups with neighboring oxygen atoms or probe molecules will leads to a downfield shift of 1–20 ppm. For example, in a layered sodium disilicate material [5], isolated SiOH groups gives rise to ^{1}H resonances at 0–3 ppm, while inter-layer hydrogen-bonded SiOH groups correspond to a ^{1}H signal at 14 ppm, and strongly hydrogen-bonded silanols with the proton bonded to non-bridging oxygen at the same silicon atom shift the resonance position to 18.7 ppm. The advantage of ^{1}H MAS NMR over IR spectroscopy lies in the quantitative measurement of signal intensities, allowing an accurate determination of the OH concentrations [1]. Besides, some double resonance methods, such as ^{1}H/^{27}Al Transfer of Populations in Double Resonance (TRAPDOR) NMR technique [6], can correlate the various hydroxyl groups with the neighboring Al spins, while a spin echo pulse sequence is applied to proton and ^{27}Al is irradiated simultaneously during one of the echo period in the experiment. Under the ^{27}Al irradiation, the signals of protons that are strongly coupled with aluminum spins will be significantly suppressed while those that are not coupled with aluminum atoms remain unaffected. Therefore, the heteronuclear dipolar interactions between the two spins and the ^{1}H/^{27}Al internuclear distances can thus be extracted. As an example, Figure 1 shows the ^{1}H/^{27}Al TRAPDOR NMR of the ultrastable Y, the 2.2 ppm signal, which is due to non-acidic SiOH groups at the framework defects, is almost unaffected under ^{27}Al irradiation, while the signals at 4.3 and 5.2 ppm due to two types of the bridging OH groups and the signal at 3.0 ppm arising extra-framework AlOH groups that are all close to the Al atoms are significantly reduced [7].

Using various probe molecules, the surface acidity of heterogeneous catalysts can be well characterized. ^{15}N-enriched pyridine [8] and trimethylphosphine (TMP) [9] are two extensively used probe molecules for discriminating Brönsted and Lewis acid sites and quantitatively determining their concentrations. Both of the probe molecules give rise to large ^{15}N and ^{31}P chemical shift ranges of 100

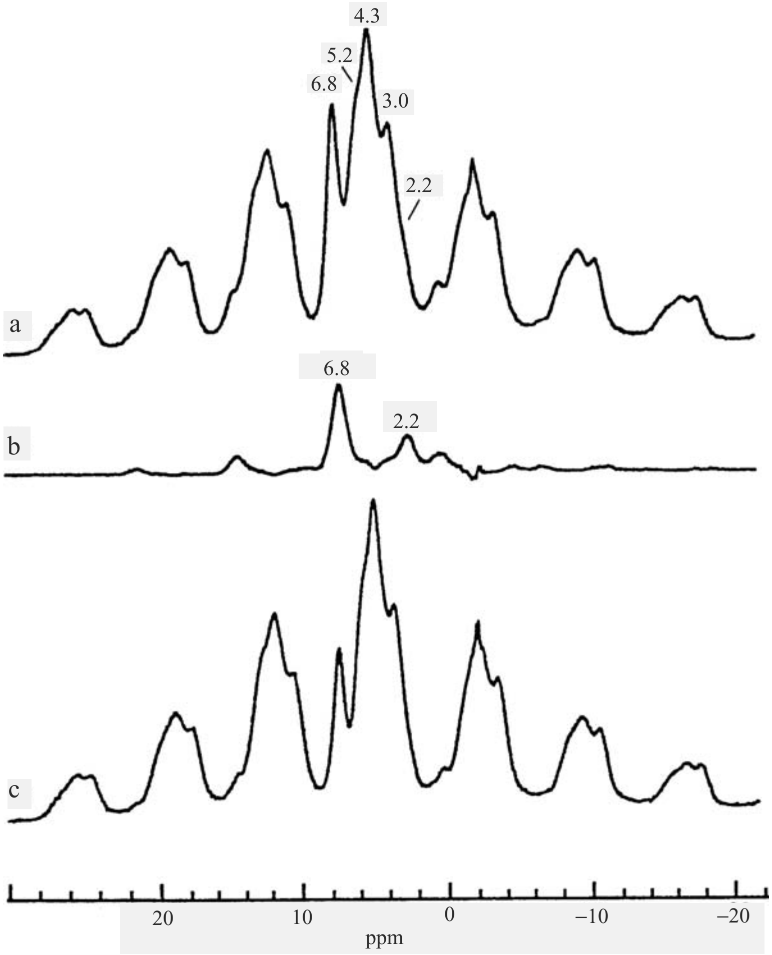

Fig. 1. $^{1}H/^{27}Al$ TRAPDOR NMR spectra of ultrastable HY. (a) without ^{27}Al irraiation, (b) with ^{27}Al irradiation. (c) the different spectrum of (a) and (b) [7].

and 60 ppm, respectively. One important advantage of the TMP over pyridine is the relatively high NMR sensitivity of ^{31}P, which is very useful in the cases where the concentration of the acid sites is very low. When Brönsted or Lewis acid sites are present in zeolites, protonated adduct, $TMPH^{+}$, or Lewis-bound TMP complex are confirmed. The $TMPH^{+}$ is characterized by a ^{31}P resonance at ca. -4 ppm and a J_{P-H} coupling of approximately 500 Hz for zeolites, while the Lewis-bound TMP complexes give rise to resonances in the shift range from -32 to -58 ppm, and the physisorbed or weakly bound TMP has a resonance at ca. –60 ppm. $^{27}Al/^{31}P$ and $^{27}Al/^{1}H$ rotational echo double-resonance (REDOR) NMR methods [10] have been applied to measure Al-P and Al-H_B (H_B is the Brönsted acidic proton) distances in zeolite HY for the acid site-TMP complex of 3.95 and 2.8–3.1 Å, respectively. A P–H_B distance of 1.40 Å was obtained by fitting the spinning sidebands in the ^{1}H MAS spectrum. As shown in Figure 2, combining the NMR results with *ab initio* calculations provides a more detailed description of the exact structure of TMP-Brönsted acid site complex formed in the zeolite.

Various probe molecules are used for determination of the acid strength of surface OH groups. Deuterated pyridine [11] is one of probe molecules for this purpose. The formation of a hydrogen bond between pyridine and non-acidic silanol group (SiOH) shifts the ^{1}H MAS NMR signal position from 2 to ca. 10 ppm. In the case of acidic OH groups (Brönsted acid sites), the adsorption of pyridine results in ^{1}H NMR signals at chemical shifts in the

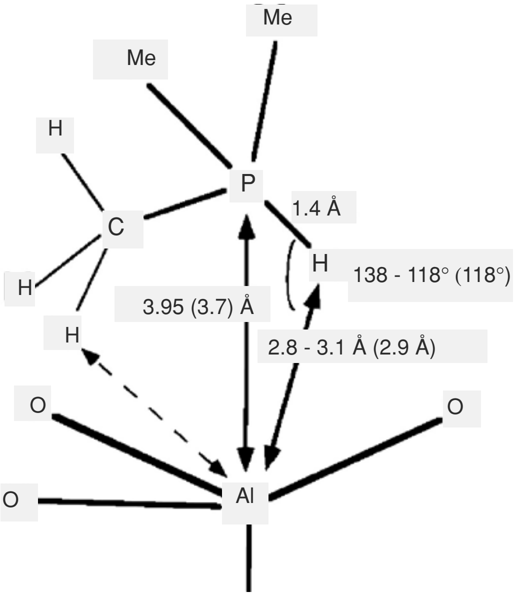

Fig. 2. Comparison of the NMR experimental and calculated distances. Calculated distances and angles obtained for the $TMPH^{+}$-Z_2^{-} cluster are given in parentheses. The dashed line indicates that an interaction between the two spins was observed experimentally, but the distance was not quantified [10].

range 12–19 ppm. The down-field signals result from a proton transfer to the probe molecule, forming pyridine ions. However, no quantitative correlation has been established between the acid strengths and the down-field shift of the ^{1}H signal. A more precise measurement of the acid strength of Brönsted and Lewis sites can be achieved with the aid of the ^{13}C chemical shift of the carbonyl atom of adsorbed 2-^{13}C-acetone [12,13]. The different degrees of interaction between the carbonyl oxygen of adsorbed acetone and the acid site result in different ^{13}C downfield shifts of the carbonyl carbon. By comparing the chemical shifts of 2-^{13}C-acetone adsorbed on various solid catalysts with the resonance position of the molecule in 100% H_2SO_4 solution, Haw *et al.* [13] proposed that the solid acid strengths scale with the ^{13}C NMR isotopic chemical shift of adsorbed 2-^{13}C-acetone (Table 1). According to the scale, the acid strength of the bridging hydroxyl groups in zeolite HZSM-5 corresponds to that of 80% H_2SO_4 solution.

Catalytic Reaction on the Surface of Heterogeneous Catalysts

In situ solid state NMR spectroscopy has been demonstrated to be a very powerful method to study the heterogeneously catalyzed reactions [3, 4, 13–15]. The detection of the change of both active sites on the catalysts and species (such as reactants, products, and intermediates) adsorbed on the surface of catalyst in the process of the reaction can provide more direct information about what happens on the catalyst surface than that obtained by using off-line techniques, such as gas chromatograph (GC) and mass spectroscopy (MS). The large chemical shift of ^{13}C MAS spectra (more than 300 ppm) enables differentiation of various organic species by their characteristic resonances. For example, in the study of methanol to gasoline (MTG) reaction [16], Klinowski *et al.* had (i) identified 29 different adsorbed organic species and monitored their fate during the reaction; (ii) directly observed various kinds of shape selectivity in zeolite ZSM-5; (iii) discriminated mobile species from attached species. These results will assist in the design of shape-selective catalysts and provide a better understanding of the catalytic reaction. *In situ* ^{13}C NMR technique was also employed to study methane dehydroaromatization on Mo/HZSM-5 catalyst. Not only the products, such as benzene, ethane, and ethylene, but also the active phase Mo_2C were directly observed by ^{13}C NMR spectroscopy (Figure 3). The NMR results support the following reaction mechanism [17]:

Table 1: ^{13}C MAS NMR isotopic chemical shift (in ppm) of carbonyl carbon of 2-^{13}C-acetone on (or in) different solid (or liquid) acids [12]

Acetone	208
SAPO-34	217
$CF_3CH(OH)OCF_3$	221
HZSM-5	223
$MgCl_2$	221
$ZnCl_2$	230
$AlBr_3$	243
100%H_2SO_4	244
$AlCl_3$	245
SbF_5	250

(1) During induction period

$$MoO_3 + CH_4 \rightarrow Mo_2C + CO + CO_2 + H_2O + H_2$$

(2) Formation of C_2(Mo_2C species as active center)

$$CH_4 \rightarrow C_2H_4 + C_2H_6$$

(3) Production of benzene (Brönsted acid sites as active center)

$$C_2H_4 \rightarrow C_6H_6 + H_2$$

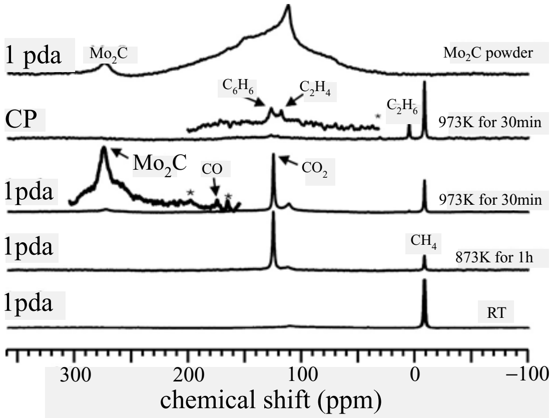

Fig. 3. ^{13}C MAS NMR spectra of methane (^{13}C, 99%) reaction on 6Mo/HZSM-5 at different temperatures, which were acquired at room temperature using one pulse with ^{1}H decoupling (1pda) or ^{1}H–^{13}C cross polarization (CP). For comparison, ^{13}C MAS NMR spectrum of molybdenum carbide powder was also shown. Asterisks denote spinning sidebands. The signal at 112 ppm is due to background of spinning module [17].

Since NMR is a quantitative method, the concentration of the adsorbed species on the surface of catalysts can thus be directly obtained, which is very helpful for investigation of the reaction mechanism. The sensitivity of natural abundance ^{13}C surface species is usually not enough for ^{13}C MAS NMR detection. Although ^{1}H–^{13}C cross polarization experiment can be used to enhance the sensitivity of ^{13}C MAS spectra, ^{13}C isotope-enriched reactants are usually required for the *in situ* NMR study. In some cases, selectively labeled reactants are very much useful to identify the catalytic reaction pathway by monitoring the fate of the labeled atoms at specific sites in the process of the reaction [18].

In the earlier studies, *in situ* MAS NMR experiments were usually carried out under batch condition. The simple and very commonly used method employs a particularly symmetrical glass ampoule [19], which fits well into MAS rotor in order to achieve a stable high magic angle spinning rate at about 3–4 kHz. For the sample preparation of *in situ* MAS NMR measurements, the catalyst is packed into the glass ampoule and activated under a vacuum line at a specified temperature. A known amount of reactant in gas or liquid state is introduced onto the catalyst by freezing with liquid N_2, and then the ampoule is carefully sealed by flame. The reaction is allowed to occur in an oven at a specified temperature for a period of time and quenched with liquid N_2, and then the sealed ampoule is transferred to MAS rotor for NMR observation. Another method for sample preparation employs a specially designed device named CAVERN (CAVERN: cryogenic adsorption vessel enabling rotor nestling, Figure 4)[13], which allows the sample preparation in the MAS rotor with a gas-tight sealed cap. This device can be connected to a vacuum line. Activation of catalysts, adsorption of ^{13}C-enriched reactants, transfer of the loaded catalysts into the MAS rotor, and sealing of the MAS rotor are all carried out in this device,

preventing the samples from the exposure of atmosphere. The sealed MAS rotor can be transferred into NMR probe. The reaction is allowed to take place at a specified temperature in NMR magnet for a period of time and then the temperature is allowed to return to room temperature for the *in situ* ^{13}C MAS measurement. This apparatus is suitable for the study of reaction that begins to occur at low temperature. For example, since ethylene is very active on HZSM-5 zeolite at the room temperature, the CAVERN device can realize the adsorption and transfer of the sample at the liquid N_2 temperature, and the ^{13}C MAS NMR observation of the reaction from 77 to ca. 600 K in NMR magnet. The Haw's group has done a large number of *in situ* ^{13}C MAS NMR studies with this device [13]. It is well known that heterogeneously catalyzed reactions are usually operated under the flow condition and the reaction products under the batch condition are different from those under the flow condition. Several groups attempt to develop *in situ* MAS NMR techniques for flow condition measurement [20–25]. Hunger *et al.* [14, 25] reported a device for real continuous-flow MAS measurement (Figure 5). In their device, the activated catalyst bed is pressed as a hollow cylinder in the MAS rotor and an injection tube is inserted into the hollow catalyst via a hole on the cap of rotor, which allows a continuous-flow introduction of reactants into the catalyst during the NMR experiment. The reaction products leave the MAS NMR rotor continuously through an annular gap in the rotor cap. It is possible to couple the *in situ* MAS device directly with an on-line GC [4]. Another *in situ* MAS NMR technique introduced by the Haw's group for the flow condition measurement includes a quench-reactor device coupled with GC and MS (Figure 6) [24]. A significant feature of the apparatus lies in that catalytic reactions can be quenched with cryogenically cooled nitrogen within a few hundred milliseconds. The catalyst loaded with reactants and products is then transferred to the NMR rotor in a glove box at room temperature prior to ^{13}C MAS NMR measurement. Figure 7 shows the pulse-quench ^{13}C NMR spectra [26] of ethylene on HZSM-5 zeolite at 623 K with the reaction time varying from 0.5 to 16 s. The most prominent peaks in the spectrum obtained for the 0.5 s reaction are all almost due to cyclopentenyl cation. As the catalyst ages for 2–4 s, signals from the carbenium ion decrease with a commensurate increase in the signals due to toluene. With further aging in the flow reactor, signals due to toluene and other organic species diminish, and after 16 s only a modest amount of the carbenium ion remains in the catalyst bed. A semilog fit of the decrease of the cyclopentenyl cation over time yielded an approximate half-life time of 6 s at 623 K.

In the last two decades, various catalytic reactions have been studied by *in situ* MAS NMR spectroscopy.

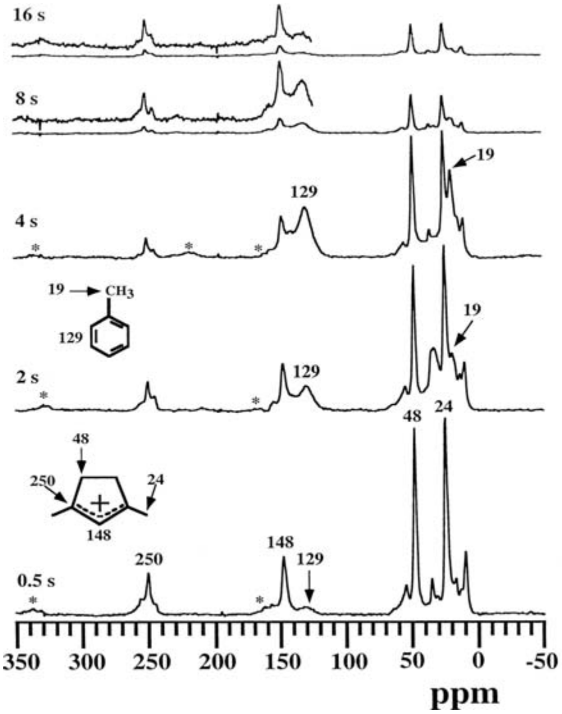

Fig. 7. ^{13}C MAS NMR spectra of ethylene-$^{13}C_2$ adsorbed on zeolite HZSM-5 at 623 K for various reaction time [26].

The formation of alkoxy species, such as methoxy groups ($\delta = 58$ ppm), ethoxy groups ($\delta = 68$ ppm), and isopropoxy groups ($\delta = 87$ ppm), have been observed by ^{13}C NAS NMR following the adsorptions of the olefines and alcohols onto acidic H-ZSM-5 and H–Y zeolites. These species are confirmed to act as reactive components that play an important role in the course of the reaction [4]. Methanol to hydrocabon conversion has been extensively investigated by *in situ* MAS NMR under either batch or flow condition, and the experimental results shed insight on the mechanism of reaction [26,27]. In the reaction of ethylene, methanol, acetone on acidic zeolite, alkyl-substituted, cyclic structure carbenium ion have been observed under batch /flow condition by *in situ* ^{13}C MAS NMR [13, 26], and it was proposed that these carbenium ions and related neutral species might function as reaction centers (hydrocarbon pool species) for the conversion of methanol to hydrocarbon.

Isotope Labeling

Recent Developments in Stable-Isotope-Aided Methods for Protein NMR Spectroscopy

Shin-ya Ohki[1] and Masatsune Kainosho[2]

[1]Japan Advanced Institute of Science and Technology (JAIST), Ishikawa 923-1292, Japan; and
[2]CREST-JST and Department of Chemistry, Graduate School of Science, Tokyo Metropolitan University, Tokyo 192-0397, Japan

Introduction

The existence of stable isotopes, such as ^{2}H, ^{13}C, and ^{15}N, is a blessing from nature for protein NMR spectroscopy, because protons, carbons, and nitrogens are the major components of proteins. Thus, protein NMR has deeply benefited from these stable isotopes. Since their natural abundance is very low, selective enrichment and/or depletion of these nuclei for incorporation into proteins have/has been desired. These skills are called stable isotope labeling, which is an old technique that is undergoing renewal in protein NMR spectroscopy. Various stable-isotope-labeling methods are illustrated in Figure 1.

Labeling methods can be generally classified into *positive* and *negative*. The former methods use NMR active nuclei, such as ^{13}C and ^{15}N, meaning that this labeling enables the monitoring of only the labeled sites in molecules [1]. The most famous example of the latter category is deuteration. The replacement of ^{1}H by ^{2}H can erase undesired peaks in the ^{1}H NMR spectra [2,3]. Thus, in other words, positive and negative mean “visible” and “invisible,” respectively, for NMR spectroscopy. Such labeling methods were already proposed even in earlier one-dimensional (1D) NMR studies, before the strategy for the three-dimensional (3D) structure determination of proteins was established.

In another context, the labeling methods can be classified as *selective* and *uniform*. Examples of the former are the introduction of ^{13}C and/or ^{15}N into certain site(s) in protein samples. The latter labeling strategy, “uniform labeling,” is the preparation of protein samples in which all of the carbon and nitrogen atoms are labeled with stable isotopes, ^{13}C and ^{15}N, respectively. Then, all of the carbon, nitrogen, and proton atoms in the proteins become visible in NMR experiments. This was first reported with the adoption of new pulse sequences for the separation of peaks into multiple dimensions [4,5]. Nowadays, uniform labeling and multidimensional NMR measurements are standard for the structure determination of proteins smaller than ∼20 kDa.

The demands for NMR have become more complicated lately: structure determination of large molecules, quick structure determinations of proteins with moderate molecular weights, determination of protein structures at higher resolution with high accuracy and precision, identification of ligand-binding sites on the surface of proteins, detailed studies of molecular dynamics, structural transitions, etc. To satisfy these requests, numerous stable isotope techniques have been proposed as an extension of the methods mentioned above. For all of the cases, the key is how ^{2}H, ^{13}C, and ^{15}N are placed in the protein samples, and their concepts can simply be characterized using combinations of the four words: *positive, negative, selective*, and *uniform*. In this chapter, the stable isotope techniques developed in the past several years will be reviewed, and a novel labeling approach of the post-genomic era will be described.

Positive Labeling (Use of ^{13}C and ^{15}N)

About 20 years ago, the strategy to determine the 3D structures of proteins by solution NMR was established [6]. With parallel progress in homonuclear ^{1}H two-dimensional (2D) experimental techniques and computational algorithms, the structure determination of small polypeptides in solution became routine. For proteins larger than ∼10 kDa, however, the cross peaks are crowded in the 2D ^{1}H NMR spectra, so their structures are extremely difficult to determine. To investigate larger molecules, a new labeling technique was proposed in 1990 [4,5]. In that method, all of the carbon and nitrogen atoms in the protein sample are labeled with NMR active stable isotopes by a method called uniform labeling or ^{13}C, ^{15}N-double labeling. Then, all of the proton, carbon, and nitrogen atoms in the uniformly labeled protein become detectable with NMR.

The employment of ^{1}H, ^{13}C, and ^{15}N enables the use of heteronuclear one-bond or two-bond spin–spin couplings in pulse sequences, and thus their through-bond correlations can be monitored. These experimental data

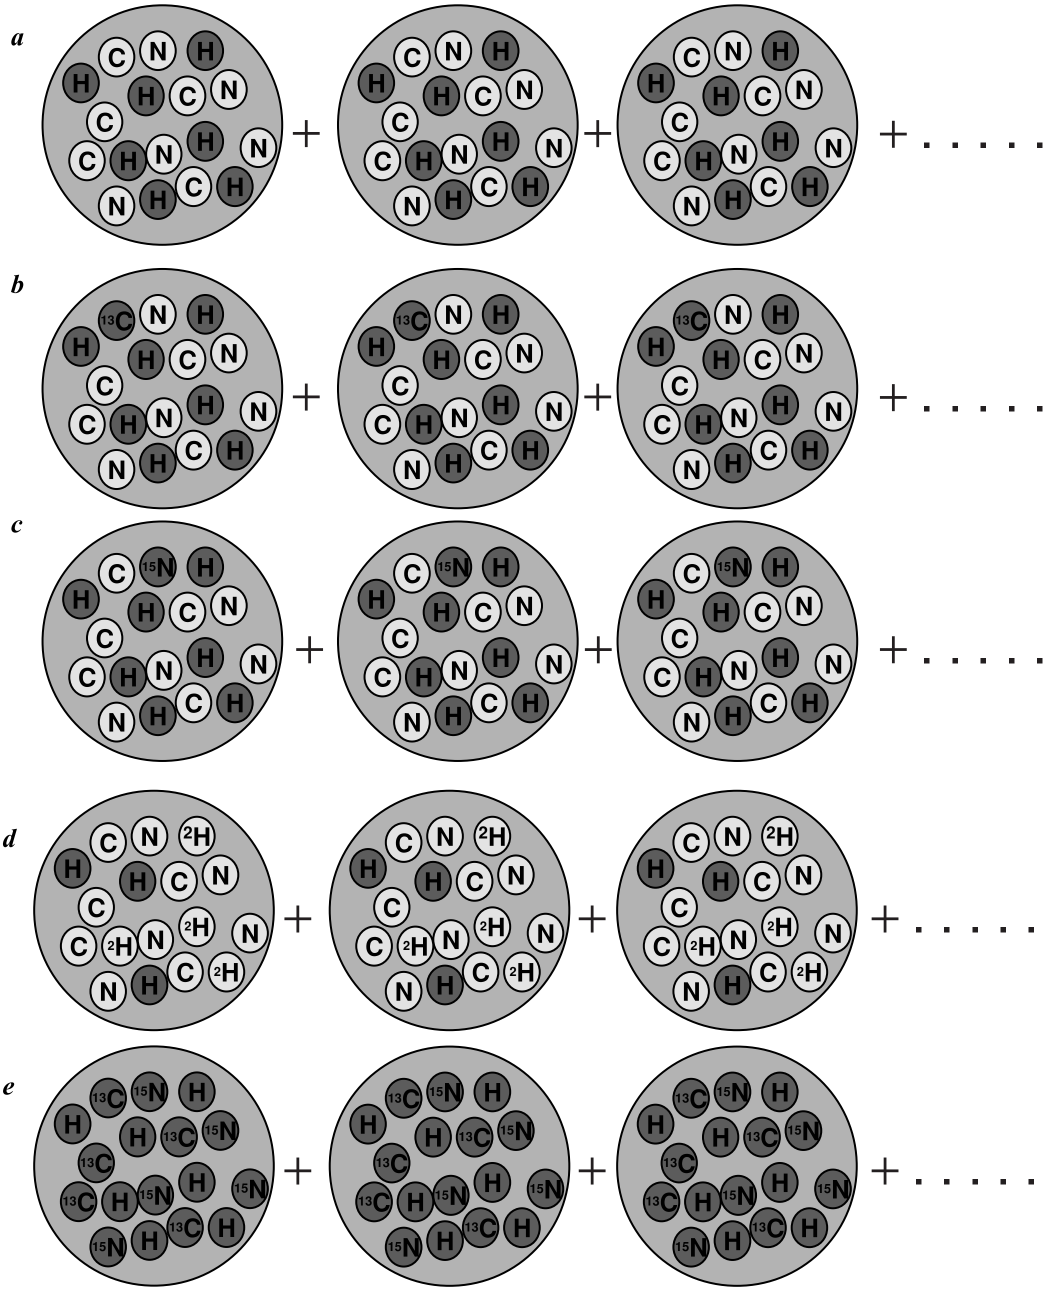

Fig. 1. Cartoons showing protein molecules with various stable-isotope-labeling patterns. Each yellow circle indicates a protein molecule. The small circles labeled H, C, and N indicate atoms. NMR observable and unobservable atoms are colored red and cyan, respectively. (a) Unlabeled, (b) selectively positive-labeled with ^{13}C, (c) selectively positive-labeled with ^{15}N, (d) selectively negative-labeled with ^{2}H, (e) uniformly ^{13}C, ^{15}N-labeled, (f) random-fractionally uniformly deuterated, and uniformly ^{13}C, ^{15}N-labeled, (g) site-specifically protonated, but otherwise uniformly ^{2}H, ^{13}C, ^{15}N-labeled, (h) protein–protein complex (uniformly labeled monomer and unlabeled one), and (i) segmental labeling (N-terminal half of the protein labeled with ^{13}C and ^{15}N). (See also Plate 25 on page XXVII in the Color Plate Section.)

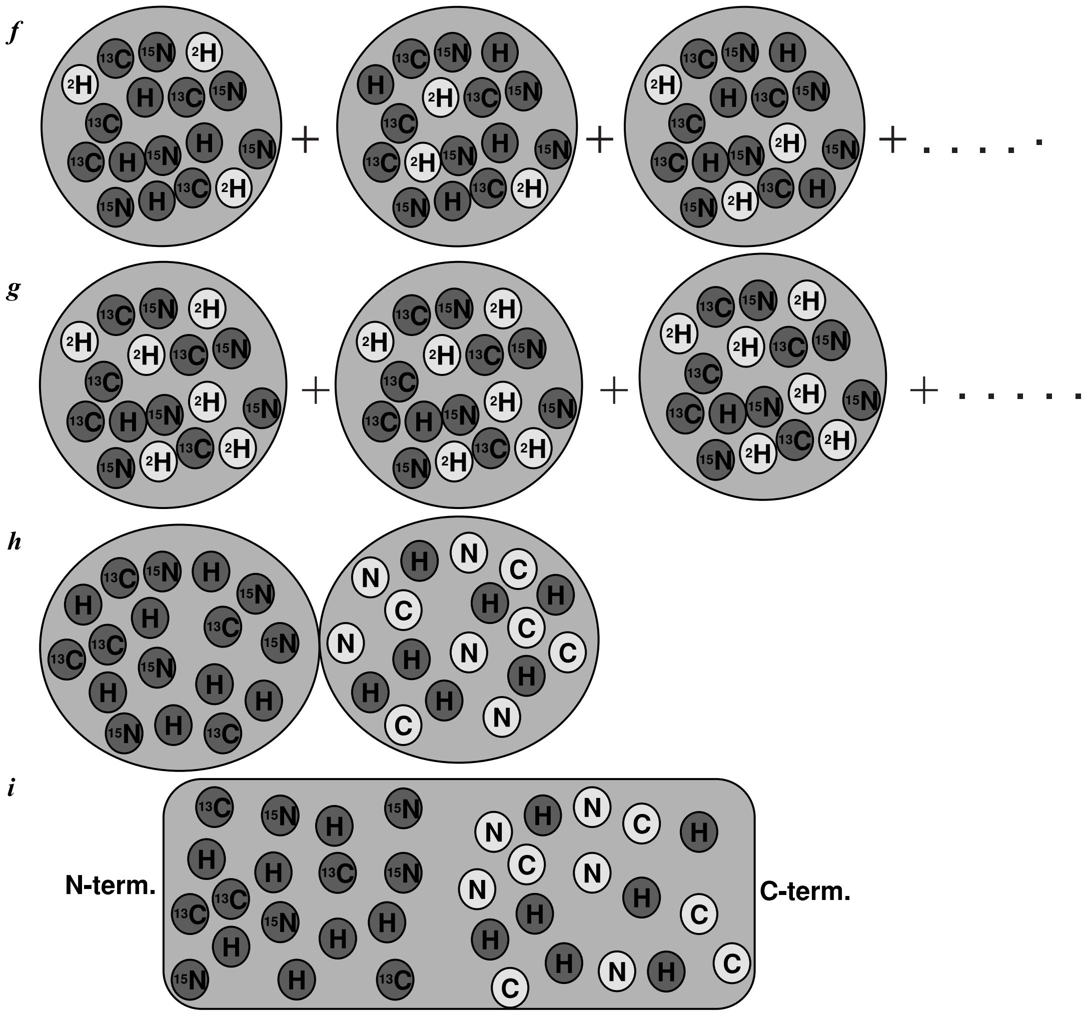

Fig. 1. (*Continued*) (See also Plate 25 on page XXVIII in the Color Plate Section.)

can provide the chemical shifts for all of the ^{1}H, ^{13}C, and ^{15}N in proteins unambiguously. Various *J* coupling constants are also obtainable with such samples, and they provide angle information for the protein backbone and side chains. Furthermore, the novel pulse sequences using ^{13}C or ^{15}N can separate crowded ^{1}H 2D NOESY spectra into several planes with the chemical shifts of the hetero nuclei attached to ^{1}H, thus enabling the identification of numerous NOE peaks for structure calculation. The strategy has expanded the possibility of NMR structure determination for proteins smaller than ~20 kDa.

Uniform labeling has also been adapted to protein complexes. Several labeling approaches have been proposed to study protein-protein complexes and symmetrical oligomers. The most popular method is mixing labeled and unlabeled components, which yields a complex in which one subunit is labeled with ^{13}C and ^{15}N, and the other is unlabeled. The binding surface is identified by intermolecular NOEs using isotope-filtered NMR experiments [7].

In the early 1990s, experimental methods in molecular biology were widely adopted by NMR laboratories, and uniform labeling instantly become a standard technique.

Various vectors and cells are commercially available today, and thus it has become routine to prepare expression systems for proteins from a wide variety of sources. Commonly, bacteria, *Phicia pastoris*, and insect or mammalian cells are used for NMR sample preparation. The uniform labeling is generally achieved by the addition of labeled chemicals into the growth medium. For the ^{13}C-precursors, ^{13}C-labeled glucose, ^{13}C-acetic acid, or ^{13}C-methanol is frequently used, with ^{15}N-labeled NH_4Cl or NH_4SO_4 as the ^{15}N-precursors. In an alternative method, a ^{13}C, ^{15}N-labeled amino acid mixture can be included in the medium.

Amino acid type selective labeling to simplify NMR spectra has been used as a powerful tool to study local conformations. This method can be applied to large proteins, and thus it is still useful in current research. For this case, ^{13}C and ^{15}N are employed as labels, and an expression or chemical synthesis method is needed to prepare the protein samples. When we use *Escherichia coli* to express the NMR samples, it is easy to label the Ile, Leu, Val, Phe, and Tyr residues. However, for several amino acids including Glu, Gln, Asp, and Asn, the selective labeling is not achieved with standard *E. coli* strain such as BL21, because of isotope scrambling and dilution during expression. To overcome these problems, a new set of genetically engineered *E. coli* strains with lesions in the biosynthetic pathways of certain amino acids has been developed [8]. The use of these extraordinary *E. coli* systems is one of the solutions to achieve amino acid type selective labeling. Another choice for sample preparation is to use cell-free protein synthesis. A cell-free system has the potential for robust isotope labeling without isotope scrambling and dilution [9]. The system can also be used for toxic proteins and membrane proteins [10], which are difficult to express in bacteria, and it can be extended to incorporate non-natural amino acids containing spin or fluorescent labels [11].

For large proteins, an attractive labeling method, segmental labeling, has been proposed. This method is used to prepare a protein in which a part is labeled, and is based on peptide splicing reactions with inteins. Inteins are inserted amino acid sequences that splice themselves out after translation [12]. In the first demonstration, the isotopic-labeled N-terminal (or C-terminal) half of a protein was ligated to the unlabeled C-terminal (or N-terminal) half [13]. As a modification of the original method, labeling at the central region of a protein is also possible [14].

Negative Labeling (Use of ^{2}H)

The application of multidimensional NMR experiments for larger proteins (> 20 kDa) often yields poor NMR spectra, due to two factors. One is severe line broadening and the other is overlapping of numerous peaks. The former is caused by the shorter spin–spin relaxation time (T_2) and the latter is due to the number of protons. In the past decade, great progress has been made to overcome these problems. The breakthrough was achieved with new pulse sequences based on the transverse relaxation-optimized spectroscopy (TROSY) technique and a combination of ^{2}H negative labeling and ^{13}C, ^{15}N positive labeling.

The TROSY principle was originally found as a modification of ^{1}H–^{15}N HSQC (heteronuclear single quantum coherence spectroscopy) on biomolecules. The critical feature of TROSY is that heteronuclear one-bond ^{1}H–X ($X = {}^{13}$C, ^{15}N) splitting should not be decoupled. Then, each peak is split into four in the 2Dplane. The line widths of the doublet components in both dimensions are different, because they have different relaxation mechanisms. In the original TROSY experiment, only the sharpest component, which shows the longest T_2, was observed by a phase cycling scheme that cancels the three broader peaks of the multiplet [15,16]. The higher field magnets (800–900 MHz) that are currently available are suitable for obtaining the maximum TROSY effect, and thus the NH detection period in many triple resonance pulse sequences has been rewritten, based on the TROSY technique, for larger proteins [17].

Negative labeling, using of ^{2}H, has been employed to reduce the number of peaks in ^{1}H NMR spectra. This was recognized as a powerful technique even in earlier 1D NMR [2,3]. Moreover, the use of ^{2}H yields another benefit, in that it strengthens and sharpens the signals in NMR spectra. Since ^{2}H has a significantly lower gyromagnetic ratio as compared with ^{1}H ($\gamma[^2\mathrm{H}]/\gamma[^1\mathrm{H}] = 0.15$), the use of ^{2}H can contribute toward eliminating the ^{1}H–^{1}H dipolar and ^{1}H–X ($X = {}^{13}$C, ^{15}N) heteronuclear spin relaxation pathways, resulting in a longer T_2. The first experiments using ^{2}H labeling combined with triple resonance multidimensional NMR experiments were reported in 1993 [18]. The effect of ^{2}H in ^{13}C, ^{15}N-labeled proteins is very successful, and thus many applications using this labeling scheme have been published [19–21]. A recent study has shown that the triple labeling method coupled with TROSY-based NMR analysis can work even for a 900 kDa protein complex [22].

In earlier application of triple-resonance multidimensional experiments with ^{2}H decoupling, the uniformly random fractional incorporation of ^{2}H into the non-exchangeable ^{1}H sites in proteins was employed. In general, the degree of the ^{2}H labeling level affects the quality of the NMR spectra, so a higher level of random uniform ^{2}H labeling yields sharper signals and thus is better for main chain assignments. However, the absence of ^{1}H at non-exchangeable sites is disadvantageous to side chain analysis, especially for the observation of ^{1}H–^{1}H NOEs for structure determination. Thus, 50–90% uniformly

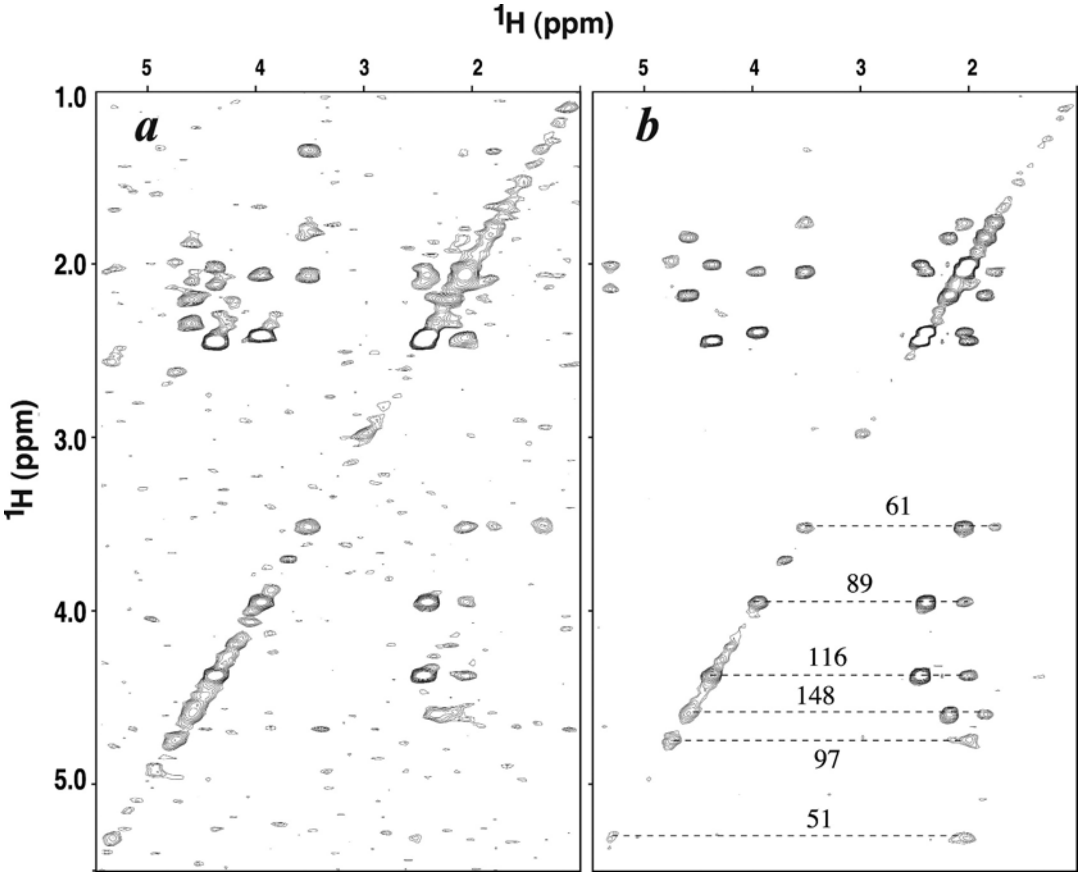

Fig. 3. Two-dimensional HCCH-TOCSY of an 18.2 kDa protein, EPPIb (S. Ohki, T. Hayano, T. Terauchi, M. Kainosho, unpublished data). The sample contains with uniformly ^{13}C, ^{15}N-labeled Gln, [ul-^{13}C,^{15}N]-Gln, (a) and SAIL-Gln (b), respectively. The intra-residue connectivity for each residue is shown by a dotted line with the residue number.

random fractional ^{2}H labeling is frequently employed for analysis, but this has considerable problems related to isotopomers. For example, each methyl group of Ala, Leu, Ile, Val, and Met contains isotopomers, i.e. CH_3, CH_2D, CHD_2, and CD_3. Three of the four isotopomers give NMR signals, and they appear at slightly different chemical shifts due to the isotope shift. Then, the methyl region signals become crowded, which hinders extensive analysis. However, the methyl group is interesting as a probe for protein dynamics. In some cases, $^{13}CH_2D$ is monitored, but the topic of protein dynamics is beyond the scope of this review. Although an optimized sample preparation method and pulse sequences to observe one isotopomer in the sample solution have been reported [23], the signal intensity is lower than expected, because the actual number of detectable molecules is much less than the total sample concentration. If one obtains fine filtered NMR spectra using such pulse techniques, then the number of ^{1}H to be analyzed increases with the molecular weight, and thus the amount of effort is never reduced.

To improve the spectral complexity, alternative labeling methods have been proposed by using ^{2}H, ^{13}C, and ^{15}N. The method is amino acid type selective labeling in deuterated proteins. In other words, the method is selective protonation. In an earlier report of this strategy, the labeled protein sample was expressed in minimal medium containing 95% D_2O, ^{2}H-labeled glucose, $^{15}NH_4SO_4$, and $^{1}H/^{13}C/^{15}N$-{Ile, Leu, Val} amino acids [24]. The samples gave very clear ^{1}H–^{13}C HSQC and NOESY for these hydrophobic residues. The aliphatic–aliphatic NOEs combined with the ^{1}HN–^{1}HN NOEs can

(b) Structures using all NOEs theoretically observed, and (c) structures using NOEs expected for the SAILed protein. (See also Plate 26 on page XXVIII in the Color Plate Section.)

be subjected to structure calculations; however, only the global fold is available. Although several ^{13}C precursors, such as ^{13}C pyruvate [23,25,26] or [2-^{13}C]glycerol [27], were examined for the selective labeling, further structural information, such as residual dipolar couplings (RDC), was needed to determine the high-resolution NMR structures of large proteins [28].

Recently, a novel labeling method termed stereo-arrayed isotope labeling (SAIL) has been developed [29]. In this labeling method, the ^{2}H labeling sites and the occupancy are controlled at an extremely high level. The arrayed deuteration sites in proteins are designed to suppress redundant structural information [30]. The SAIL amino acids, shown in Figure 2, are chemically and enzymatically synthesized. Then, these amino acid compounds are incorporated into the cell-free synthesis system for sample protein preparation. The SAILed proteins have ~50% protons as compared to fully protonated proteins, and the SAILed protein molecules in the sample solution represent only one isotopomer. Thus, the NMR spectra are simplified, with very narrow signals. Figure 3 indicates an example of the NMR data. In both samples, only Gln residues were labeled with uniformly [ul-^{13}C, ^{15}N]-Gln (Figure 3a) or SAIL-Gln (Figure 3b). Obviously, the SAIL method gives much better NMR spectrum. Furthermore, a simulation of the structure calculation indicates that obtainable NOEs must be sufficient to solve the structure at high resolution and accuracy (Figure 4). The application of SAIL method promises to relieve the limitation of molecular weight for NMR analyses and to contribute to high-throughput structure determination in the post-genomic era.

Concluding Remarks

The recent progress in stable-isotope-labeling strategies has provided opportunities for NMR studies of a wide range of proteins and their complexes. The advance of methodologies for sample preparation, including conventional expression systems, cell-free systems, and chemical synthesis, will continuously propose various labeling strategies. In concert with improved instruments, novel experimental techniques, and faster computing, the stable-isotope-labeling will become increasingly significant for studying larger biological systems by NMR in the future.

Introduction

Recent advances in structural biology have made possible the high-throughput structural determination of proteins, which is reflected in the very rapid growth of Protein Data Bank content. In structural proteomics, recombinant proteins used for structural determination by NMR spectroscopy and X-ray crystallography are conventionally produced by use of bacterial expression systems or recently by cell-free protein expression systems and therefore do not possess carbohydrate moieties. However, many of the proteins in the living systems are covalently linked to carbohydrate moieties, which mediate molecular recognition involved in cell–cell communication, contribute to solubility and structural integrity of proteins, and determine the fates of glycoproteins in cells, i.e. folding, transport, and degradation via interactions with a variety of intra-cellular lectins [1,2].

Although the biological importance of glycans expressed on proteins has been widely recognized, little is known about their specific roles from the structural aspect. This deficiency in our knowledge is largely due to the lack of an appropriate methodology to deal with glycoproteins as targets of structural biology. The carbohydrate moieties of glycoproteins generally exhibit microheterogeneities and possess a significant degree of freedom in internal motion, which hampers crystallization or interpretation of electron density [3,4]. NMR spectroscopy can potentially provide us with information on structure and dynamics of glycoproteins in solution. However, there are few reports of structural determination of glycoproteins by NMR spectroscopy [5–7]. The desirable methods for NMR structural biology of glycoproteins and carbohydrate–protein interactions are

1) Production of a large amount of isotopically labeled glycoprotein by appropriate expression systems.
2) Determination of a covalent structure of target glycoprotein including carbohydrate moieties.
3) Preparation of a large amount of isotopically labeled oligosaccharides that can be used as ligands.

Three-Dimensional HPLC Mapping

Prior to NMR analyses of glycoproteins, it is essential to obtain information concerning the covalent structures of their carbohydrate moieties. Takahashi and coworkers have established a method to identify asparagine-linked oligosaccharides rapidly on inspection of HPLC elution profiles of their pyridylamino (PA)-derivatives [8]. On the basis of the combination of the retention time data on the three kinds of HPLC columns, i.e. anion exchange, ODS, and amide–silica columns, the elution map of the 500 different PA-oligosaccharides has been established. Based on this three-dimensional HPLC map combined with mass spectrometric data, we have recently made GALAXY (http://www.glycoanalysis.info/), a web application that greatly facilitates NMR structural biology of glycoproteins [9]. The HPLC method is also useful for isolation of PA-oligosaccharides discriminating isomeric structures [10], which can be used as ligand for NMR analyses of carbohydrate–protein interactions.

Stable Isotope Labeling of Glycoproteins

The authors have been developing a systematic method for isotope labeling of glycoproteins for NMR analyses using immunoglobulin G (IgG) as model system [11,12]. The Fc portion of IgG possesses one conserved glycosylation site at Asn-297 in each of the two heavy chains, where biantennary complex-type oligosaccharides (Figure 1) are expressed. These carbohydrate chains are essential for the binding to effector molecules such as Fcγ rceptors [13,14]. The carbohydrate chains exhibit microheterogeneities resulting from the presence or absence of the non-reducing terminal galactose (Gal), core fucose (Fuc), and bisecting *N*-acetylglucosamine (GlcNAc)

residues depending upon physiological and pathological states [15,16]. For example, agalacosylation of serum IgG is associated with a variety of diseases such as rheumatoid arthritis [17].

Figure 2 illustrates the scheme of strategy for stable isotope labeling of the Fc glycans. For incorporation of the labeled precursors into the glycoprotein, we use two alternative methods. One is metabolic labeling via biosynthesis pathway of mammalian cells. The other is *in vitro* labeling by use of enzymatic glycosylation onto isolated glycoproteins.

In vitro Labeling of Sugar Chains

Enzymatic attachment of isotopically labeled sugar onto the carbohydrate moiety is a conventional method of selective isotope labeling of the non-reducing terminal sugar

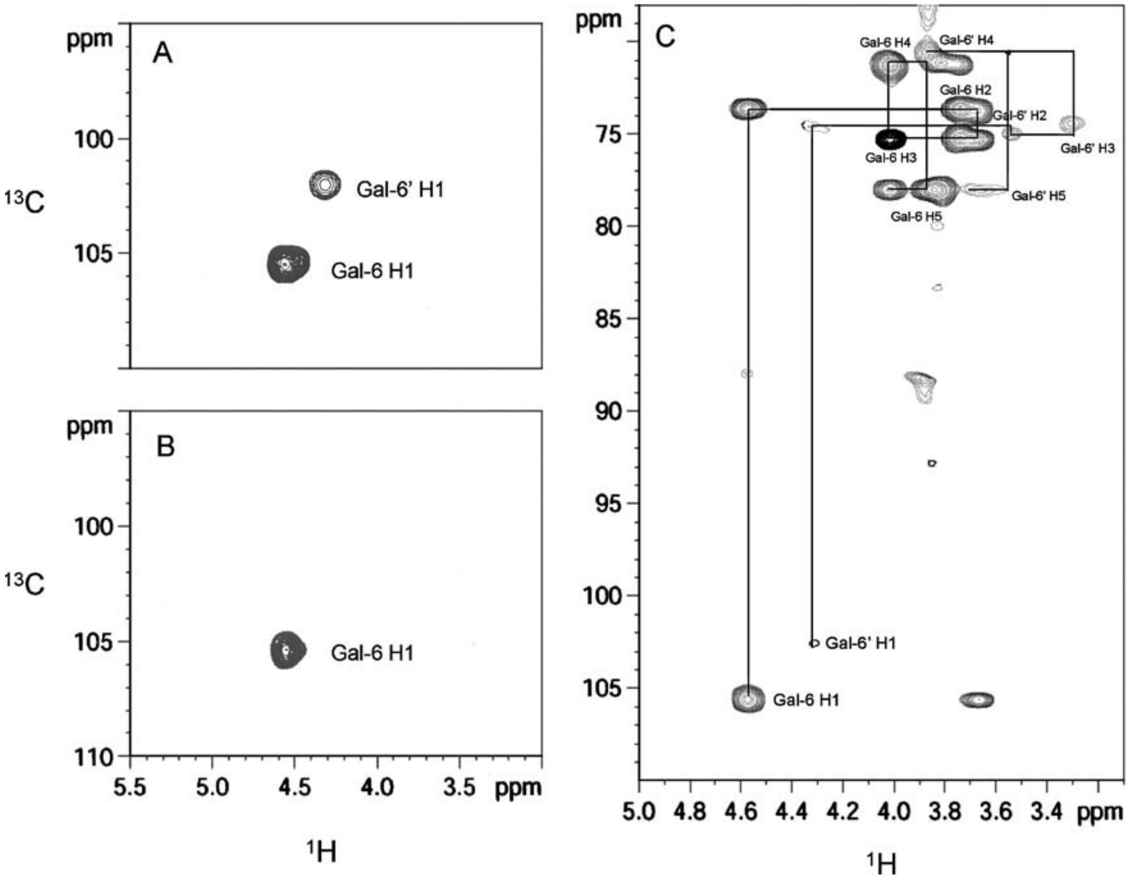

Fig. 3 ^{1}H–^{13}C HSQC of galactosyl Fc in which the Gal residues are fully (A) or partially (B) labeled with ^{13}C by using UDP-[1-^{13}C]Gal and (C) 2D HCCH-COSY spectrum of galactosyl Fc in which the Gal residues are fully labeled with ^{13}C by using UDP-[u-$^{13}C_6$]Gal.

residues such as Gal and sialic acids. Figure 2 shows the scheme of *in vitro* labeling of the terminal Gal residues [12,18]. [1-^{13}C]Gal can be converted to UDP-[1-^{13}C]Gal through the successive enzymatic reactions using galactokinase and galactose-1-phosphate uridyl transferase and then attached by using galactosyltransferase onto the non-reducing ends of the Fc carbohydrate chains, which are degalactosylated in advance. The Fc preparation gave two HSQC peaks originating from the anomeric groups of the terminal Gal residues, i.e. Gal-6 and Gal-6′ (Figure 3A). Under the mild reaction condition using small amount of unlabeled UDP-Gal, galactosylation occurs fully and partially at the mannose (Man) α1-6 and Manα1-3 branches, respectively. The unoccupied Manα1-3 branches of this Fc preparation can be fully galacosylated by use of enough amount of UDP-[^{13}C]Gal, giving rise to Fc labeled with ^{13}C exclusively at Gal-6′. HSQC spectrum of this Fc preparation gave a single anomeric peak originating from Gal-6 (Figure 3B) and therefore led us to assign the peaks shown in Figure 3A to each of the Gal residues. Starting from the anomeric peaks thus assigned, intra-residue scalar connectivities were identified by HCCH-COSY spectrum of the isotopically labeled Fc prepared by using UDP-[1-$^{13}C_6$]Gal (Figure 3C).

It should be noted that the peaks originating from Gal-6 gave much narrower peak than those from Gal-6′, indicating that Gal-6 is much more mobile than Gal-6′. This is consistent with the crystallographic data of Fc, which shows that Gal-6 makes contacts with an inner surface of the C_H2 domain, while the Manα1-3 branch protrude to a space between the C_H2 domains [19]. Hence, ^{13}C resonances can be useful probes to provide us with information

F, fucose; GN, *N*-acetylglucosamine; M, mannose.

on dynamics of the carbohydrate moieties of glycoproteins at atomic resolution. Similar technique can be applied for isotope labeling of the terminal sialic acid residue on galactosylated ovalbumin [20].

Metabolic Labeling of Sugar Chains

The major drawback of *in vitro* labeling method is that it can only be applied to the NMR analyses of nonreducing terminal residues of glycans in glycoproteins. By contrast, metabolic labeling can be applicable for the observation of NMR signals originating from all the sugar residues. For expression of isotopically labeled glycoproteins subjected to NMR analyses, mammalian [5,21], plant [22], yeast [23,24], insect cells [25], and cellular slime mold [26] have so far been available. The authors have developed protocols of metabolic labeling of IgG glycoproteins by cultivating hybridoma cells in a serum-free medium that contains isotopically labeled amino acids and/or sugars [12,27].

Since glucose can be metabolically converted to all of the sugar residues in biosynthetic pathways, isotope labeling using [u-$^{13}C_6$]glucose (Glc) as a metabolic precursor results in uniform ^{13}C labeling of their carbohydrate moieties of glycoproteins. Figures 4A and B compare a part of an HSQC spectrum of uniformly ^{13}C-labeled Fc (agalactosyl form) thus prepared with that of a glycopeptide derived from it by V8 protease digestion. In this spectral region, the peaks originating from the CH groups of carbohydrate moieties are observed. The HSQC peaks originating from the glycopeptide can be unambiguously assigned since their ^{1}H and ^{13}C chemical shifts are in agreement with those of isolated oligosaccharides [28]. On the other hand, significant differences were observed in the chemical shifts of most of the peaks between Fc and the isolated glycopeptide, indicating that the glycans are surrounded by a different environment when they are built in Fc. Especially, two anomeric peaks exhibit pronounced low frequency ^{1}H chemical shift values (<3.5 ppm).

To classify the peaks for Fc in a residue-specific manner, selective isotope labeling techniques are quite useful. Yamaguchi *et al*. have demonstrated advantage of metabolic labeling by using [u-$^{13}C_6$, $^2H_7$]Glc for residue-specific resonance assignments of the peaks originating from carbohydrate moieties of the Fc glycoproteins [11]. In the ^{1}H–^{13}C HSQC spectra of the Fc preparation metabolically labeled by using [u-$^{13}C_6$, $^2H_7$]Glc as a metabolic precursor, peaks originating from part of the CH groups of the carbohydrate moieties are partially observed (Figure 4C) because hydrogen from the medium is incorporated into the CH groups of the sugar residues during the metabolic conversion of [u-$^{13}C_6$, $^2H_7$]Glc to GlcNAc, Man, and Fuc residues of the Fc glycans. The degree of the proton incorporation varies for the different positions of sugar ring and different types of sugar residues. In this example, ^{2}H to ^{1}H exchange ratio at the C1 position of the GlcNAc residues was approximately 20% while those of the Man and Fuc residues were approximately 80%, which was estimated based on relative intensities of the unambiguously assigned HSQC peaks from the glycopeptide derived from the same Fc preparation. Therefore, the peaks originating from those anomeric groups of the Fuc and Man residues are observed with higher intensities than those from the GlcNAc residues. On detailed inspection of relative peak intensities in comparison with those observed for Fc labeled with [u-$^{13}C_6$]Glc, one can achieve residue- (and position-) specific resonance assignments.

Residue- and position-selective ^{13}C labeling of the carbohydrate chains also facilitates spectral assignments of glycoproteins [12]. Figure 4D shows a ^{1}H–^{13}C HSQC spectrum of an Fc that was prepared by cultivating the hybridoma cells in the medium containing D-[1-^{13}C]glucosamine (GlcN). Since GlcN is converted to the GlcNAc residues of glycans, only peaks originating from the four GlcNAc residues are observed. Spectral comparison allows us to identify the GlcNAc peaks. Reversely, metabolic labeling using a medium containing [u-$^{13}C_6$]Glc and unlabeled GlcN results in selective disappearance of the GlcNAc resonances from the spectrum.

Based on the residues-specific resonance assignments and intra-residue scalar connectivities, sequence-specific resonance assignments can be achieved by identification of the inter-residue sequential NOE connectivities.

Carbohydrate–Protein Interactions

Stable isotope labeling of sugar chains is also useful for NMR analyses of carbohydrate–protein interactions. Chemically or enzymatically ^{13}C-labeled oligosaccharides have been used for NMR analyses of interactions of oligosaccharides with their cognate proteins [7,29–31]. The authors used glycopeptides derived from isotopically labeled Fc glycoproteins as ligands. The Fc fragment metabolically labeled with [u-$^{13}C_6$]Glc was digested by V8 protease and trypsin and the isolated glycopeptide was subjected to galactosidase and hexosaminidase treatments for trimming of its carbohydrate moiety giving rise to Manα1-6(Manα1-3)Manβ1-4GlcNAcβ1-4(Fucα1-6)GlcNAcβ1-peptide.

Figure 5 shows HMQC-NOESY spectrum of the ^{13}C-labeled glycopeptide in association with the sugar-binding domain (SBD) of Fbs1, a substrate-binding component of sugar-recognizing ubiquitin ligase SCF$^{\text{Fbs1}}$ [32,33]. Intermolecular NOE connectivities between the anomeric proton of the innermost GlcNAc residue and the aromatic ring of Tyr-279 as well as inter-residue NOE connectivity within the carbohydrate moiety were observed in the spectrum. These data provide us with information of conformation and binding mode of the glycan in association with the SBD of Fbs1.

Concluding Remarks

Conformational analyses of carbohydrate moieties covalently attached to or non-covalently interacting with a protein are very important for obtaining unique knowledge that has never been possible with liberated oligosaccharides and provide information regarding the structural basis of functions of glycans and of rational design of sugar mimics. By stable isotope labeling of glycans, it becomes feasible to elucidate the conformation and dynamics of glycans attached to proteins based on NMR parameters, i.e. chemical shifts, NOEs, or relaxation rates. At higher magnetic field, it becomes possible to observe residual dipolar couplings of isotopically labeled glycoprotein molecules weakly oriented in the presence of ordering media [34,35].

Structural glycobiology is an unexplored field beyond structural genomics. Stable-isotope-assisted NMR spectroscopy will open up a new avenue in this field and greatly contribute to decoding the glycocodes.

Lipid Bilayer and Bicelle

Development and Application of Bicelles for Use in Biological NMR and Other Biophysical Studies

Charles R. Sanders

Department of Biochemistry and Center for Structural Biology, Vanderbilt University, Nashville, TN 37232-8725, U.S.A.

The term "bicelles" was first proposed in 1995 to describe aqueous assemblies of detergent and lipid that were believed to be "**bi**nary, **bi**layered mixed mic**elles** bearing a resemblance to the classical model for **bi**le salt-phosphatidylcholine aggregates" [1]. At that time, bicellar mixtures had already been in use for several years as magnetically alignable model membranes in solid-state NMR studies of membrane-associated molecules (Figure 1). Since 1995, there have been dramatic advances both in the applications of bicelles and in our understanding that bicellar mixtures are morphologically more complex than originally thought. Here, we trace the development and application of bicelles from their initial development in the late 1980s. Other reviews of bicelles and related developments in NMR and sample alignment methods are also available [2–10].

Bicelle Roots

That phospholipid/detergent mixtures believed to form discoidal bilayered mixed micelles can be aligned in a high magnetic field was first demonstrated in the lab of James Prestegard at Yale University. Preetha Ram, a graduate student, observed magnetic alignment of anionic bile salt-phosphatidylcholine mixtures in 1988 [11]. Leading to this achievement were earlier developments in disparate fields:

1. It was known that phospholipid vesicles could be aligned using a strong magnetic field in a way that distorted the (ideally) spherical vesicles to permit a large fraction of the lipid bilayers present to be preferentially aligned with the magnetic field (with bilayer normals orthogonal to the magnetic field) [12–16]. In other words, it was already established that lipid bilayers have significant anisotropy of diamagnetic susceptibility. The magnetic susceptibility tensor of hydrocarbon-based phospholipids is aligned within the molecular frame such that lipids prefer to align with their long axes orthogonal to the direction of the applied magnetic field. Lipid bilayers, therefore, prefer to be uniaxially aligned such that bilayer normals are perpendicular to the field.
2. Through many years of effort by membrane biophysicists, it was already believed that lipids sometimes form discoidal aggregates with detergents of the digestive system (bile salts) [17–19] and with certain amphipathic proteins [20–24]. Thus, bicelles were already known entities, although these systems had not been exploited as model membrane media or subjected to magnetic alignment.
3. By 1988 there were already a number of abiological aqueous lyotropic and nematic liquid crystals that were believed to be either bilayered-discoidal or tubular in morphology and that were known to align in the presence of a strong magnetic field [25–28]. For those believed to be disk-like, systems were available that aligned either with their bilayer normals orthogonal or parallel to the applied field. Several papers were published in the late 1980s in which some of these systems were used as model membrane media for NMR studies of biomolecules trapped in the aligned phases [29–31].
4. The utility of using aligned samples to facilitate measurement of solid-state NMR spectra was already well established (c.f. [32, 32–38]). However, there were limitations and drawbacks associated with existing methods of alignment, providing impetus for bicelle development.
5. The need for methods to attain weak magnetic alignment of molecules for NMR was already manifest. It had been demonstrated in the 1960s that even for highly mobile molecules yielding sharp line widths, induction of too high a degree of molecular alignment leads to NMR spectra of almost unfathomable complexity [39,40]. Later, Bothner-By and co-workers demonstrated the marginal unimolecular alignment of small molecules by very high magnetic fields [41], while MacLean had explored the use of electric fields for the same purpose [42]. Under conditions of marginal alignment, spectral complexity is manageable, so that structurally useful anisotropic parameters such as dipolar couplings can easily be measured. This set the stage not so much for initial bicelle development as for the later application of bicelles as a matrix for soluble protein alignment introduced in 1997 by Tjandra and Bax (see below).

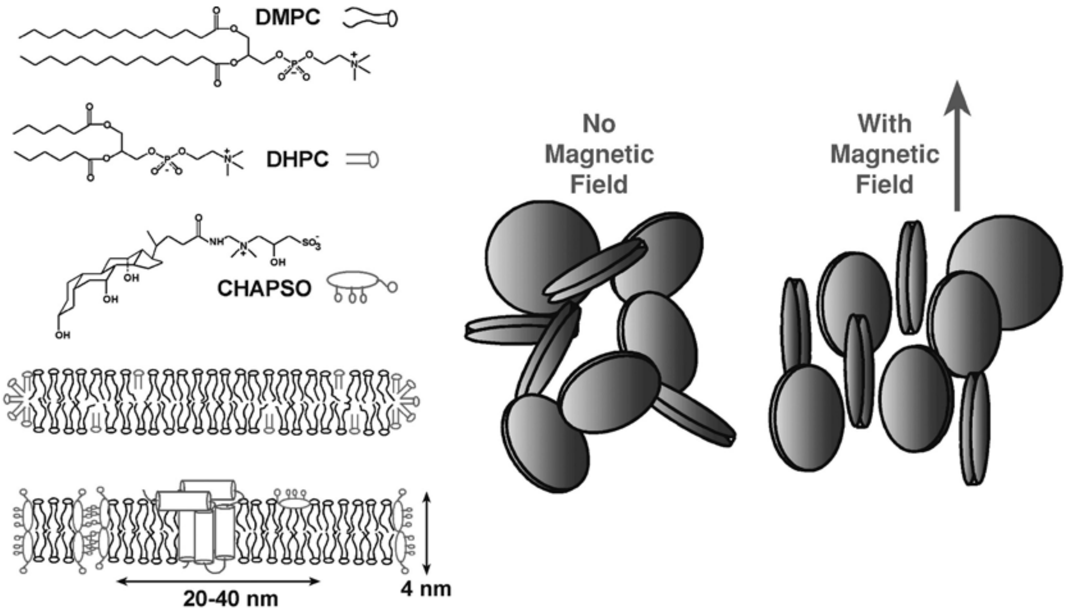

Fig. 1. Classical model for bicellar DMPC-CHAPSO and DMPC-DHPC assemblies (left) and for magnetic alignment of bicelles (right). This figure is reprinted from Sanders CR, Prosser RS. *Structure*. 1998;6:1227–1234 [6] with permission from Elsevier. (See also Plate 27 on page XXIX in the Color Plate Section.)

Early 1990s

Following the original report of bicelle alignment, anionic bile salts were replaced with a mild zwitterionic bile salt derivative, CHAPSO, to yield CHAPSO-dimyristoylphosphatidylcholine (DMPC) mixtures that were observed to be magnetically alignable over a wide range of compositions and temperatures [43]. Moreover CHAPSO-DMPC mixtures were non-denaturing toward soluble proteins. This system was soon employed as a model membrane medium in studies of a number of lipids [44–49]. It was also observed that the usual 90° orientation of CHAPSO-DMPC bicelles in a magnetic field could be flipped to align the bilayer normals with the field by adding certain amphiphilic aromatic hydrocarbons [50].

In 1992, the nascent Sanders lab at Case Western Reserve University introduced bicelles in which bile salt derivatives used in the original bicelle system were replaced by dihexanoyl-PC (DHPC) [51]. Part of the motivation for developing DHPC/DMPC bicelles arose from the fact that the NMR facilities then present at Case were 1970s-vintage. The bicelle project was among the most interesting NMR projects the author could think of that was feasible using such out-of-date instrumentation! This work built upon previous characterization of short-chain phosphatidylcholine micelles and their interactions with phospholipids carried out by the lab of Mary Roberts in Boston [52–55]. DHPC/DMPC mixtures were observed to undergo magnetic alignment over a wide range of compositions. Similar to CHAPSO/DMPC bicelles, alignment was observed to occur only above the gel-to-liquid crystalline phase transition of DMPC—below this temperature both CHAPSO/DMPC and DHPC/DMPC bicelles become isotropic.

^{31}P, ^{13}C, and ^{2}H NMR studies indicated that the dynamics and conformations of the phosphatidylcholine molecules present in the bilayered domain of aligned bicelles are quite similar to those present in bilayered L_α-phase vesicles [56]. It was also demonstrated that the activity of an integral membrane enzyme, diacylglycerol kinase (DAGK), could be supported when this protein was reconstituted into bicelles [1,57]. Most of the DAGK molecule is bilayer-embedded and one of its substrates is a lipid. Moreover, its active site is believed to lie at the water-membrane interface. Therefore, DAGK's functional reconstitution provided a strong biochemical validation of the use of bicelles as model membranes.

In the mid-/late 1990s, the first reports of membrane protein alignment using bicelles were reported for surface-associated membrane proteins [1,58–61] as well as for integral membrane proteins [1,62]. For surface-associating membrane proteins, motion, and orientational disorder are often quite high, such that NMR spectra of very high quality (narrow lines) have been obtained. For transmembrane proteins, the number of spectra reported using aligned bicelles of both the conventional and flipped (see below) variety remains fairly small (cf. [63–65]), although there seems to be renewed interest in exploring the potential of bicelles as a medium for solid-state NMR studies of transmembrane proteins [66].

Late 1990s

Vold, Prosser, and and co-workers made two seminal contributions to bicelle development in the late 1990s. First, they introduced the use of paramagnetic lanthanide ions to induce a change in sign of the anisotropy of magnetic susceptibility of bicelles, such that magnetic alignment takes place with bilayer normals parallel to the field direction [67]. This was an important development because it provided a means by which oriented-sample spectra could be obtained from bicelle-associated molecules even in the absence of rapid rotation around the bilayer normal. Not only was it shown that lanthanide ions confer parallel alignment, but ion-chelating lipids were developed in order to sequester the bicelle-associated ions to prevent unwanted free radical or oxidative chemistry that might damage bicellar molecules [68,69]. A second important contribution of Vold and Prosser was to explore and advocate the use of isotropic bicelles as a medium for solution state NMR of membrane proteins [59,70], which continues to be an area of interest [71]. Isotropic bicelles form below the gel-to-liquid crystalline phase transition of the lipid component of bicelles and at relatively high detergent-to-lipid ratios.

By 1997, it had been demonstrated that biomacromolecules could be magnetically aligned to a degree which allowed many small dipolar couplings to be measured [72–75], heralding the now widespread acquisition and utilization of residual dipolar couplings in solution NMR-based structural analyses. However, unimolecular alignment required both that very high magnetic fields be employed and (usually) that the protein of interest must contain a tightly associated paramagnet in order to provide sufficient magnetic susceptibility. It was therefore a very important development in the field of biomolecular NMR when Bax and Tjandra showed that bicelles could be used as an alignment matrix for water soluble biomolecules [75,76]. Not only was this method widely applicable, it also provided a means by which the degree of alignment could be tuned by varying bicelle/buffer composition. Following this breakthrough were several developments: (1) Classical bicelle mixtures were improved by extending their temperature range and enhancing their chemical and morphological stability [77–83]. (2) The use of additives to bicelles was investigated for a variety of purposes [67–69, 84–93]. For example, by varying bicelle surface charge it is sometimes possible to vary the alignment tensor of the guest proteins, a great advantage for downstream structural calculations. (3) The use of various membranes and liquid crystals has been explored or re-explored, leading to the introduction of alternative membrane-like systems for achieving magnetic alignment of biomolecules [78,84,93–98]. (4) Radically different methods for attaining molecular alignment were developed [95,99–109] such as the use of magnetically aligned phage particles and the use of strained polyacrylamide gels. These methods have been particularly significant for those biomolecules that interact with bicelles and related systems in such a manner that the degree of molecular alignment is too high for solution NMR. Alternative methods of alignment are also welcome in cases where the bicelle matrices are disrupted by the biomolecular solute, or where the structure of the solute of interest is perturbed by bicelles.

2000–2005

The past few years have seen three particularly interesting developments. First, bicelles have been employed in biostructural studies extending beyond the realm of NMR spectroscopy. Lorigan and co-workers have embarked upon a continuing exploration of bicelles as a medium in which to conduct EPR spectroscopy [110–118]. Moreover, James Bowie's lab has shown that polytopic membrane proteins can be crystallized from bicellar mixtures, leading to high-resolution X-ray crystal structures of polytopic integral membrane proteins [119]. The bicelle crystallization approach offers a distinct alternative to crystallization using classical detergent or lipidic cubic phases as the host model membrane medium for the membrane protein of interest. It will be extremely interesting to see whether a range of membrane proteins can be crystallized from bicelles or whether only a few membrane proteins prove to be susceptible to this approach.

A second innovation associated with bicelles is the exploration by several labs of the potential of combining the use of bicelles with rapid sample spinning methods at various sample rotation angles with respect to the magnetic field [120–127]. This work builds upon previous work by a number of labs in which the physics and spectroscopy of liquid crystals under conditions of rapid sample spinning have been explored [128]. The use of rapid sample spinning methods in conjunction with bicelles offers exciting possibilities for manipulating sample orientation and effective orientational order in conjunction with the application of sophisticated solid-state NMR pulse technology.

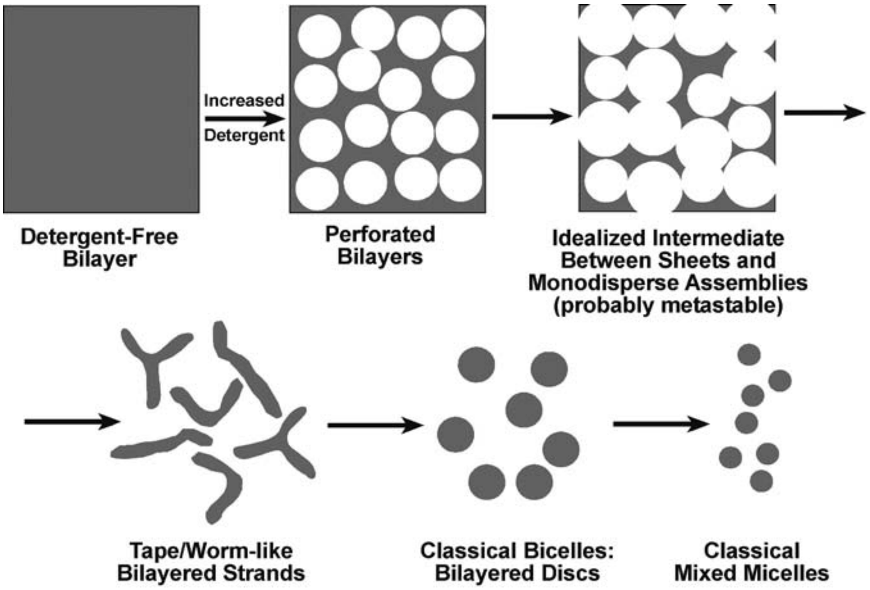
The other major development in the years leading to 2005 is that the classical "bilayered-disk" model for bicelle aggregate morphology has been challenged. Early characterization of bicelles was almost exclusively NMR in nature. An "Occam's razor" approach was used to argue that the bilayered-disk model (Figure 1) was the most reasonable model that could account for the available NMR data for magnetically alignable bicelles (review in [6,9]). However, the bilayered-disk model could not easily explain the very high viscosity of bicelle mixtures under conditions where magnetic alignment can take place. It was also hard to explain why, for a given bicelle composition, aligned bicelle order remains fairly constant over a wide range of total lipid + detergent content (5–40%, by weight).

Based on more recent, often non-NMR data, from the labs of Katsaras and others it now appears clear that the bilayered-disk model is inadequate to describe all of the detergent-lipid assemblies that fall within compositions typically described as being bicellar—particularly for compositions and temperatures at which magnetic alignment can take place [71,129–137]. While this work is ongoing, it appears that at higher lipid-to-detergent ratios, bicelle morphology can be likened to that of Swiss cheese-like perforated bilayered-lipid sheets. As the detergent-to-lipid ratio is increased, the sheets most likely break up into interconnected bilayered tape-like strands. Continuing to increase detergent content then leads to discoidal bilayer fragments and, finally, to classical mixed micelles (Figure 2).

Recently, Sligar and co-workers have developed bilayered-discoidal aggregates referred to as "nanodiscs" that are composed of mixtures of lipids with amphipathic lipoprotein mimetics [138–140]. These aggregates appear to conform quite closely to the classical bicelle morphology over a wide temperature range. To our knowledge, the potential that nanodisc mixtures can be magnetically aligned has yet to be tested.

Conclusion: How Good are Bicelles as Model Membranes?

The above emerging model for bicelles in which several different morphologies are possible, depending on exact composition and temperature, is very tentative. It will take much time and effort to use multiple techniques to systematically explore the very wide range of temperature and composition space that is inhabited by mixtures falling within the "bicelle" regime. In the meantime, it is likely that bicelles will continue to be employed as model membranes for biophysical studies of membrane-associated molecules. For any class of model membrane, it is reasonable to consider to what extent "native membrane" conditions are reflected by the model system. This question can be experimentally addressed in four ways. First, for a molecule of interest, structural measurements may be repeated in more than one type of bicelle [141]. If the same structural conclusion is reached in multiple systems, the notion that structure is native-like is supported. Second,



Increased
Detergent
Detergent-Free Bilayer
Perforated Bilayers
Idealized Intermediate Between Sheets and Monodisperse Assemblies (probably metastable)
Tape/Worm-like Bilayered Strands
Classical Bicelles: Bilayered Discs
Classical Mixed Micelles

Fig. 2. Emerging model for morphological transitions occurring in bicelle mixtures as detergent is added to a fixed amount of lipid. The view is looking down onto the bilayer surface. The highly tentative nature of this model is emphasized.

measurements may be repeated as the lipid:detergent ratio is increased [1,141]. By extrapolating anisotropic parameters to a detergent-free limit, it is possible to estimate structural parameters for the solute of interest in lipid bilayers in the absence of detergent. Third, if a solute has an assayable function, a test for native-like function may be carried out under bicellar conditions [57]. Finally, direct verification that a bicelle-derived structure is the same as the structure solved under non-bicellar conditions may sometimes be possible [119]. The limited data generated thus far from these types of control experiments are extremely encouraging in affirming that bicelles typically maintain the native-like structure and dynamics of guest molecules.

Nuclear Magnetic Resonance of Oriented Bilayer Systems

Akira Naito, Shuichi Toraya, and Katsuyuki Nishimura
Graduate School of Engineering, Yokohama National University, Hodogaya-ku, Yokohama 240-8501, Japan

Introduction

It is important to elucidate the membrane bound structure of biologically active molecules such as membrane associated peptides and membrane proteins. It is also realized that not only the structure but also the orientations are important factors to understand the biological activity of the molecules. To obtain the information of structure and orientation for the biomolecules bound to membrane, it is useful to uniformly align the membrane in the NMR spectrometer related to the magnetic field direction. Because a number of peptides and membrane proteins are strongly bound to membrane, these biomolecules can also be aligned to the magnetic field provided that the lipid bilayers are aligned to the magnetic field.

The ordering of the lipid bilayers with respect to the magnetic field can be achieved in one of two ways as shown in Figure 1. First, lipid can be macroscopically oriented by pressing lipid–water dispersions between flat glass plates, thus orienting the membrane microdomains by mechanical shearing forces [1–3]. This method has advantages to change the direction of alignment by rotating the supporting glass plate in the magnetic field. This is important because the resolution in the sample is largely depending on the orientation. Second, lipid molecules themselves can be aligned spontaneously to the magnetic field because of their diamagnetic anisotropy [4,5]. This spontaneously magnetically oriented bilayer system has advantages over the mechanically oriented bilayer systems because they show a highly hydrated state compared with the mechanically oriented bilayer systems. Since spontaneously oriented system does not need to use glass plate, it has large filling factor in the receiver coil of the probe and hence higher sensitivity can be expected over the mechanically oriented systems.

Magnetically Oriented Bilayer Systems

Magnetic ordering of lipid bilayers has been reported for pure and mixed phosphatidylcholine bilayers [6–8], including melittin-phospholipid systems [9–12]. Subsequently, such magnetic ordering has been reported in a detergent/lipid mixture called a bicelle [13–15], which was shown to be oriented in the magnetic field by the negative magnetic anisotropy of the lipid acyl chain [16]. Therefore, acyl chain tends to orient perpendicular to the magnetic field if a large number of lipid molecules are ordered in the liquid crystalline phase to possess a sufficient degree of magnetic anisotropy to align the lipid bilayers along the magnetic field.

Principle of Spontaneous Magnetic Orientation

Because small molecules usually have diamagnetic anisotropy, they have different magnetic moments depending on the molecular orientation with respect to the strong magnetic field. Thus, molecules in the magnetic field have a preferential orientation in the magnetic field. However, magnetic alignment of the small molecule cannot be observed because the orientation of the molecule can be easily disturbed by much larger thermal energy.

The interaction of the diamagnetic anisotropy with the magnetic field is given by

$$F = -\left(\frac{1}{2}\right) H_0^2 \left\{\chi_\perp + (\chi_{||} - \chi_\perp)\cos^2\theta\right\}, \tag{1}$$

where F is the interaction energy, and $\chi_\perp$ and $\chi_{||}$ are the perpendicular and parallel components of the magnetic susceptibility, respectively. θ is the angle between the $\chi_{||}$ and the magnetic field. Therefore, orientation energy of the lipid bilayer with N number of lipids is expressed as

$$N\Delta F = -\left(\frac{1}{2}\right) N\Delta\chi H_0^2, \tag{2}$$

where, $\Delta F = F(\theta = 0^\circ) - F(\theta = 90^\circ)$ and $\Delta\chi = \chi_{||} - \chi_\perp$. In the case of phospholipid molecule, negative value, $\Delta\chi = -2 \times 10^{-6}\mathrm{erg/G^2/mol^2}$, is reported [16]. Therefore, lipid molecule tend to be oriented with the unique molecular axis perpendicular to the magnetic field, namely parallel to the bilayer normal because $\Delta\chi$ has negative value for phospholipids. If N is a small number, the orientation energy is again not strong enough to align the macrodomain of lipid bilayer because the thermal energy, kT, tend to disturb the alignment of molecules. In the case of phospholipid bilayers at room temperature,

macrodomain of lipid containing 10^6 number of lipid molecules can be spontaneously aligned to the magnetic field. Because orientation energy is proportional to the square of magnetic field, one can expect that a higher-order alignment can be achieved in the very strong magnetic field. This fact is very promising for getting better alignment of the magnetically oriented system because a strong magnetic field is now demanding.

Bicelle

When phospholipid was mixed with a kind of detergent, CHAPSO (3-((3-cholamidopropyl)dimethylammonio)-2-hydroxyl-propane sulfonate) or phospholipid with short acyl chain, dihexanoylphosphatidylcholine (DHPC) with the range of molar ratios from 2:1 to 5:1, edges of bilayers are surrounded by CHPSO [13] or DHPC [14] to form discoidal shape of particle called bicelle [15]. The bicelle is known to be aligned spontaneously to the magnetic field [13,14]. The diameter of the biclelle is about 400 Å, and hence 5000–10,000 of lipid molecules consist of the bicelle [17]. Thus, one bicelle particle has no sufficient orientational energy to be aligned to the magnetic field. It is reported that bicelle particles are stacked each other as disclosed from the small angle X-ray scattering experiments [18]. In this case, if more than 100 bicelles are associated with each other, whole body of bicelle aggregates can have a sufficient orientational energy and the bilayer planes are oriented parallel to the magnetic field (Figure 1B). The degree of magnetic ordering of the bicelle is known to be independent of their concentration in the diluted bicelle media [19] because the associated aggregate is formed even in the diluted solution [18].

When the lanthanide ions, Eu^{3+}, Er^{3+}, Tm^{3+}, or Yb^{3+}, are mixed in the bicelle systems, orientation of bicelle altered 90° to the magnetic field because the magnetic anisotropy of the lanthanide metal has positive and much larger than the diamagnetic anisotropy. This metal is associated with the phosphate group of lipid molecule to cause the positive anisotropy in the bicelle particle leading to the 90° alternation of the orientation as shown in Figure 1B [20,21].

Magnetically Oriented Vesicle Systems

Spontaneous magnetic orientation of lipid bilayer to the external magnetic field has been observed in pure phosphatidylcholine and mixed phophatidylcholine systems [4–8]. In these systems, partly extended vesicles are formed as shown in Figure 1C and the long axis is aligned parallel to the magnetic field [16]. ^{31}P NMR spectra clearly show that in the moderately high concentration of melittin incorporated into the dimyristoylphosphatidylcholine (DMPC) bilayer (DMPC/melittin = 10:1 molar ratio), the bilayer shows lysis and fusion at temperatures lower and higher than the T_c. Above the T_c, giant vesicles were observed for the melittin-DMPC bilayer systems [12]. This lipid bilayer systems shows the very high magnetic ordering at a temperature higher than the T_c. Therefore, it is suggested that elongated bilayer vesicles rather than discoidal bilayers are formed above the T_c in the case of the melittin-DMPC bilayer systems, in which most of the surface area of the bilayers is oriented parallel to the magnetic field, as shown in schematically in Figure1 C. Thus, a large magnetic anisotropy can be induced because most of the phospholipids, which have negative magnetic anisotropy along the acyl chain axes, are aligned perpendicular to the magnetic field by forming elongated vesicles. Since the sizes of the vesicles are the diameter of 20 μm, one vesicle can have enough orientational energy, in contrast to the case of bicelles.

This kind of magnetically oriented system is also formed in DMPC-dynorphin bilayer systems [22]. The line shape of the elongated vesicle for the DMPC-dynorphin has been analyzed by looking at the line shape of the ^{31}P NMR spectra of the elongated vesicle. Line shape of the ^{31}P NMR spectra clearly indicates that the long axis of the elongated vesicle is at least 5 times longer than the short axis.

It is important to point out that the process of lysis and fusion is a prerequisite to allow the orientation of lipid bilayers to the magnetic field. It is also found that membrane surface in the DMPC-melittin system is flexible near at T_c, indicating that the vesicle shape can be reformed to the elongated shape in the magnetic field [23].

Mechanically Oriented Bilayer Systems

Oriented Bilayer on the Glass Plates

Mechanically aligned lipid bilayer system, which is established by casting the lipid bilayer on the glass plate followed by hydrated under high humidity environment [1–3,24]. In this system acyl chain can be aligned perpendicular to the glass plate (Figure 1A). The protein–lipid mixture can be prepared by reconstituting the purified protein or peptide either in an organic solvent followed by solvent removal. The protein–lipid mixture are deposited on the glass slides to form a thin film of sample material, and the solvent is subsequently evaporated. Typically, 10–40 slides are then stacked on top of each other to achieve the required amounts needed for NMR experiments. On hydration and annealing under an atmosphere of controlled humidity, typically several thousands of oriented bilayers form between each pair of slides. Finally, prior to performing the solid-state NMR experiments, the sample is sealed to maintain the hydration levels of the lipid bilayers during experimentation. It is advantageous to use this mechanically aligned lipid bilayer system, because it is possible to align the lipid bilayer surface in any orientation with respect to the magnetic field. Disadvantage of this bilayer system is a low filling factor because of the presence of glass plate in the NMR coil leading a low sensitivity for obtaining NMR signals.

Magic Angle-Oriented Sample Spinning Experiment

Mechanically oriented sample can be prepared on circular plate and can be mounted inside a rotor [25]. Bilayers can also be spread on polymer sheets and rolled up with their central axis collinear with the spinning axis at the magic axis (Figure 1A) [26]. When magic-angle spinning (MAS) is applied to these oriented samples (magic angle-oriented sample spinning, MAOSS), the spinning side band intensities are sensitive to partial or complete ordering within the samples [25]. This technique is useful to investigate the alignment and membrane interactions of phospholipids, peptides, or proteins within oriented bilayer samples [27–29]. Due to the suppression by the support of membrane undulation that occur on a slow timescale, the spectral line width of these samples is considerably reduced and resolution concomitantly improved.

Orientation Dependence of Chemical Shift Interaction

Orientation of peptides bound to the magnetically aligned lipid bilayer can be discussed by looking at the chemical shift anisotropy of the carbonyl carbon in the backbone in the peptide chain. Chemical shift tensors of the carbonyl carbons are well characterized as shown in Figure 2. When the peptide is completely rigid, 150 ppm of anisotropy will be observed in low-temperature experiment. On the other hand, when the temperature is increased to T_c, molecules have large amplitude motion about the bilayer normal. In this case, axially symmetric powder pattern is seen as shown in Figure 2b. Since bilayers tend to align to the magnetic field, slow MAS experiment can be applied to give an axially symmetric powder pattern. It turned out that the molecule actually reorientational motion about the bilayer normal because the axially symmetric pattern was seen in the DMPC-melittin bilayer systems [12]. When the spinning was stopped, lipid bilayer will be spontaneously oriented to the magnetic field and the membrane bound molecule also align to the magnetic field. In most case, membrane bound biomolecule rotates about the membrane normal because of the lateral diffusion of the lipid molecule in the liquid crystalline phase. In the case of melittin, entire molecule form α-helix in the membrane bound state and the helix axis is rotated about the bilayer normal with the tilt angle of ζ and the phase angle γ. Under this dynamic state, the chemical shift anisotropy, $\Delta\delta = \delta_{||} - \delta_{\perp}$ can be expressed as [30]

$$\Delta\delta = \frac{3}{2}\sin^2\varsigma\left(\delta_{11}\cos^2\gamma + \delta_{33}\sin^2\gamma - \delta_{22}\right) + \left(\delta_{22} - \frac{\delta_{11}+\delta_{33}}{2}\right). \qquad (3)$$

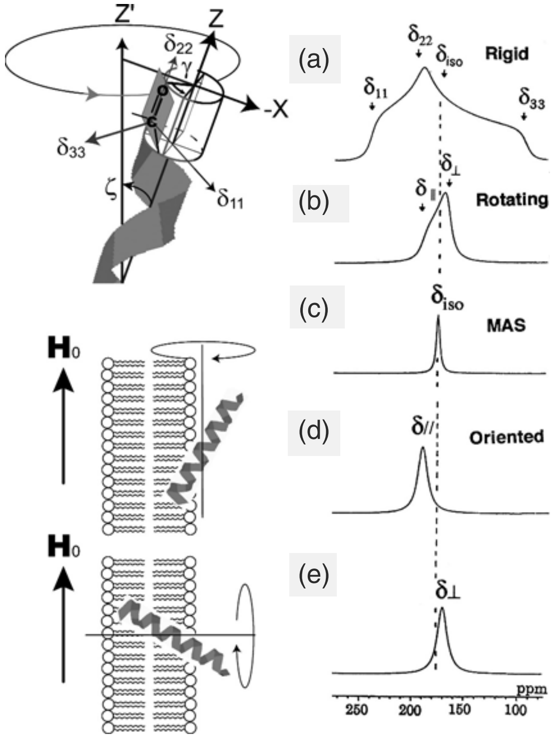

Fig. 2. Direction of the principal axis of the ^{13}C chemical shift tensor of the C = O group, the helical axis, and the static magnetic field (H_0), and ^{13}C NMR spectral patterns of the C = O carbons corresponding to the orientation of the α-helix with respect to the surface of the magnetically oriented lipid bilayers. Simulated spectra were calculated using $\delta_{11} = 241$, $\delta_{22} = 189$, and $\delta_{33} = 96$ ppm for the rigid case (a), rotation about the unique axis (slow MAS) (b), magic-angle spinning (c), magnetic field parallel to the unique axis (d), and magnetic field perpendicular to the magnetic field (e).

In this equation, $\Delta\delta$ values oscillate in the function of γ with the oscillation amplitude of (3/2) $\sin^2\zeta$, that is referred to the chemical shift oscillation [30]. When the α-helical peptide has a large tilt angle, $\Delta\delta$ value changes a large extent as shown in Figure 3. Using this property of $\Delta\delta$, the tilt angle of the α-helix with respect to the bilayer normal can be determined by comparing the anisotropic patterns of carbonyl carbons of consecutive amino acid residues which form α-helix, with the chemical shift values of the corresponding magnetically aligned state (Figure 4). When the peptide is formed an ideal α-helix structure, it can be assumed that the inter-peptide plane angle for consecutive peptide planes is 100°. This tilt angle can be accurately obtained by taking root mean-square deviation (RMSD) values between the observed

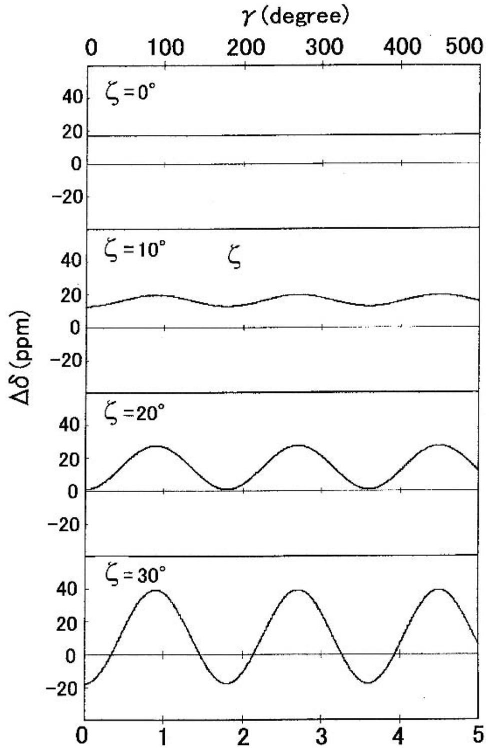

Fig. 3. Plot of chemical shift anisotropy, $\Delta\delta = \delta_{\|} - \delta_{\perp}$ against the phase angle, γ, of the peptide plane for the consecutive amino acid residues as a function of the tilt angles, ζ.

and calculated a chemical shift anisotropy as given by

$$\mathrm{RMSD} = \left[\sum_{i=1}^{N} \left\{ (\Delta\delta_{\mathrm{obs}})_i - (\Delta\delta_{\mathrm{cal}})_i \right\}^2 \Big/ N \right]^{1/2}. \tag{4}$$

Actually, the tilt angles were determined to be −33° and −36° for the N-terminals and 21° and 25° for the C-terminals in the melittin molecule bound to dilauroylphosphatidylchpline (DLPC) and dipalmitoylphosphatidylcholine (DPPC) vesicles (Figure 4) [30].

Orientation Dependence of Dipolar Interaction

Similar information can be obtained by looking at ^{15}N–^{1}H dipolar interaction of the peptide backbone. Polarization Inversion Spin Exchange at the Magic Angle (PISEMA) experiment is a kind of separated local field 2D NMR experiment and gives the excellent resolution for the dipolar dimension in the correlation spectra between ^{15}N chemical shift values and ^{15}N–^{1}H dipolar interaction [31]. It is of interest to note that a characteristic circle pattern, called Polarity Index Slant Angle (PISA) wheels, is seen when α-helix is formed in the membrane and the shape of wheel is sensitive to the tilting angle of the α-helix with respect to the bilayer normal [32–34]. When one observes this PISA wheel, one can evaluate the amino acid residues involved in the α-helix even if amino acid sequence is not known.

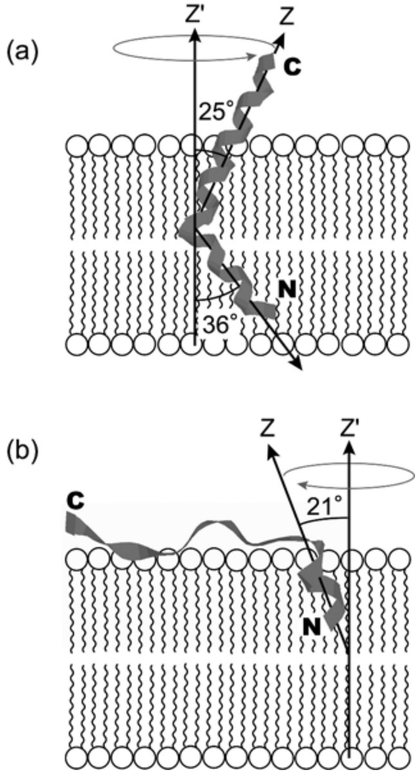

Fig. 4. Schematic representation of the structures and orientations of melittin (a) and dynorphin (b) bound to lipid bilayers. The N- and C-terminal helices are inserted into the bilayers with the tilt angles of (36° and 33°) and (25° and 21°), respectively for melittin. The N-terminal helix inserted into the lipid bilayer with the tilt angle of 21° and the center to the C-terminal show disordered and lies on the surface of the lipid bilayers.

Membrane bound form of the coat protein possesses two distinct domains, a TM helix as well as an amphipathic helix lying on the membrane surface [35]. In contrast, when embedded in the phage particle, the protein forms a single, almost straight α-helix. To solve the assignment problem inherent to the uniformly ^{15}N-labeled samples used for this study, a “shotgun” approach was employed [36]. By analyzing a spectra with a small number of labeled sites from protein samples, which were sparsely ^{15}N-labeled in only one type of amino acid, the complete assignment of PISEMA spectra from uniformly ^{15}N-labeled samples became accessible. This is possible because secondary structure elements, such as α-helices, are mapped to characteristic patterns in the PISEMA spectrum, and a few connectivities between these two representations of the protein structure are sufficient to correlate both. In the case of the filamentous coat protein, the concept of dipolar waves was used to characterize the details in the helix structure. By plotting the ^{15}N–^{1}H dipolar coupling as a function of residue number, an oscillatory pattern becomes apparent. The amplitude, pitch, and offset of these dipolar waves characterize the local structure of helix segments, and regions with different orientation as well as a small helix could be identified.

Structure Determination of Membrane Associated Peptides in the Magnetically Oriented Systems

Dynamic structure of melittin bound to the MOVS consisting of DPPC and DLPC were investigated by analyzing the ^{13}C anisotropic and isotropic chemical shifts of selectively ^{13}C-labelled carbonyl carbons of melittin under the static and MAS conditions [30]. These results indicate that melittin molecules adopt an α-helix structure and laterally diffuse to rotate rapidly around the membrane normal with tilt angles of the N-terminal helix being -33° and -36° and those of the C-terminal helix being 21° and 25° for DLPC and DPPC vesicles, respectively Figure 4a. Although RMSD method successfully determined the tilt angle, ζ and $-\zeta$ cannot be distinguished because of the symmetry relation of Equation (3). Then the rotational echo double resonance method was used to measure the interatomic distance between [1-^{13}C]Val^{8} and [^{15}N]Leu^{13} to further identify the bending α-helical structure of melittin to posses the interhelical angle of 126° and 119° in DLPC and DPPC membranes, respectively. These analyses further lead to the conclusion that α-helices of melittin molecule penetrate the hydrophobic core of the bilayers incompletely as a pseudo-transmembrane structure and indicate fusion and disruption of vesicles.

Secondary structure and orientation of dynorphin bound to DMPC bilayer systems were investigated by solid-state ^{13}C NMR spectroscopy [37]. For this purpose, ^{13}C NMR spectra of the site-specifically ^{13}C-labeled dynorphin were measured in the membrane bound state under static, MAS and slow MAS conditions. It was found that dynorphin adopts an α-helical structure in the N-terminus from Gly^{2} to Leu^{5} by analysis of the isotropic chemical shift obtained from the MAS experiments. In contrast, it adopts disordered conformations from the center to the C-terminus and is located on the membrane surface. The static ^{13}C NMR spectra indicated that MOVS-bound dynorphin was oriented to the magnetic field and rotated rapidly about the bilayer normal. Subsequently, the ^{13}C chemical shift tensor of carbonyl carbons in the peptide backbone was considered by the rotational motion of the N-terminal α-helix. It was revealed that the N-terminal α-helix is inserted into the membrane with the tilt angle of 21° to the bilayer normal as shown in Figure 4b. This structure suggests a possibility that dynorphin interacts with the extracellular loop II of the k-receptor through a helix–helix interaction.

Dynorphin-DMPC MOVS was used as a oriented media to gain insight into the orientation of a transmembrane peptide [1-^{13}C]Ala^{14}-labeled A(6–34) of bacteriorhodopsin. It was found from the ^{13}C NMR spectra that the helical axis of A(6–34) is oriented parallel to the bilayer normal irrespective of the presence and absence of reorientational motion about the helical axis at temperatures above and below the gel to liquid crystalline phase transition temperature [38].

The membrane-disruptive antimicrobial peptide PGLa is found to change its orientation in a DMPC bilayer when its concentration is increased to biologically active levels [39]. The alignment of the α-helix was determined by observing ^{19}F dipolar couplings on CF$_3$-labeled side chains in ^{19}F solid-state NMR, and supported by a non-perturbing ^{15}N label. At a low peptide lipid ratio of 1:200, the amphiphilic peptide resides on the membrane surface in the so-called S-state. However, at high peptide concentration (>1:50 molar ratio) the helix axis changes its tilt angle from about 95° to approximately 125°, with the C-terminus pointing toward the bilayer interior. This tilted "T-state" represents a novel feature of antimicrobial peptides, which is distinct from a membrane inserted I-state. At intermediate concentration, PGLa is in exchange between the S- and T-states in the timescale of the NMR experiment. In both states the peptide molecules undergo fast rotation around the membrane normal in liquid crystalline bilayers, hence large peptide aggregates do not form. Very likely the obliquely tilted T-state represents an antiparallel dimmer of PGLa that is formed in the membrane at increasing concentration.

Conclusions

It is clearly demonstrated that oriented bilayer media can give useful information on structure, orientation, and dynamics of biologically active peptides which are strongly bound to the membranes. Spontaneously oriented bilayer system such as MOVS is shown to be an excellent media to study membrane associated peptides because they show excellent magnetic alignments of molecules bound to the membranes if one carefully prepare the sample. Since the magnetic field will be going higher by the development of higher field magnet, the magnetic alignment of molecule bound to membrane will be much promising in the future. Mechanically aligned bilayer system will be a very good media since one can adjust the orientation to get more information on the membrane bound molecules. The combination of glass aligned sample with the MAS provide high-resolution signals in the oriented systems to provide more information of the structure of membrane associated biologically active molecules.

Solid-state NMR spectroscopy is widely applicable to the investigation of non-crystalline or amorphous materials, e.g. polymers, glasses, protein precipitates, and membrane proteins. Rather than being mainly an alternative to X-ray crystallography, solid-state NMR is virtually unique among current analytical and spectroscopic methodologies in that it provides both structural and dynamical information at an atomically resolved level. In solid-state NMR, the structural information is obtained from the static or motionally averaged coupling tensors due to dipolar, chemical shift, or quadrupolar interactions [1,2]. Corresponding dynamical information is acquired from the tensor fluctuations, which depend on the mean-squared amplitudes and rates of the motions and affect the NMR lineshapes and relaxation times. For these reasons, solid-state NMR is finding increasing applicability in the chemistry of materials, structural biology, and genomics research, and this trend can be expected to continue well into the future.

One area of solid-state NMR spectroscopy that has proven fruitful with regard to the investigation of membranes is ^{2}H NMR spectroscopy. Previous detailed reviews of ^{2}H NMR as applied to membrane lipids are available [3–7]. Recently, ^{2}H NMR has been used to investigate raft-like lipid mixtures implicated in membrane signaling functions [8–10], and moreover ^{2}H NMR studies of membrane proteins [11–15] and DNA fibers [16] have also been conducted. The present chapter is focused on the liquid-crystalline state of membrane lipids as investigated from combined ^{2}H NMR lineshape and relaxation studies. A related aspect entails the correspondence of ^{2}H NMR studies to molecular dynamics simulations [17]. The salient aspects of ^{2}H NMR are that it enables both membrane lipids and membrane proteins to be studied by substitution of ^{2}H for ^{1}H; the structural data are highly complementary to X-ray [18–21] and neutron diffraction studies [22,23], and virtually unique information regarding the functional dynamics of membrane constituents can be acquired.

Equilibrium and Dynamical Properties of Membrane Lipids are Studied by Solid-State Deuterium NMR

Phospholipid bilayers are classified as smectic A lyotropic liquid crystals, and an illustration of the liquid-crystalline lamellar phase is shown in Figure 1. The hydrophobic effect leads to a sequestering of the nonpolar acyl chains within the bilayer interior, whereas the polar head groups interact with water at the membrane surface. The nanostructure of a membrane lipid aggregate is the result of a delicate balance of forces acting at the level of the polar head groups and hydrocarbon regions of the membrane [24–27]. Representative glycerophospholipids are depicted in Figure 2, in which the polar head groups differ in their size, capacity for hydrogen bonding, and charge, whereas the nonpolar acyl chains vary in their length and degree of unsaturation. The phase equilibria of phosphatidylcholines in excess water include three regions as temperature increases, a lamellar gel phase with tiled chains ($L_{\beta}{}'$), an intermediate ripple phase ($P_{\beta}{}'$), and a lamellar liquid-crystalline phase (L_{α}) [25]. Other types of phospholipid nanostructures are possible, for instance unsaturated phosphatidylethanolamines form the reverse hexagonal (H_{II}) phase, and cubic phases can also be present [25]. Moreover, when cholesterol is present lipid mixtures can form condensed complexes [28], microdomains [29], or undergo phase separation [30] which may be associated with rafts and caveloae in cellular membranes [31].

An important feature of ^{2}H NMR spectroscopy is that one introduces site-specific ^{2}H labels, corresponding to the individual C–^{2}H bonds, and in this way obtains atomically resolved information for liquid-crystalline systems. In liquid-crystalline membranes, the residual quadrupolar couplings correspond to the segmental order parameters of the flexible molecules—they can be directly measured as experimental observables. Moreover, the nuclear spin relaxation rates can be determined, e.g. the relaxation of

Zeeman order (R_{1Z}) or quadrupolar order (R_{1Q}), which depend on the molecular mobility. By combining ^{2}H NMR order parameter measurements with relaxation studies, one can probe the structural fluctuations of fluid membrane lipids that give rise to averaging of the coupling tensors in solid-state NMR spectroscopy.

Deuterium NMR Spectroscopy Allows Direct Observation of Coupling Tensors Related to Molecular Structure and Dynamics

Besides the Zeeman interaction of the nuclear spin with the external magnetic field, additional perturbations are due to magnetic interactions (dipolar coupling, chemical shift) and electric interactions (quadrupolar coupling). These couplings provide a wealth of information regarding both the structure and dynamics of biomolecular systems. Generally speaking the principal values and principal axis systems (PAS) of the various coupling tensors yield structural knowledge, whereas their fluctuations give rise to spectral transitions, and are related to the dynamics of the system of interest.

Deuterium NMR spectroscopy is particularly valuable as an illustration of the principles of solid-state NMR as applied to molecular solids, liquid crystals, and biomembranes [32]. This is because a single coupling is very large—the electric quadrupolar interaction dominates over the magnetic dipolar couplings of the ^{2}H and ^{1}H nuclei, as well as the ^{2}H chemical shifts. The ^{2}H nucleus has a spin of $I = 1$, and hence there are three Zeeman energy levels corresponding to the projection of the nuclear spin angular momentum, with eigenstates $|m>=|0\rangle, |\pm1\rangle$ given by the Hamiltonian $\hat{H}_Z$. According to quantum mechanics, transitions between the adjacent spin energy levels are allowed giving two single-quantum nuclear spin transitions. In ^{2}H NMR the degeneracy is removed due to the coupling of the quadrupole moment of the ^{2}H nucleus with the electric field gradient (EFG) of the C–^{2}H bond, as given by the Hamiltonian $\hat{H}_Q$. (An electric quadrupole interacts with an EFG analogously to the interaction of an electric dipole with an electric field.) This is illustrated in Figure 3, part (a), together with a representative ^{2}H NMR spectrum of a solid polymer, PMMA-d_8, as shown in part (b) which will be discussed subsequently.

A general prescription for calculating the ^{2}H NMR transition frequencies and spectral lineshapes is the

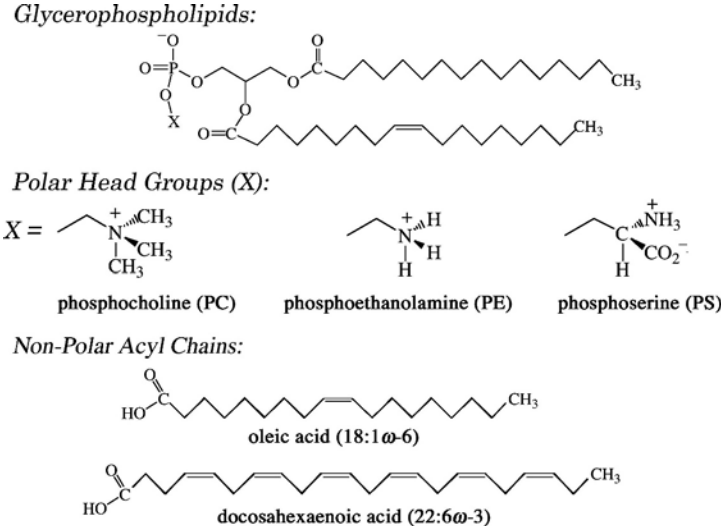

Fig. 2. Chemical structures of representative glycerophospholipids. The polar head groups vary in their size, capacity for hydrogen bonding, and charge. Representative examples are indicated for the zwitterionic head groups phosphocholine (PC) and phosphethanolamine (PE), and the anionic head group phosphoserine (PS). The non-polar acyl chains vary in their length and degree and position of unsaturation.

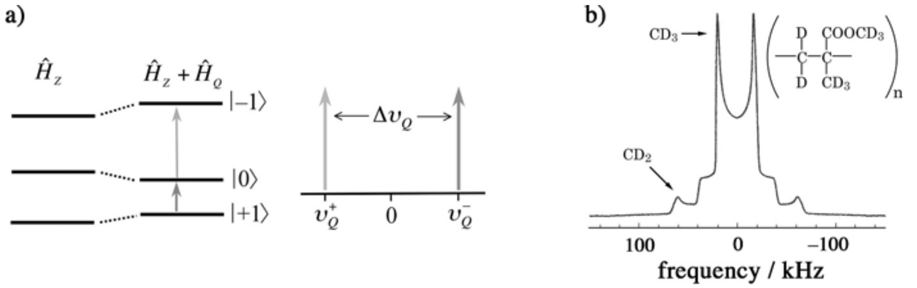

Fig. 3. (a) Energy levels and resonance lines in ^{2}H NMR spectroscopy. The Zeeman Hamiltonian $\hat{H}_Z$ is perturbed by the quadrupolar Hamiltonian $\hat{H}_Q$ giving an unequal spacing of the nuclear spin energy levels, indicated by $|m\rangle$ where $m = 0, \pm 1$. The quadrupolar splitting $\Delta\nu_Q$ is the difference in the frequencies ($\nu_Q^{\pm}$) of the single-quantum transitions, and is due to the perturbing interaction of the ^{2}H nuclear quadrupole moment with the EFG of the C–^{2}H bond. (b) Representative ^{2}H NMR spectrum of an unoriented powder sample of deuterated plexiglass, PMMA-d_8. The contributions from the C^{2}H$_2$ groups differ from those of the C^{2}H$_3$ groups, which undergo rapid threefold motion on the NMR timescale (cf. the text).

following. First one starts with the perturbing Hamiltonian; next Schrödinger's equation is solved to obtain the energy levels; and lastly one introduces the spectroscopic selection rules to calculate the frequencies of the spectral lines. This gives as a final result for the quadrupolar frequencies ($\nu_Q^{\pm}$) that

$$\nu_Q^{\pm} = \pm\frac{3}{4}\chi_Q\left\{D_{00}^{(2)}(\Omega_{PL}) - \frac{\eta_Q}{\sqrt{6}}\left[D_{-20}^{(2)}(\Omega_{PL}) + D_{20}^{(2)}(\Omega_{PL})\right]\right\}. \quad (1)$$

Here $\chi_Q \equiv e^2qQ/h$ is the *static* quadrupolar coupling constant, η_Q is the corresponding asymmetry parameter of the EFG tensor, and $\Omega_{PL} \equiv (\alpha_{PL}, \beta_{PL}, \gamma_{PL})$ are the Euler angles relating the PAS of the EFG tensor (P) and the laboratory frame (L). The experimentally observed ^{2}H NMR quadrupolar splitting (Figure 3) is then given by the difference in the frequencies of the spectral lines, $\Delta\nu_Q \equiv \nu_Q^+ - \nu_Q^-$. One should note that the development is also applicable to other second-rank tensors; for instance the magnetic dipolar interaction and the chemical shift [1,2,32].

Molecular Structures and Motions are Revealed by Deuterium NMR Lineshapes

Measurement of the deuterium (^{2}H) NMR lineshapes yields knowledge of the average structure through the principal values of the coupling tensor, as well as the PAS. For the sake of illustration, let us first consider a static oriented sample, e.g. a single crystal in the absence of motions. The crystal can be rotated with respect to the laboratory frame, giving discontinuities in the NMR spectrum, which correspond to the main external magnetic field aligned along each of the three principal axes of the coupling tensor. The case of an aligned dispersion of phospholipid bilayers deposited on a planar surface is exactly analogous. Here one has a residual or effective coupling tensor, which is pre-averaged by the motions of the flexible lipid molecules in the L_α state, but otherwise the transformation under rotations is identical. In either case, the principal axes and principal values of the static coupling tensor, or the residual tensor in the presence of motions, can be obtained from the rotation pattern according to Equation (1). But often one has a polycrystalline sample with a random or spherical distribution of the various C–^{2}H bond orientations. A powder (or powder-type) spectrum is then obtained, from which one can "read off" the principal values of the coupling tensor directly from the spectral discontinuities [1]. In this case a drawback is that the orientation of the PAS of the coupling tensor within the crystal frame is unavailable, since the spectral discontinuities correspond to the laboratory system.

Returning to Figure 3, an experimental ^{2}H NMR spectrum of a randomly oriented, powder-type sample of deuterated plexiglass, PMMA-d_8, is shown in part (b). Here the outer splitting (±60 kHz) of the powder pattern is due to the C^{2}H$_2$ groups of PMMA-d_8. For the C^{2}H$_2$ groups, motion is essentially absent on the ^{2}H NMR timescale, and the *static* coupling tensor is observed. The experimental ^{2}H NMR splitting (due to the large peaks) represents the $\theta = 90^\circ$ orientation, for which $-3\chi_Q/4 = -127.5$ kHz in the case of immobile methylene groups. (Weaker shoulders are also evident, corresponding to the $\theta = 0^\circ$ orientation with a splitting of $3\chi_Q/2 = 255$ kHz.) On the other hand, the central component (±20 kHz) of the

^{2}H NMR spectrum is due to the methyl groups, which are rapidly rotating in the solid state. The threefold rotation about the methyl axes means that the static coupling tensor is averaged to yield a *residual* coupling tensor, which is axially symmetric ($\eta_Q^{\text{eff}} = 0$), and whose largest principal value (χ_Q^{eff}) is correspondingly reduced by a factor of $-1/3$. Hence, for the $\theta = 90^\circ$ orientation, the C^{2}H$_3$ splitting is $(-3\chi_Q/4)(-1/3) = 42.5$ kHz in good agreement with the experimental spectrum. (The weaker shoulders correspond to the $\theta = 0^\circ$ orientation with a splitting of $\chi_Q/2 = -85.0$ kHz.) According to this example, one can essentially "read off" the coupling parameters, and hence the types of motions, directly from the experimental ^{2}H NMR spectrum [1].

In passing, we note that rather different, uniaxial powder-pattern lineshapes are observed for certain membrane proteins, such as bacteriorhodopsin [13,33] or rhodopsin [15], and also for nucleic acid fibers [16]. From such ^{2}H NMR lineshape investigations, one is able to extract information about the molecular structure, as well as the disorder of the sample in terms of the appropriate distribution functions [15,34].

Our next example involves the case of membrane lipid bilayers, where rapid axial averaging occurs about the normal to the membrane film surface, referred to as the director axis. For membranes in the fluid state, the quadrupolar splittings are due to the orientational order parameters of the individual C–^{2}H-labeled groups, leading to a profile as a function of acyl position. The segmental order parameter S_{CD} describes the amplitudes of the angular excursions of the C–^{2}H-labeled groups and is given by [6]:

$$S_{\text{CD}} \equiv \left\langle D_{00}^{(2)}(0, \beta_{\text{PD}}, 0) \right\rangle = \langle P_2(\cos\beta_{\text{PD}}) \rangle, \qquad (2a)$$

$$= \frac{1}{2}\left\langle 3\cos^2\beta_{\text{PD}} - 1 \right\rangle. \qquad (2b)$$

In the above formula, $D_{00}^{(2)}(\Omega_{\text{PD}})$ is a Wigner rotation matrix element, $P_2(x)$ is the second Legendre polynomial where $x \equiv \cos\beta_{\text{PD}}$, and β_{PD} is the time-dependent angle between the C–^{2}H bond axis and the director axis (perpendicular to the surface of the membrane). The angular brackets mean an average over all the motions faster than the inverse of the anisotropy in the static quadrupolar coupling ($<10^{-5}$ s). The observed quadrupolar splitting then reads

$$\Delta\nu_Q = \frac{3}{2}\chi_Q S_{\text{CD}} \frac{3\cos^2\beta_{\text{DL}} - 1}{2}, \qquad (3)$$

where β_{DL} is the angle between the bilayer normal (director) and the main external magnetic field direction. The segmental order parameters constitute experimental obervables and are related to the equilibrium properties and average structure of the system.

Deuterium NMR Provides Order Parameters Related to Average Membrane Properties

^{2}H NMR spectra of phospholipids in water allow the quadrupolar couplings of the C–^{2}H-labeled segments to be observed directly, e.g. as in the case of the acyl chains [3,5,21,35,36] and head groups [37,38]. What can be learned about the micro- and nanostructures of membrane lipids from ^{2}H NMR spectroscopy? First we note that the ^{2}H NMR spectra of multilamellar dispersions of randomly oriented phospholipids reveal weak singularities arising from the $\theta = 90^\circ$ orientation of the bilayer normal (director axis) relative to the main magnetic field, whereas the weaker shoulders are due to $\theta = 0^\circ$. A characteristic profile of residual quadrupolar couplings is evident for phospholipids having either specifically deuterated [3,39,40] or perdeuterated [4,5,21,27,41–47] acyl chains in the liquid-crystalline (L_α) phase. The largest values correspond to the segments close to the lipid polar head groups, with a progressive reduction along the lipid acyl chains [6]. Comparison of the residual quadrupolar splittings to the static coupling constant (see above) indicates that the acyl groups are considerably disordered in the liquid-crystalline state.

In Figure 4, we show representative ^{2}H NMR spectra for mixtures of a representative acyl (chain) perdeuterated phospholipid, 1,2-diperdeuteriomyristoyl-*sn*-glycero-3-phosphocholine, abbreviated DMPC-d_{54}, at $T = 44\,^\circ$C containing cholesterol. For acyl chain perdeuterated phospholipids, one can deconvolute or de-Pake the powder-type spectra of random multilamellar dispersions to obtain more highly resolved subspectra corresponding to the $\theta = 0^\circ$ orientation [4,48,49]. Upon de-Pakeing, the majority of the acyl C^{2}H$_2$ and C^{2}H$_3$ groups give resolvable signals, and it can be seen that a progressive increase in the splittings occurs with increasing mole fraction of cholesterol. Interaction with the rigid sterol frame leads to a substantial reduction of the number of degrees of freedom of the flexible phospholipids, as evinced by the larger residual quadrupolar splittings, Figure 4.

Now according to Equation (3) the observed residual quadrupolar coupling $\Delta\nu_Q$ is directly related to the segmental order parameter S_{CD}. The residual quadrupolar couplings vary substantially, giving a profile of the segmental order parameters $|S_{\text{CD}}^{(i)}|$ as a function of chain position (index i). This inequivalence arises from the effects of the bilayer packing on the *trans*(t)–*gauche*(g) isomerizations of the acyl groups. Figure 5 shows that the splittings can be expressed in terms of the segmental order parameters $S_{\text{CD}}^{(i)}$, which are plotted as a function of the acyl position (index i) for DMPC-d_{54} alone and

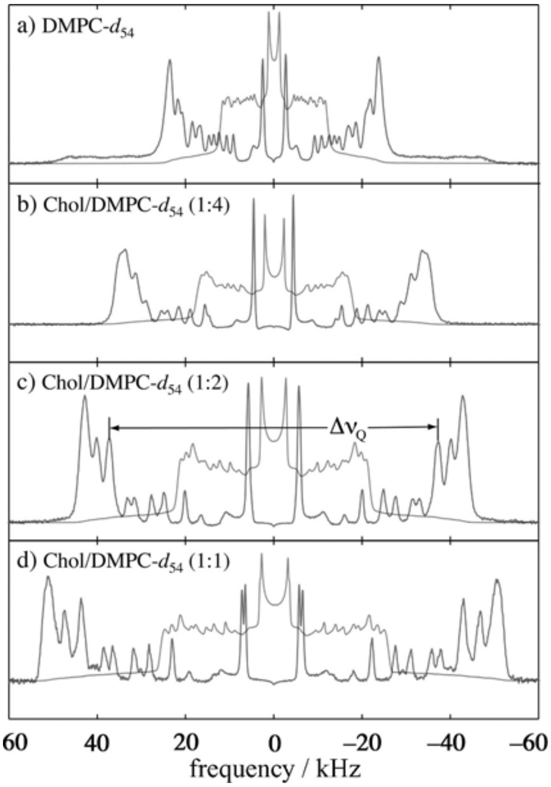

Fig. 4. Representative solid-state ^{2}H NMR spectra for (a) DMPC-d_{54} in the L_α phase and (b)–(d) DMPC-d_{54} containing increasing mole fractions of cholesterol in the liquid-ordered phase. The samples contained 50 wt% $^1\mathrm{H}_2 0$ at 44 °C and the data were acquired at 76.8 MHz (magnetic field strength of 11.7 T). Powder-type spectra (light blue) of randomly oriented multilamellar dispersions were numerically inverted (de-Paked) (dark red). Note that a distribution of residual quadrupolar couplings is evident. (See also Plate 29 on page XXIX in the Color Plate Section.)

DMPC-d_{54} in the presence of cholesterol (1:1). Knowing the assignments from studies of specifically deuterated systems [50], essentially complete order profiles can be obtained. This disorder manifests *trans–gauche* rotational isomerizations of the acyl groups, together with the effects of molecular motions or whole bilayer collective motions.

Referring to Figure 5, the plateau in the order profiles can be explained in terms of preferred configurations of the acyl chains parallel to the membrane normal. For DMPC-d_{54} in the presence of cholesterol (1:1), the segmental order parameters approach the limiting value of $S_{\mathrm{CD}} = -1/2$ expected for an all-*trans* rotating polymethylene chain. The additional disorder can be due to internal degrees of freedom of the acyl chains, e.g. rotational isomerizations, molecular motions, or thermal disturbances of the bilayer lipids. In the absence of cholesterol, the smaller $|S_{\mathrm{CD}}^{(i)}|$ values for DMPC-d_{54} manifest additional degrees of freedom. For a simple crank shaft model, consideration of 3-site jumps together with the statistical weights gives $\langle S_{\mathrm{CD}}\rangle = -1/3$ for a mix of kink ($tg^{\pm}\ tg^{\mp}$) and jog ($tttg^{\pm}\ tttg^{\mp}$) conformations, whereas $\langle S_{\mathrm{CD}}\rangle = -1/4$ for kinks only. Assuming the disorder of the DMPC- d_{54} bilayer is due mainly to rotational isomerism, the acyl chains fall somewhere between a limiting crankshaft model with $\langle S_{\mathrm{CD}}\rangle = -1/4$ and the classical oil-drop model having $\langle S_{\mathrm{CD}}\rangle = 0$. Lastly, for DMPC-$d_{54}$ both in the presence and absence of cholesterol, the increased disorder toward the chain ends must involve further acyl configurations. Within the hydrocarbon core the chains are more disordered to occupy the free volume due to chain terminations, approaching the "oil-drop" limit for very long acyl chain lengths. Note that the presence of an order profile suggests that variations in the degree of chain entanglement are likely as a function of depth in the bilayer.

Now in the lamellar state of membrane lipids, the structural properties include the average thickness $\langle L\rangle$ of the bilayer hydrocarbon region together with the mean interfacial area $\langle A\rangle$ [6,19,27,51,52], which plays a key role in molecular dynamics simulations of lipid bilayers and membranes [53–55]. Starting with the experimental $|S_{\mathrm{CD}}^{(i)}|$ order profiles, one can calculate the bilayer structural parameters using a mean-torque model for the acyl chain distributions [21,27,46]. By interpreting the ^{2}H NMR spectra in terms of the distribution functions for the segment orientations, one is able to gain insight into the intermolecular interactions governing the nanostructures of various membrane lipids. Very briefly, the mean-torque model relates the experimental order parameters to the moments $\langle\cos\beta\rangle$ and $\langle\cos^2\beta\rangle$ [27]. For a disaturated phospholipid such as DMPC-d_{54}, the mean area per molecule at the aqueous interface is given by $\langle A\rangle = 4V_{\mathrm{CH2}}q/D_{\mathrm{M}}$, where $q \equiv \langle 1/\cos\beta\rangle \approx 3 - 3\langle\cos\beta\rangle + \langle\cos^2\beta\rangle$. Here β is the angle between the vector connecting the two neighboring carbons of the ith methylene segment of a saturated acyl chain and the bilayer normal, V_{CH2} is the volume per methylene group, and D_{M} is the projected length along the all-*trans* reference axis (2.54 Å). The volumetric thickness of the bilayer is then given by $D_{\mathrm{C}} = 2V_{\mathrm{C}}/\langle A\rangle$ where V_{C} is the hydrocarbon chain volume. Chain packing profiles can also be obtained which describe the accumulated segmental projections along the membrane normal, proceeding from the midpoint of the bilayer toward the aqueous interface [27].

The above ^{2}H NMR approach has been applied to a homologous series of various phosphatidylcholines, in which both or one of the acyl chains at the *sn*-1 and *sn*-2 positions of the glycerol backbone has been ^{2}H-labeled

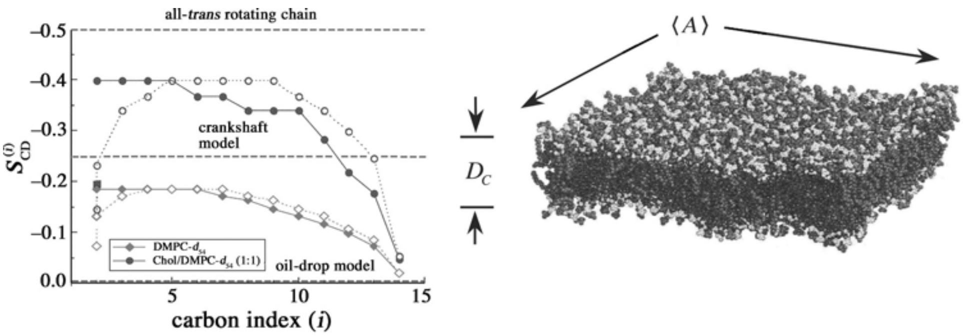

Fig. 5. Profiles of segmental order parameters $S_{\mathrm{CD}}^{(i)}$ as a function of acyl chain position (i) for (♦,◊) DMPC-d_{54} and (●,○) DMPC-d_{54}/cholesterol (1:1) at 44 °C. Filled and open symbols refer to the inequivalent *sn*-1 and *sn*-2 acyl chains, respectively. Reference values of the order parameters for the limiting cases of an oil drop-model ($\langle S_{\mathrm{CD}}\rangle = 0$), a crankshaft model ($\langle S_{\mathrm{CD}}\rangle = -1/4$), and an all-*trans* rotating chain ($S_{\mathrm{CD}} = -1/2$) are indicated for comparison. Bilayer dimensions are described in terms of $\langle A\rangle$, the interfacial or cross sectional area per lipid molecule, and D_{C}, the volumetric thickness of the bilayer (cf. the text). (See also Plate 30 on page XXX in the Color Plate Section.)

by perdeuteration [27]. The main effect of increasing the acyl chain length is an increase in the bilayer hydrocarbon thickness rather than the area per lipid at the aqueous interface. The homologous series of phosphatidylcholines exhibits a universal chain packing profile differing from that of phosphatidylethanolamines. With increasing acyl length the lipid area becomes smaller at a given temperature, reflecting stronger van der Waals attractions for longer lipid chains. Studies of the lateral compressibility of phospholipid bilayers have also been carried out using ^{2}H NMR methods [35]. Additional comparative investigations have focused on a homologous series of mixed chain, saturated–polyunsaturated phosphatidylcholines [21,41–43,45,46]. Highly polyunsaturated acyl chains yield significant disordering of the bilayer, increasing the cross-sectional area per lipid head group relative to disaturated lipid bilayers. The resulting spontaneous curvature (or equivalently the lateral pressure profile) may affect the conformational energetics of membrane proteins such as rhodopsin [56]. Lipids in non-lamellar phases have also been investigated with ^{2}H NMR, including the hexagonal (H_{I}) and reverse hexagonal (H_{II}) phases [57–59], which are implicated in protein-mediated functions of biomembranes [56].

Deuterium Spin–Lattice Relaxation Times Reveal Dynamical Properties of Lipid Membranes

Turning next to the topic of nuclear spin relaxation, for membranes in the liquid-crystalline state a complex hierarchy of motions is to be expected. How can NMR relaxation help to disentangle the various types of motions that account for the statistically averaged membrane properties? Generally speaking, one can separate the motions into broad classes with characteristic mean-squared amplitudes and timescales, which may be related to the material or biological properties of the system of interest. Examples of fast segmental motions include *trans–gauche* isomerizations of the flexible phospholipids in the liquid-crystalline state, whereas slower motions may be due to non-collective rotational diffusion of the lipid molecules or collective disturbances and excitations of the bilayer itself [6,60–65].

The mechanism of NMR relaxation originates from fluctuations of the coupling Hamiltonian arising from the various possible motions of the lipid molecules within the bilayer. In applying ^{2}H NMR spectroscopy to membrane lipids, one is often interested in the relaxation of the Zeeman order ($R_{1\mathrm{Z}}$) or the quadrupolar order ($R_{1\mathrm{Q}}$). Experimentally, the spin–lattice relaxation rates $R_{1\mathrm{Z}}$ and $R_{1\mathrm{Q}}$ are measured by a pulse sequence designed to perturb the magnetization away from the equilibrium value—effectively we can think of these as "magnetization jump" experiments. The subsequent return to equilibrium can then be followed by "reading out" the remaining magnetization as a transverse coherence, which is detected as an oscillating NMR signal and picked up by the radio frequency coil of the spectrometer probe.

An example is provided in Figure 6, which depicts an inversion-recovery measurement of the $R_{1\mathrm{Z}}$ values for a random dispersion of DMPC-d_{54}/cholesterol (1:1) in the liquid-ordered phase. The partially relaxed ^{2}H NMR spectra in part (a) correspond to superposition of Pake doublets due to the various motionally inequivalent C–^{2}H bonds (*vide supra*). Following the inverting π pulse, the z-magnetization appears negative and gradually recovers to equilibrium as the delay increases. In part (b) of Figure 6, the various partially relaxed ^{2}H NMR spectra have

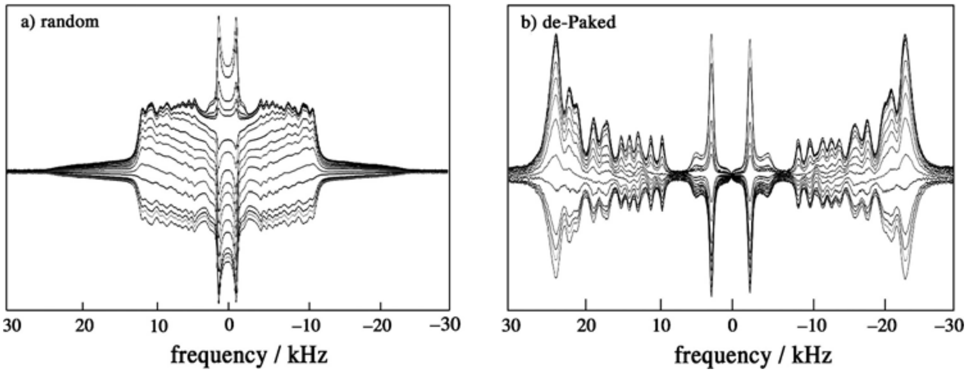

Fig. 6. Example of partially relaxed ^{2}H NMR spectra of DMPC-d_{54} multilamellar dispersion in the liquid-crystalline (L_α) state at 44 °C. Panel (a) shows the experimental ^{2}H NMR spectra, and panel (b) the numerically inverted (de-Paked) ^{2}H NMR spectra ($\theta = 0°$) as a function of the variable delay between the inversion pulse and the spectral acquisition. Data were obtained at 76.8 MHz (magnetic field strength of 11.7 T) using an inversion-recovery pulse sequence, $(\pi\text{p})_x - t_1 - (\pi/2)_x - \tau_1 - (\pi/2)_{\pm y} - \tau_2$ – acquire, with the variable delay t_1 ranging from 5 ms to 3 s [87].

been numerically inverted (de-Paked) to yield the spectra corresponding to the $\theta = 0°$ orientation. The increased resolution allows a more accurate determination of the R_{1Z} rates. It can be seen that the magnetization recovery becomes progressively faster as the residual quadrupolar splittings increase. This behavior points to the influences of order fluctuations, in which the pre-averaged or residual coupling tensor remaining from the local segmental motions is modulated by slower membrane motions, e.g. due to molecular fluctuations or whole bilayer disturbances (*vide infra*).

According to time-dependent perturbation theory, the relaxation is due to orientational fluctuations of the individual C–^{2}H bonds, which induce transitions between the various energy levels of the ^{2}H nuclear spin system. The observable relaxation rates are related to the spectral densities of the various motions within the laboratory frame. According to theory, the R_{1Z} and R_{1Q} rates are given to second order by:

$$R_{1Z} \equiv \frac{1}{T_{1Z}} = \frac{3}{4}\pi^2 \chi_Q^2 [J_1(\omega_D) + 4J_2(2\omega_D)], \quad (4)$$

$$R_{1Q} \equiv \frac{1}{T_{1Q}} = \frac{9}{4}\pi^2 \chi_Q^2 J_1(\omega_D). \quad (5)$$

In these formulas R_{1Z} is the spin–lattice (longitudinal) relaxation rate, where T_{1Z} is the corresponding spin–lattice relaxation time; and R_{1Q} is the spin–lattice relaxation rate for the decay of quadrupolar order, in which T_{1Q} is the quadrupolar order relaxation time. The symbols $J_m(\omega)$ denote irreducible spectral densities of motion, where $m = 1, 2$ and ω_D is the deuteron Larmor (resonance) frequency.

The spectral densities $J_m(\omega)$ express the power spectrum of the motions as a function of frequency ω. They correspond to the fluctuations of the individual Wigner rotation matrix elements which transform the coupling (EFG) tensor from its PAS to the laboratory frame, and are given by the Fourier–Laplace transform:

$$J_m(\omega) = \mathrm{Re} \int_{-\infty}^{\infty} G_m(t) e^{-i\omega t}\, \mathrm{d}t, \quad (6)$$

The autocorrelation functions $G_m(t)$ depend explicitly on time and characterize the C–^{2}H bond fluctuations; they read

$$G_m(t) = \left\langle D_{0m}^{(2)^*}(\Omega_{\mathrm{PL}}; 0) D_{0m}^{(2)}(\Omega_{\mathrm{PL}}; t) \right\rangle - \left| \left\langle D_{0m}^{(2)}(\Omega_{\mathrm{PL}}) \right\rangle \right|^2, \quad (7)$$

where $D_{0m}^{(2)}(\Omega_{\mathrm{PL}})$ denotes a Wigner matrix element (rank 2). Here the symbol Ω_{PL} indicates the three Euler angles [66] (α_{PL}, β_{PL}, γ_{PL}) which rotate the PAS of the EFG coupling tensor to the laboratory frame [6]. Note that the temporal decay of the correlation function is due to the angular reorientations of the C–^{2}H-labeled molecular segments, whereas the long-time values correspond to the average bilayer properties.

Model-Free Analysis Suggests that Collective Membrane Motions Govern the Relaxation

Let us next turn to consider those aspects of the relaxation that are independent of a specific motional model.

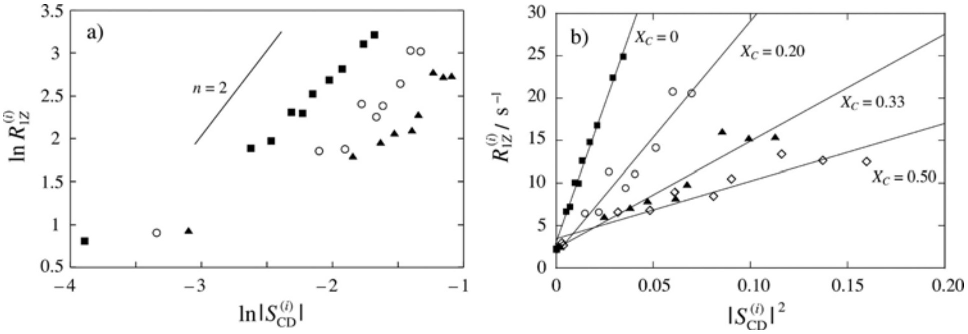

Fig. 7. Dependence of relaxation rate $R_{1Z}^{(i)}$ and order parameter $|S_{CD}^{(i)}|$ profiles for DMPC-d_{54}/cholesterol mixtures at 44 °C. Data for randomly oriented (powder-type) samples were acquired at 76.8 MHz (magnetic field strength of 11.7 T) and numerically inverted (de-Paked). In panel (a) logarithmic plots are shown for three different cholesterol mole fractions X_C . The data are compared to the slope of $n = 2$ predicted for order fluctuations in the limit of a small constant contribution. Panel (b) assumes a square-law functionality of the corresponding relaxation and order profiles for the different values of X_C. Reprinted with permission from Ref. [86]. © 2002 American Physical Society.

We would like to identify the major features of the dynamics in a more or less coarse-grained fashion, leaving the details for subsequent atomistic computer simulations [53–55,67]. We naturally make recourse to relatively fast and relatively slow motions, which successively yield further averaging of the coupling interaction on down to the final residual value. The segmental order parameters clearly depend on the amplitudes of the C–^{2}H bond fluctuations, whereas the relaxation rates depend on both the orientational amplitudes and the rates of the C–^{2}H bond fluctuations. As a result, the ordering and rate of motion must be distinguished in explaining the relaxation of lipid bilayers [68].

Recall that in ^{2}H NMR of membranes, the spectroscopic observables essentially comprise the order parameter and the relaxation rate profiles—thus it is useful to inquire as to the existence and nature of their functional dependence [60]. According to the foregoing development, Equations (4)–(7), the interaction strength (the matrix element) is squared in the transition probabilities that govern the relaxation rates (Fermi's golden rule). Now the fast or local motions modulate the *static* coupling constant, in which case the relaxation profile along the chains is governed essentially by the motional rates [39]. But for slow motions, the *residual* coupling tensor varies along the chains due to the pre-averaging by the faster segmental motions, giving a profile of the interaction strength. If the slow motions affect the lipid molecules to nearly the same extent, e.g. due to molecular rotations or whole bilayer lipid excitations (called order-director fluctuations, ODF), then the relaxation rates depend on the local order parameter squared.

In Figure 7 representative examples of such a square-law dependence of the relaxation and order parameter functions from ^{2}H NMR spectroscopy of fluid lipid bilayers are depicted. In part (a) double-logarithmic plots of $R_{1Z}^{(i)}$ against $|S_{CD}^{(i)}|$ are summarized for different molar ratios of the DMPC-d_{54}/cholesterol bilayers. (Note that the individual acyl positions are not distinguished.) The approximately linear region has a slope of nearly $n = 2$, consistent with a simple square-law functional dependence of $R_{1Z}^{(i)}$ on $|S_{CD}^{(i)}|$. Part (b) of Figure 7 shows the corresponding square-law plots for the multilamellar dispersions of DMPC-d_{54}/cholesterol having different molar ratios of the two lipid components. It can be seen that a square-law functional dependence of the $R_{1Z}^{(i)}$ rates vs. the order parameters $|S_{CD}^{(i)}|$ along the entire acyl chain is indeed observed [60]. Moreover, as the cholesterol mole fraction X_C increases, the slopes of the plots are systematically reduced, paralleling the macroscopic stiffening action of cholesterol [5,69].

Spectral Densities and Correlation Functions are Derived for Simplified Models in Closed Form

The next question we can ask is: what are the slow motions that yield the order fluctuations and produce the square-law functional dependence? First we can consider a simple non-collective model as a description of the effective rotations of the flexible phospholipids in the liquid-crystalline state [60,70,71]. In the case of phospholipids, rapid motions of the flexible molecules yield a reduced moment of inertia tensor, whose principal axes and principal values correspond to the off-axial and axial diffusion constants $D_\perp$ and $D_\parallel$. Modulation of the average or residual coupling tensor by rotations of the "average molecule" about its average principal axes would then produce the relaxation. For such a *non-collective molecular model*, the spectral densities then read

$$J_m^{\mathrm{mol}}(\omega) = \left|\left\langle D_{00}^{(2)}(\Omega_{\mathrm{PI}})\right\rangle\right|^2 \sum_q \sum_n \left| D_{0g}^{(2)}(\Omega_{\mathrm{IM}}) - \frac{\eta_{\mathrm{Q}}^{\mathrm{eff}}}{\sqrt{6}}\left[D_{-2q}^{(2)}(\Omega_{\mathrm{IM}}) + D_{2q}^{(2)}(\Omega_{\mathrm{IM}})\right]\right|^2 \left[\left\langle\left|D_{qn}^{(2)}(\Omega_{\mathrm{MD}})\right|^2\right\rangle - \left|\left\langle D_{qn}^{(2)}(\Omega_{\mathrm{MD}})\right\rangle\right|^2 \delta_{q0}\delta_{n0}\right] j_{qn}^{(2)}(\Omega_{\mathrm{MD}};\omega)\left|D_{nm}^{(2)}(\Omega_{\mathrm{DL}})\right|^2. \tag{8}$$

where $\eta_{\mathrm{Q}}^{\mathrm{eff}}$ is the effective asymmetry parameter of the residual EFG tensor due to averaging by the faster segmental motions. In Equation (8) the Euler angles Ω_{PI}, Ω_{IM}, Ω_{MD}, and Ω_{DL} denote transformation from the PAS (P) of the EFG tensor to an intermediate frame (I), from the intermediate frame to the molecular frame (M), from the molecular system to the director frame (D), and lastly from the director to the laboratory axes system (L) [65]. The symbols $j_{qn}^{(2)}(\Omega_{\mathrm{MD}};\,\omega)$ indicate Lorentzian reduced spectral densities, whose correlation times τ_{qn} depend on the principal values of the rotational diffusion tensor, viz. $D_\perp$ and $D_\parallel$ [72].

Note that in Equation (8) the spectral densities are pre-multiplied by the quantity $|\langle D_{00}^{(2)}(\Omega_{\mathrm{PI}})\rangle|^2$, where Ω_{PI} has to do with only the fast motions. This is merely the square of the fast order parameter $S_{\mathrm{f}}^{(2)}$—hence a squared dependence on the order parameter is predicted in agreement with the experimental finding (Figure 7). However, a molecular rotational diffusion model alone does not describe the NMR relaxation in the MHz range for phospholipids in the liquid-crystalline state, since the distribution of correlation times is not sufficiently wide [60]. Rather a significant contribution from slow motions such as vesicle tumbling is also needed, as obtained from the ^{2}H NMR spectral line width [71].

Yet another possibility is to model the relatively slow order fluctuations in terms of collective thermal disturbances of the bilayer arising from the ensemble of interacting molecules [60]. The bilayer is approximated as a continuous material, and the relaxation is assumed to be due to a distribution of modes, each undergoing overdamped or viscous relaxation. Within this framework, the spectral densities $J_m^{\mathrm{col}}(\omega)$ due to collective excitations of the bilayer are given by [73]

$$J_m^{\mathrm{col}}(\omega) = \frac{5}{2}\left|\left\langle D_{00}^{(2)}(\Omega_{\mathrm{PD}})\right\rangle\right|^2 D\omega^{-(2-d/2)}\left[\left|D_{-1m}^{(2)}(\Omega_{\mathrm{DL}})\right|^2 + \left|D_{1m}^{(2)}(\Omega_{\mathrm{DL}})\right|^2\right], \tag{9}$$

where D is a viscoelastic constant that depends on the elasticity, viscosity, and temperature of the bilayer, and d is the dimensionality of the bilayer thermal excitations. Here the Euler angles Ω_{PD} rotate the PAS of the C–^{2}H bond to the director frame, and the angles Ω_{DL} transform from the bilayer director to the laboratory system. According to Equations (2) and (9) the spectral densities $J_m(\omega)$ depend on the square of the observed order parameter S_{CD}, and the slope of the square-law plot is inversely related to the softness of the membrane.

For such collective bilayer excitations, one can distinguish between two possible limits, depending on the wavelengths of the fluctuations relative to the membrane thickness and the interlamellar separation. Collective order fluctuations in 2-D are described by a *flexible surface model*, e.g. in analogy with smectic liquid crystals, where the finite thickness of the membrane bilayer is neglected. In keeping with Equation (9), for $d = 2$ the spectral densities $J_m^{\mathrm{col}}(\omega)$ have an ω^{-1} frequency dependence [64,74,75]. Alternatively, 3-D order fluctuations are described by a *collective membrane deformation model*, where the bilayer is modeled analogously to a nematic liquid crystal. Equation (9) then predicts an $\omega^{-1/2}$ dependence of the spectral densities $J_m^{\mathrm{col}}(\omega)$ ($d = 3$). Although a 3-D director fluctuation model adequately describes the frequency dispersion of the ^{2}H $R_{1\mathrm{Z}}$ rates for DMPC vesicles [73,76], by itself it does not explain the orientation dependence of the ^{2}H $R_{1\mathrm{Z}}$ and $R_{1\mathrm{Q}}$ relaxation data [77].

How can one simultaneously account for both the orientational anisotropy of the relaxation and the frequency dependence of lipid bilayers in the fluid state? Here we are struck by the fact that the collective membrane deformation model explains the frequency dependence, whereas the non-collective molecular model best explains the angular anisotropy. We are naturally led to consider a composite membrane deformation model, in which collective axial rotations of the flexible phospholipid molecules are superimposed onto the collective bilayer excitations in the liquid-crystalline state [78]. For such a composite process, the laboratory frame spectral densities read

$$J_m(\omega) = J_m^{\mathrm{mol}}(\omega) + J_m^{\mathrm{col}}(\omega) + J_m^{\mathrm{mol-col}}(\omega) \tag{10}$$

in which the small contribution from segmental motions is neglected and the spectral densities $J_m^{\mathrm{mol}}(\omega)$ and $J_m^{\mathrm{col}}(\omega)$ are given above, Equations (8) and (9). The cross-term $J_m^{\mathrm{mol-col}}(\omega)$ is geometrical in origin [78] and cross-correlations between the molecular fluctuations and the collective fluctuations are neglected as a simplifying approximation. Current data indicate that such a composite model can explain the angular and frequency dependencies of the NMR relaxation for lipid bilayers in the fluid phase [78].

In Figure 8 the frequency dispersion of the R_{1Z} rates is shown for vesicles of DMPC in the liquid-crystalline state, comprising a total of 12 different magnetic field strengths. Note that the R_{1Z} values depend on frequency over the entire range from 2.5 to 95.3 MHz—there is no plateau value at either low frequency or high frequency. One cannot identify a regime where a single type of effective motion dominates the relaxation. The non-collective molecular model does not fit the low frequency end of the relaxation dispersion, even if an extreme value of the diffusion tensor anisotropy ($\eta \equiv D_{\|}/D_{\perp}$) is assumed [79]. Consequently an additional contribution from the vesicle tumbling is needed to explain the lower frequency data [71]. The 2-D flexible surface model is characterized by an ω^{-1} dependence and provides a rather poor fit to the data; it is probably most appropriate for interpreting the relaxation at very low frequencies in terms of collective undulations [70]. By contrast the 3-D collective membrane deformation model fits the frequency-dependent R_{1Z} data within the MHz range by an $\omega^{-1/2}$ dependence. Moreover, one can extend the effective frequency range by considering the relaxation of the ^{13}C nucleus, which has a larger magnetogyric ratio than ^{2}H [80]. In the case of ^{13}C NMR the relaxation is due to the magnetic dipolar interaction of the nucleus with its directly bonded hydrogen. The combined frequency-dependent data are described by a simple relaxation law of the form $R_{1Z}^{(i)} = A\tau_{\mathrm{f}} + B|S_{\mathrm{CD}}^{(i)}|^2$, where τ_{f} is the fast correlation time and A and B are constants, which is characteristic of ODF [81].

It follows that NMR results for soft membrane bilayers, involving flexible lipid molecules with many degrees of freedom, can be interpreted using fairly simple concepts inspired by the physics of materials. The small contribution from internal motions of the acyl chains matches the frequency independent relaxation rates of liquid *n*-alkanes [81] and agrees with more recent molecular dynamics simulations [82]. Thus the bilayer microviscosity, where a bulk viscosity cannot be measured, is comparable to an *n*-paraffin such as *n*-hexadecane [81]. The reason why the relaxation is governed by collective order fluctuations is that the local segmental motions of the lipids are very fast ($\tau_{\mathrm{f}} \approx 10$ ps), with spectral densities extending to very high frequencies. Basically the membrane lipids are tethered to the aqueous interface via their polar head groups, and the bilayer interior is essentially liquid hydrocarbon. The experimental findings imply that quasi-coherent order fluctuations are already present in lipid bilayers involving lengths on the order of approximately the bilayer thickness and even less, i.e. the mesoscopic length scale, as illustrated in Figure 9.

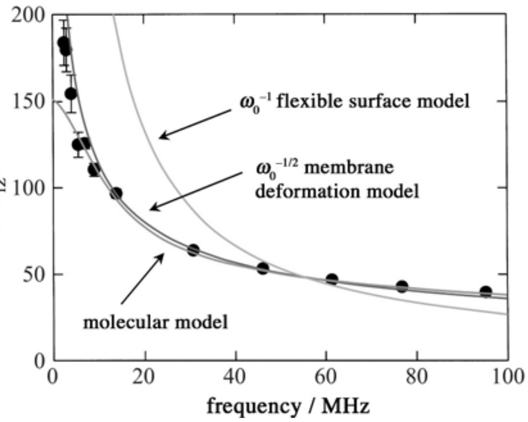

Fig. 8. Experimental ^{2}H R_{1Z} relaxation rates plotted as a function of frequency for vesicles of DMPC deuterated at the C_3 acyl segment in the liquid-crystalline state at 30 °C. Data were acquired at 12 different frequencies (magnetic field strengths) and are shown together with theoretical fits to various motional models (cf. the text) [73].

Deuterium NMR Relaxation Allows Detailed Comparison of the Structural and Dynamical Properties of Membranes

Clearly an illuminating new aspect of the work described above is the extension of the concept of membrane elasticity to relatively short distances. This work provides striking evidence that membrane deformational fluctuations occur over a wide range of length and timescales, which depend on the bilayer lipid composition. Indeed, the current results give evidence for a connection between emerger properties on the mesoscopic scale, as studied by NMR relaxation, and macroscopic properties of the bulk material. According to the foregoing development, by combining the ^{2}H NMR relaxation data with the order parameters, we obtain a more comprehensive picture of the biophysical properties of membrane lipids than would be otherwise the case. Using ^{2}H NMR relaxation, the influences of the acyl length (bilayer thickness), polyunsaturation, lipid polar head groups (interfacial area per molecule), addition of a cosurfactant, and incorporation of sterols have been studied and interpreted in terms of the bilayer viscoelastic properties [21,83–87]. The rotational dynamics of the phospholipid and cholesterol components in binary mixtures have also been studied as a probe of their intermolecular interactions [79,88–92]. A scale of bilayer softness is evident, ranging from highly deformable, surfactant or polyunsaturated bilayer systems, to systems containing phosphatidylethanolamine with an increased bilayer stiffness, and ultimately the very rigid yet fluid bilayers containing cholesterol [85]. The theoretical interpretation of the NMR relaxation data correlates well with previous macroscopic studies of membrane bending deformations. Future applications of ^{2}H NMR spectroscopy include studies of membrane lipid nanostructures and lipid-protein interactions, as well as investigations of the structure and dynamics of membrane proteins in relation to their characteristic biological modes of action.

Solid State ^{19}F-NMR Analysis of Oriented Biomembranes

Anne S. Ulrich

Institute of Organic Chemistry, University of Karlsruhe, and Forschungszentrum Karlsruhe, 76131 Karlsruhe, Germany

Introduction

The ^{19}F nucleus offers numerous advantages for solid state NMR, being first and foremost its high sensitivity that is only exceeded by ^{1}H. Especially in non-crystallizable biological samples, such as membranes and fibers, the lack of a natural abundance background often makes selective ^{19}F-labeling the method of choice [1–3]. Anisotropic interactions are accessible in robust 1-pulse experiments on macroscopically oriented samples, whose spectral lineshapes are readily interpreted. This strategy is thus particularly useful for oriented membranes and aligned fibers. Magic angle spinning experiments are not covered here, though they are of course also a fruitful source of information [4–7]. In the following, we will describe how one or a few fluorine labels in a synthetic peptide can provide information about its local alignment, its dynamic behavior, and its three-dimensional architecture in a lipid membrane. Further details about the methodological aspects of ^{19}F-NMR structure analysis and biological applications to membrane-active peptides are covered in recent reviews [8–11].

^{19}F-NMR Experimental Aspects

The ^{19}F nucleus has a spin of $I = 1/2$ and a high gyromagnetic ratio $\gamma/2\pi = 40.03$ MHz/T, which provides it with an exceptional NMR sensitivity and strong dipolar couplings [12–14]. Given that the intrinsic sensitivity scales with γ^3, ^{19}F should exceed that of ^{2}H and ^{15}N by a factor of 100 and 1000, respectively. In practice, a 10-fold and 100-fold gain in sensitivity is experienced [15]. Another benefit of strong dipolar couplings lies in the possibility to address long-range distances. If a 30 Hz homonuclear coupling can be resolved, this would correspond to an accessible distance of 7 Å for a ^{13}C spin pair, while up to 18 Å should be feasible by ^{19}F-NMR [16,17].

On a standard solid state NMR spectrometer the high-frequency channel is usually optimized for ^{1}H. For pure ^{19}F-NMR observation it may be sufficient to re-tune the transmitter, amplifiers, and probe, but for ^{1}H-decoupling it is necessary to implement designated ^{19}F-NMR hardware with two separate channels [11,14,18]. A double-resonance ^{19}F-{^{1}H} probe should be capable of handling high power levels, the two frequencies should be insulated by at least 60 dB, and additional external high-power filters are advisable. Teflon and any other materials containing traces of ^{19}F give serious background signals, even when positioned far away from the receiver coil.

A designated flat-coil probe is recommended for determining orientational constraints in uniaxially aligned membranes. Measurements are always carried out at a tilt angle of $\alpha = 0°$ where the sample normal N is aligned parallel to the static magnetic field direction B_0. It is useful to be able to tilt the sample at $\alpha \neq 0°$, for which the solenoid coil has to be equipped with a goniometer. Macroscopically oriented membranes are usually prepared on small glass slides [11,15,19–25], which carry about 3000 fully hydrated lipid bilayers each. Typically 20 such glass plates are stacked, and wrapped in polyethylene foil to prevent dehydration. For chemical shift referencing $CFCl_3$ is used as the standard with 0 ppm, and for oriented membrane samples we recommend to fill a thin glass box with a 1 M NaF solution [26,27]. In a similar approach, macroscopically aligned fibers are prepared as bundles, such as silk fibroin [28–30].

For ^{19}F-NMR studies of polypeptides in liquid crystalline membranes, a simple 1-pulse experiment is often adequate to reveal the necessary anisotropic information. In many cases the line-narrowing effect of ^{1}H-decoupling reaches a plateau at about 30 kHz field strength [15], hence moderate decoupling fields are sufficient. A Carr-Purcell-Meiboom-Gill (CPMG) sequence (without ^{1}H-decoupling) can be used to acquire homonuclear dipolar spectra from static samples for distance measurements between ^{19}F-spins [19,31–34]. The echo delay period has to be minimized (<50 μs) to prevent artifacts due to dephasing, which can become severe at high magnetic field strengths. The CPMG duty cycle has to be extrapolated to zero, and performance is generally improved by an xy8 phase cycle and composite refocusing pulses.

Strategies for Structure Analysis

With a focus on macroscopically oriented biomembranes and fibers, the two most useful structural parameters reviewed here are (i) the angle θ of a ^{19}F-labeled segment with respect to the static magnetic field direction B_0 (see Figure 1), and (ii) the internuclear distance r between a

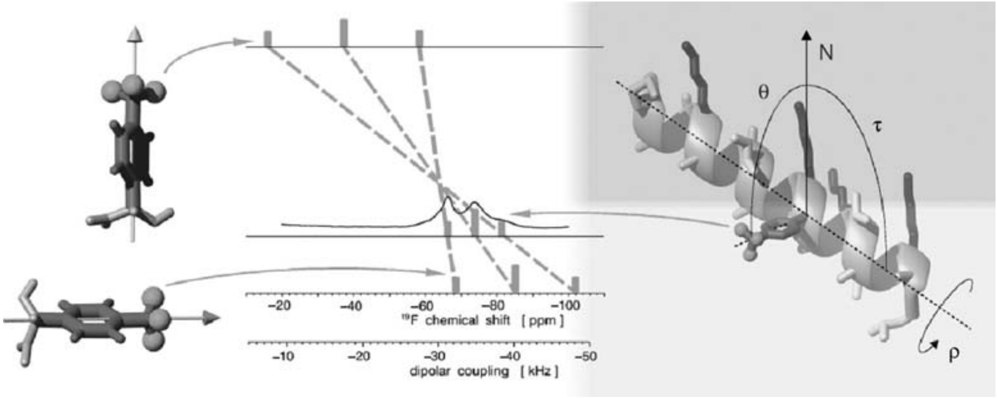

Fig. 1. Solid state ^{19}F-NMR analysis of macroscopically aligned samples is used to collect orientational constraints on membrane-embedded peptides carrying suitably ^{19}F-labeled side chains. For example, the anisotropic dipolar coupling within the rapidly rotating CF_3-group is analyzed to determine the angle θ of the CF_3-Phg side chain, which reflects the alignment of the peptide backbone. The stick spectra (green bars) illustrate the ($3\cos^2\theta$-1)-dependence over the full angular range. The dipolar splitting in the experimental 1-pulse spectrum reveals the magnitude of the dipolar coupling, and its sign is directly available from the chemical shift anisotropy of the triplet signal. Using a set of several orientational constraints, the alignment of the α-helix is evaluated in terms of its tilt angle τ, its azimuthal rotation ρ, and an order parameter S_{mol}. (See also Plate 31 on page XXX in the Color Plate Section.)

pair of ^{19}F-labels [10,11]. When angular measurements are carried out at a sample tilt angle of $\alpha = 0°$, then θ represents the local orientation relative to the membrane normal or fiber axis. The value of θ is available either from the anisotropic chemical shift δ_{CSA} of a single label [15,21,22], from the anisotropic dipolar coupling Δ_{FF} between two labels [19,21], or from the coupling Δ_{CF3} within a CF_3-group [20,23,25,34] (see Figure 1). Distances are always measured from dipolar couplings, using for example a static CPMG experiment [19,20] or REDOR under magic angle spinning [35,36].

The resonance frequency of a single ^{19}F-label is determined by its anisotropic chemical shift δ_{CSA} according to

$$\delta_{\text{CSA}}(\theta,\varphi) = \Delta^0_{\text{CSA}}\left[\frac{\langle 3\cos^2\theta - 1 + \eta_{\text{CSA}}\sin^2\theta\ \cos 2\varphi\rangle}{2}\right] \tag{1}$$

where $\Delta^0_{\text{CSA}} = (\delta_{\text{iso}} - \delta_{11})$ is the static CSA parameter and $\eta_{\text{CSA}} = (\delta_{33} - \delta_{22})/\Delta^0_{\text{CSA}}$ defines the asymmetry [11]. The polar angles θ and φ describe the CSA tensor orientation with respect to the static magnetic field B_0, and the bracket <> denotes the time-average. For $\eta_{\text{CSA}} = 0$ the equation simplifies to

$$\delta_{\text{CSA}}(\theta) = \Delta^0_{\text{CSA}}\left[\frac{\langle 3\cos^2\theta - 1\rangle}{2}\right] \tag{2}$$

where θ is the angle between the unique axis of the CSA tensor and B_0 (see Figure 1). Dipolar couplings, which are intrinsically symmetric, obey a similar relationship

$$\begin{aligned}\Delta_{\text{FF}}(\theta) &= \Delta^0_{\text{FF}}\left[\frac{\langle 3\cos^2\theta - 1\rangle}{2}\right]\\ &= \left|\frac{3\gamma_F^2\hbar\mu_0}{4\pi}\,\frac{1}{r^3}\left\langle\frac{3\cos^2\theta - 1}{2}\right\rangle\right|\end{aligned} \tag{3}$$

where Δ^0_{FF} is the static dipolar coupling (in Hz) between immobile spins aligned at $\theta = 0°$, and where the dipolar coupling constant $\gamma_F^2\hbar\mu_0/2\pi r^3$ depends on their internuclear distance r (in Å). For two geminal ^{19}F-labels on a CF_2-segment it is $\Delta^0_{\text{CF2}} = 30.8$ kHz [19,33], and for a CF_3-group undergoing fast rotation $\Delta^0_{\text{CF3}} = 15.8$ kHz [20,25]. The experimentally observed dipolar splitting Δ_{CF3} thus depends only on the angle θ between the CF_3-axis and B_0

$$\Delta_{\text{CF3}}(\theta) = \Delta^0_{\text{CF3}}\left\langle\frac{3\cos^2\theta - 1}{2}\right\rangle \tag{4}$$

The dipolar spectrum of a CF_3-group produces a triplet with an intensity ratio of 1:2:1, the splitting being defined between adjacent components. The overall powder lineshape of CF_3-group looks rather complex as it is also affected by CSA interactions of similar magnitude. The spectrum of an oriented sample reverts to a simple triplet (see Figure 1), since both interactions are scaled by the same angle θ. This correlation is useful for discriminating positive and negative dipolar couplings, whose sign cannot be determined from the splitting but is directly available via the CSA [23,25].

When a peptide is embedded in a liquid crystalline membrane, several modes of motion have to be taken into account. Any fast rotation leads to a projection of all spin interactions onto the rotational axis, hence the time-averaged term of Equations (1)–(4) can be re-written as

$$\left\langle \frac{3\cos^2\theta - 1}{2} \right\rangle = \left\langle \frac{3\cos^2\beta - 1}{2} \right\rangle \cdot \left\langle \frac{3\cos^2\alpha - 1}{2} \right\rangle \qquad (5)$$

where β is the angle between the spin interaction tensor and the axis of averaging, and α denotes the angle between the latter and B_0. When a peptide undergoes fast long-axial rotation in the bilayer, β corresponds to the effective angle between the relevant spin interaction tensor and the local membrane normal N, and α is the angle between N and B_0. When examining an oriented sample aligned at $\alpha = 0^\circ$, it is not possible to tell whether a molecule is engaged in long-axial rotation or not, since $\beta = \theta$. Long-axial rotation is only detected upon tilting the sample to $\alpha \neq 0^\circ$, when every resonance remains narrow and moves as a function of $(3\cos^2\alpha - 1)/2$.

Local oscillations of the labeled segment or a wobble of the entire molecule lead to further time-averaging over $<3\cos^2\beta - 1/2$. To account for such motions in a simplified manner, a scaling factor between 1.0 and zero is introduced [10,11,21–23], called the molecular order parameter S_{mol}

$$\delta_{\text{CSA}} = \Delta^0_{\text{CSA}} \left\langle \frac{3\cos^2\beta - 1}{2} \right\rangle \cdot S_{\text{mol}} \qquad (6)$$

$$\Delta_{\text{FF}} = \Delta^0_{\text{FF}} \left\langle \frac{3\cos^2\beta - 1}{2} \right\rangle \cdot S_{\text{mol}} \qquad (7)$$

$$\Delta_{\text{CF3}} = \Delta^0_{\text{CF3}} \left\langle \frac{3\cos^2\beta - 1}{2} \right\rangle \cdot S_{\text{mol}} \qquad (8)$$

Now, β is the time-averaged angle of the relevant spin interaction tensor with respect to the membrane normal. The value of S_{mol} describes the extent of non-specific wobble in the bilayer, which can be vigorous for small compounds giving order parameters as low as 0.1 [19,34], while peripherally membrane-associated peptides may exhibit values around 0.3–0.5 [21,23–25], transmembrane peptides near 0.8 [15], and large membrane proteins and fibrils approach $S_{\text{mol}} \approx 1.0$ [37–40].

^{19}F-Labeling of Peptides

For a successful ^{19}F-NMR structure analysis, the reporter group should be rigidly attached to a strategic position in the molecular framework, such that its NMR parameters reflect the conformation and alignment of the entire molecule [10]. By measuring the orientation of several individual ^{19}F-labels in different positions, the overall molecular architecture and its motional averaging can be re-constructed. *Intra*-molecular distance constraints are direct probes of conformation, and *inter*-molecular dipolar couplings may reveal the formation of oligomers. Several non-natural amino acids, in which the ^{19}F-label is rigidly connected to the peptide backbone, are suitable for structure analysis. Their relevant ^{19}F-NMR parameters are summarized in Table 1: 4F-L-phenylglycine (4F-Phg), 4-CF_3-L-phenylglycine (CF_3-Phg), 3F-L-alanine (F-Ala), and 3,3,3-F_3-L-alanine (F_3-Ala). First attempts at peptide synthesis were not trivial in view of certain instabilities, but protocols have been established with good yields [10]. When working with these labeled peptides, it is essential to avoid fluorinated solvents such as TFA in the HPLC-purification protocol, or TFE in the NMR sample preparation [41].

One of the first amino acids used in ^{19}F-NMR structure analysis is 4F-Phg, which racemizes extensively during Fmoc synthesis, but the resulting epimeric peptides can usually be separated by HPLC [41]. It is a useful label for measuring distances [21]. Orientational constraints can also be extracted from the ^{19}F CSA tensor, but its intrinsic asymmetry makes it necessary to take the side chain torsion angle χ_1 of the Cα–Cβ bond into account [21,22,24]. This difficulty is eliminated with CF_3-Phg, which is a more convenient label for measuring orientational constraints. The anisotropic dipolar coupling within the CF_3-group together with the sign from the CSA provides a direct measure of the orientation of the Cα–Cβ bond (which is colinear with the CF_3-axis) [23,25]. While the phenylglycine-derivatives are suitable substitutes for large hydrophobic amino acids, alanine-derivatives are more appropriate for replacing small side chains in peptides. 3F-Ala has a tendency to eliminate HF during Fmoc coupling, but this can be suppressed using base-free conditions. Given that the CH_2F-group is motionally averaged, it is very suitable for REDOR distance measurements on peptides [35,36,42]. Qualitative orientational changes have also been detected via 3F-Ala, though quantitative angular constraints cannot yet be obtained as long as the CSA tensor alignment in the molecular frame has not been fully characterized [11,35]. The obvious candidate to overcome this difficulty is F_3-Ala, which offers all the advantages of a rotating CF_3-group and has also been successfully incorporated into peptides (unpublished results).

Structure Analysis of Membrane-Associated Peptides

Most ^{19}F-NMR studies reviewed here are based on orientational analysis. A small number of constraints are

Table 1: CSA parameters of ^{19}F-labeled amino acids used for structure analysis. Two different sets of results are separated by a slash, namely of the polycrystalline amino acids and when they are incorporated into a lyophilized peptide

	4F-Phg	CF_3-Phg	3F-Ala	F_3-Ala
				δ_{iso} (ppm)	−115/− 113	−60/− 63	−230/− 222	−74/− 63
δ_{11} (ppm)	−65/− 59	−23/− 27	−202/− 195	−31/− 27
δ_{22} (ppm)	−126/− 124	−78/− 81	−228/− 215	−92/− 81
δ_{33} (ppm)	−153/− 155	−78/− 81	−260/− 255	−98/− 81

sufficient to fully describe the peptide alignment and motional averaging in the membrane, provided that its conformation is known. This approach is usually feasible for peptides consisting of well-defined secondary structure elements such as α-helices or β-sheets. The alignment and mobility of such entity is fully defined in terms of (i) its tilt angle τ, (ii) its azimuthal rotation angle ρ, and (iii) an order parameter S_{mol} describing the extent of motional averaging (see Figure 1). It is convenient to define τ as the tilt angle of the molecular pseudo-axis (e.g. helix axis), while the rotation ρ around this axis is often used to describe its amphiphilic profile. A computational grid-search is performed by systematically varying τ, ρ, and S_{mol} until the simulated NMR spectra fit the experimental data best [10]. When using at least three or more orientational constraints, a unique solution should be found, which is displayed in a τ–ρ map whose minimum represents the peptide alignment, along with the best-fit value of S_{mol}. The secondary structure, too, can be deduced via such τ–ρ analysis, since incorrect assumptions concerning the peptide conformation should give no acceptable rmsd minimum.

Several membrane-active peptides have been analyzed this way by solid state ^{19}F-NMR [15,21–25,43]. It was generally observed that these molecules undergo structural changes upon varying the lipid composition, temperature, and most importantly their own concentration. Therefore, special attention has to be paid to the possibility that different membrane-bound states may be correlated with self-assembly, and that peptide mobility is likely to differ in different oligomeric states. One particular advantage of ^{19}F analysis lies in the high sensitivity compared to other NMR-labels, which makes it possible to scan many different samples and experimental conditions in short time. Even very low peptide/lipid ratios down to 1:3000 have been examined, given that ^{19}F-NMR spectra can be typically acquired with as little as 40 µg ($\approx$ 20 nmol) in an overnight measurement [27]. Several examples of a comprehensive ^{19}F-NMR structure analysis will now be reviewed in the following paragraphs.

Fusogenic Peptide B18

The peptide B18 (LGLLLRHLRHHSNLLANI) was identified as the minimal fusogenic sequence from the sea urchin fertilization protein "bindin," which is responsible for triggering fusion of sperm and oocyte [44]. The isolated peptide induces fusion of liposomes *in vitro*, and its interactions with lipid membranes have been thoroughly characterized [22,41,45–50]. ^{19}F-NMR analysis of a series of nine peptide analogs, individually labeled with 4F-Phg, showed that B18 assumes a well-defined helix-loop-helix structure in oriented DMPC/DMPG membranes. The N-terminal α-helix is obliquely immersed into the bilayer ($\tau \approx 53°$, $\rho \approx -67°$, $S_{mol} \approx 0.8$), while the C-terminal segment remains flat on the membrane surface with ($\tau \approx 91°$, $\rho \approx 19°$, $S_{mol} \approx 0.5$). This picture is fully consistent with the hydrophobicity profile of the folded peptide, as illustrated in Figure 2. However, the monomeric conformation is only stable at peptide/lipid ratios lower than 1:100, since aggregation takes place at

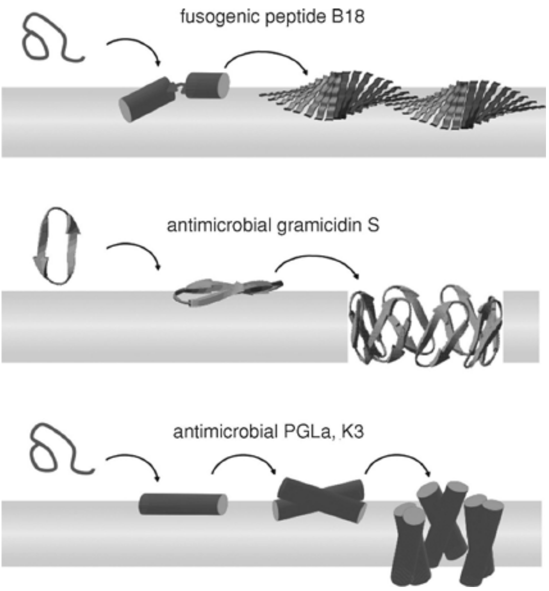

Fig. 2. Illustration of the concentration-dependent interactions of different peptides with lipid membranes, as characterized by solid state ^{19}F-NMR. The fusogenic peptide B18 folds into a helix-loop-helix structure upon membrane binding and aggregates into β-sheet amyloid fibrils at high concentration. The antimicrobial peptide gramicidin S is electrostatically attracted to negatively charged membranes and binds flat to the bilayer surface. At high concentration it can re-align and self-assemble into an oligomeric β-barrel pore. The antimicrobial peptides PGLa and K3 fold into amphiphilic α-helices upon membrane binding and re-align at an oblique tilt angle with increasing peptide concentration due to the formation of putative dimers. It has been speculated that the dimers may assemble further into a toroidal wormhole. (See also Plate 32 on page XXX in the Color PlateSection.)

higher concentration and with increasing age of the sample [24]. The aggregated state was shown to consist of cross-β-sheet amyloid fibrils, which penetrate into the hydrophobic region of the bilayer [49,50].

Antimicrobial Peptide Gramicidin S

Cationic peptide antibiotics possess an overall amphiphilic structure and act by permeabilizing bacterial membranes [43]. Gramicidin S ($[\mathrm{VOL^{D}FPVOL^{D}FP}]_{\mathrm{cyclo}}$) is produced by *Bacillus brevis* and has a cyclic β-sheet structure, stabilized by four intramolecular H-bonds. For ^{19}F-NMR structure analysis, 4F-Phg labels were substituted at the two equivalent positions of either Leu or Val. CPMG distance measurements in oriented DMPC membranes were carried out on these pairs of equivalent labels to confirm that 4F-Phg does not distort the cyclic β-sheet backbone [21]. The orientational constraints of the 4F-Phg labels revealed the peptide alignment and mobility in the membrane. At low peptide/lipid ratios ($\leq$1:80) gramicidin S lies flat on the surface, as illustrated in Figure 2, with its symmetry axis parallel to the membrane normal ($\tau \approx 0^\circ$, ρ unrestricted). In liquid crystalline bilayers the peptide is highly mobile ($S_{\mathrm{mol}} \approx 0.3$) and engaged in long-axial rotation, while in the gel phase it is immobilized ($S_{\mathrm{mol}} \approx 1.0$) and well ordered. At high concentration ($\geq$1:40) gramicidin S can flip upright in the membrane ($\tau \approx 80^\circ$, $\rho - 45^\circ$, $S_{\mathrm{mol}} \approx 1.0$) [24]. Given the ambiguity associated with the side-chain torsion angle χ_1 of 4F-Phg, the ^{19}F-NMR data was supported by independent ^{15}N-NMR measurements of backbone-labeled peptides. The upright alignment appears to reflect an oligomeric state, not only because of its concentration-dependent formation but also in view of its molecular mobility ($S_{\mathrm{mol}} \approx 1$, with fast long-axial rotation around N). Gramicidin S was thus suggested to self-assemble as a β-barrel to form a pore across the membrane, whose structure would be ideally stabilized by intermolecular H-bonds (see Figure 2). The number of monomers was not accessible by NMR, but a hexameric β-barrel has indeed been recently observed by crystallographic analysis of a modified gramicidin S analog [51].

Antimicrobial Peptide PGLa

The antimicrobial peptide PGLa (GMASKAGAIAGKIAKVALKAL-NH$_2$) from the skin of *Xenopus laevis* possesses an amphiphilic structure when folded as an α-helix. A series of peptide analogs was synthesized with 4F-Phg or CF$_3$-Phg substitutions to determine orientational constraints [23,25,27,41]. At a peptide/lipid ratio of 1:200 the helix is aligned flat in DMPC membranes ($\tau \approx 95^\circ$), and the azimuthal rotation angle ($\rho \approx 110^\circ$) agrees well with the amphiphilic character of PGLa [23]. At low concentration the peptide is monomeric and mobile in liquid crystalline bilayers ($S_{\mathrm{mol}} \approx 0.6$), undergoing long-axial rotation. In the lipid gel phase it is slightly less mobile ($S_{\mathrm{mol}} \approx 0.7$) and long-axial rotation has ceased. By varying the peptide/lipid ratio from 1:3,000 to 1:8, it was found that PGLa changes its orientation with increasing peptide concentration [27]. Broadened signals are observed at intermediate peptide/lipid ratios (1:100), showing that the structural interconversion of PGLa occurs on the NMR time-scale, unlike gramicidin S for which two distinct populations were simultaneously observed. At higher concentration ($\geq$1:50) PGLa is aligned at an oblique tilt angle ($\tau \approx 125^\circ$, with $\rho \approx 90^\circ$, see Figure 2) [25]. The concentration-dependent re-alignment was an unexpected result, as a monomer would probably not be stable at an oblique tilt angle. Notably, even at high concentration the tilted peptide undergoes long-axial rotation, and its order parameter is similar to that at low concentration, hence it cannot be extensively aggregated. PGLa was thus suggested to form dimers in the membrane, as it had been demonstrated for the two related peptides magainin (by transferred-NOE) and K3 (by REDOR NMR, see below) [35,36,52]. For PGLa a symmetric antiparallel (head-to-tail) arrangement would be consistent with the occurrence of single ^{19}F-NMR signals in the oriented samples [25]. The functional relevance of the tilted and presumably dimeric PGLa structure is not yet clear. Nevertheless, to be certain that the structure analysis did not suffer from artifacts due to the stiff and bulky ^{19}F-labels, the re-alignment was independently confirmed with entirely unperturbing ^{2}H- and ^{15}N-labels [43,53]. The tentative ^{19}F-NMR structure proved to be almost perfect at low peptide concentration, and still rather accurate at high concentration where the bulky labels might have been expected to interfere with the putative dimerization interface.

Antimicrobial Peptide K3

Based on the sequence of PGLa, an α-helical model peptide K3 [$(KIAGKIA)_3$–NH_2] had been designed with improved antimicrobial activity and reduced hemolytic side effects [54,55]. By labeling one native Ala position with 3F-Ala, the static ^{19}F-NMR spectra of K3 in oriented membranes showed that this peptide undergoes a change in its alignment and/or mobility at a peptide/lipid ratio between 1:200 and 1:20 [35]. Unlike PGLa, however, long axial rotation ceases at high peptide concentration in liquid crystalline bilayers. Further peptides were synthesized with ^{13}C-labels for REDOR distance analysis by Schaefer *et al.*, who showed that K3 forms parallel (head-to-head) dimers at high peptide/lipid ratio [35,36]. Further distance constraints between selectively labeled lipids and peptides revealed close contacts of K3 with both lipid headgroups and acyl chains [36]. Based on these indirect results, a toroidal wormhole was postulated for K3 at high peptide concentration. Given the dimeric structure of K3 (though without knowing its orientation in the membrane) and the observed re-alignment of PGLa (but without having measured intermolecular distances), a generalized course of events upon membrane binding is schematically suggested in Figure 2 for this class of α-helical antimicrobial peptides.

Perspectives

Over the recent years, sufficient experience with ^{19}F-labeling of membrane-associated peptides and their spectral analysis has been gained to allow a critical comparison with the more established solid state NMR approaches. We feel that some of the drawbacks with ^{19}F (i.e. non-trivial chemical synthesis, and unusual spectrometer hardware) are more than compensated for by the excellent sensitivity and the robustness of the ^{19}F-NMR measurements. Overall, CF_3-Phg (and possibly F_3-Ala, unpublished results) appears to be the most suitable label for measuring angular constraints in oriented membrane samples, while 3F-Ala is the best choice for determining distances by REDOR. The risk of conformational and functional perturbation by ^{19}F-labels has to be borne in mind and needs to be tested for every system under investigation. However, the accuracy of the resulting three-dimensional peptide structure does not seem to be limited by the intrinsic error range of the ^{19}F-NMR data (unless labels are placed at a dimerization interface), but it depends more on the conformational assumptions when reconstructing the molecular architecture from a limited number of constraints. Overall, it has been possible to characterize the structure and behavior of many different peptides under a wide range of relevant conditions, which provided valuable information about their functional mechanisms.

Acknowledgments

I thank all past and present members of the lab for their hard work and enthusiasm, and specifically Ralf Glaser for Figure 1. Financial support was provided by the DFG, the Universities of Jena and Karlsruhe, the Forschungszentrum Karlsruhe, and the CFN.

Introduction

Bacterial Resistance to Antibiotics

The dramatic increase in bacterial resistance to numerous conventional antibiotics has led to the need to discover and develop novel antimicrobial compounds defeating the known mechanisms of bacterial resistance by the use of novel modes of action [1]. Several research groups have turned to the investigation of antimicrobial peptides that are found in several organisms and for which the structural and functional characteristics make them very promising therapeutic agents [2–4]. Despite the fact that the exact mechanisms of action by which these antimicrobial peptides kill bacteria are still not completely understood, it has been demonstrated experimentally that the interactions between the lipid membrane and antimicrobial peptides, leading to an increase in membrane permeability, play a major role in antimicrobial activity and that because of these interactions, the antimicrobial peptides adopt a 3D structure resulting in an amphiphilic character [5]. Amongst the large number of studies on the modulation of the activity of antimicrobial peptides by the modification of structural parameters, it appears that the amphiphilic character is essential for the affinity of these peptidic units for the lipid bilayer [6–8]. In light of these studies, several general mechanisms have been proposed in the literature to explain the membrane permeability caused by antimicrobial peptides, such as the "barrel-stave," "carpet-like," "toroidal," "in-plane diffusion," and "detergent-like" models [9,10]. The first two mechanisms are illustrated in Figure 1.

Nuclear magnetic resonance (NMR) spectroscopy, and particular solid-state NMR spectroscopy, is a well-suited technique to investigate the structure and dynamics of peptides in interaction with lipid membranes. Different approaches have been developed to study these systems in which the restricted molecular motions result in broad NMR spectra. This chapter will present an overview of the use of solid-state NMR spectroscopy to investigate the structure and dynamics of antimicrobial peptides in interaction with membranes. The first section will be devoted to the study of the effect of antimicrobial peptides on the lipid bilayer by a combination of ^{31}P and ^{2}H solid-state NMR spectroscopy while the second part will present an overview of several techniques to investigate the structure and dynamics of antimicrobial peptides in membranes. Both sections will be supported by recent examples.

Effects of Antimicrobial Peptides on Model Lipid Membranes

^{31}P NMR Spectroscopy

Phosphorus-31 has a spin-1/2 and a 100% natural abundance, and, with its good sensitivity, is extremely useful to investigate the structure and dynamics of the polar headgroup of phospholipids, which are the main constituent of biological membranes [11]. In particular, it is possible to obtain static ^{31}P NMR spectra which are dominated by the chemical shift anisotropy (CSA), to use the magic-angle spinning (MAS) technique which averages the CSA to its isotropic values, and finally to use samples macroscopically oriented in the magnetic field. The main information obtained from static ^{31}P NMR spectra is the nature of the lipid phase. For example, the interactions between lipids and antimicrobial peptides can lead to the formation of non-lamellar phases, such as isotropic, cubic, and hexagonal phases. This is the case for several antimicrobial peptides of amphibian origin such as caerin 1.1, maculatin 1.1, and caerin 4.1 for which the ^{31}P NMR spectra have revealed the formation of isotropic or cubic structures within the lipid system [12], as well as for bacterial antimicrobial peptides such as gramicidin S, A, and D which are known to induce a hexagonal phase in model membranes [13–15]. Another interesting application of ^{31}P NMR spectroscopy is the study of the dynamics and orientation of the lipid polar headgroup. In fact, several natural and synthetic antimicrobial peptides have demonstrated a strong interaction with the polar headgroup and this is reflected in the ^{31}P NMR spectra by a change of the CSA [16,17]. This change of CSA can be expressed in a quantitative way by calculating an order parameter S_2 which is governed by the lipid dynamics and/or orientation and which compares the CSA of two systems [18].

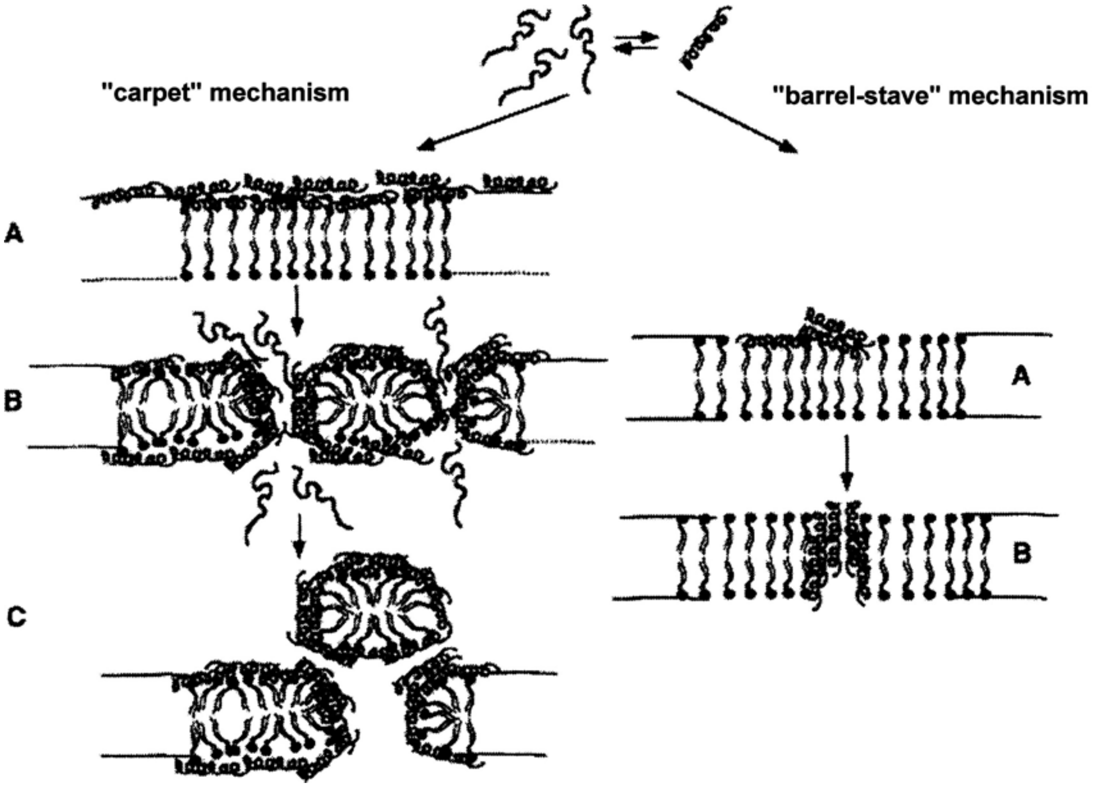

Fig. 1. Cartoon illustrating the barrel-stave (right) and the carpet-like (left) models suggested for membrane permeation. In the carpet-like model, the peptides are bound to the surface of the membrane with their hydrophobic surfaces facing the membrane and their hydrophilic surfaces facing the solvent (step A). When a threshold concentration of peptide monomers is reached, the membrane goes into pieces (steps B and C). At this stage, a transient pore is formed. Adapted from Ref. [67] and reproduced with permissions.

Using the MAS technique, ^{31}P NMR spectroscopy can allow the study of binary lipid mixtures since different lipids can be discriminated on the basis of their non-equivalent isotropic chemical shifts. For example, Bonev *et al.* have investigated the interactions between the antimicrobial peptide nisin with equimolar mixtures of dimyristoylphosphatidylcholine (DMPC) and dimyristoylphosphatidylglycerol (DMPG) and the ^{31}P MAS NMR spectra have demonstrated a preferential interaction of the peptide with the anionic lipid (DMPG) [19]. Another way to investigate the effect of antimicrobial peptides on the orientational order and conformation of lipid polar headgroups is to use samples macroscopically oriented with their normal parallel to the magnetic field B_0. The ^{31}P NMR spectra of antimicrobial peptides studied with this approach, such as LL-37 [20], protegrin [21], RTD-1 [22], and pardaxin [23], have demonstrated a shift of the lipid resonances toward lower frequencies, a line broadening and/or the presence of non-oriented lipid structures, depending on the peptide concentration and on the nature of the lipid investigated. This technique is also used to determine the alignment quality of oriented samples to be used for the determination of the membrane orientation of peptides, as discussed later in this chapter.

^{2}H NMR Spectroscopy

While ^{31}P NMR spectroscopy can be used to investigate the hydrophilic region of lipid bilayers, ^{2}H NMR spectroscopy is a very powerful technique to study the membrane hydrophobic core by replacing the acyl chain protons by deuterons. Deuterium is a spin-1 nucleus with a quadrupole moment that interacts with the electric field gradient at the nucleus, giving rise to the quadrupolar interaction. Two spin transitions are possible and a doublet of resonances is observed on a ^{2}H NMR spectrum, separated by the quadrupolar splitting $\Delta\nu_Q$. For a system with axially symmetric motions, the quadrupolar splitting is given by:

$$\Delta\nu_Q = (3/4)(e^2qQ/h)(3\cos^2\theta - 1)S_{CD} \quad (1)$$

where (e^2qQ/h) is the quadrupole coupling constant (~170 kHz for aliphatic C–D) [24], θ is the angle between the bilayer normal and the external magnetic field B_0, and S_{CD} is the order parameter of a deuterium bond vector. As described extensively, this order parameter is the product of several contributions, including intramolecular motions such as trans-gauche isomerizations, and anisotropic reorientation of the whole phospholipid molecules. Hence it is possible to determine variations in lipid chain order by monitoring changes in $\Delta\nu_Q$ values [25]. For example, the ^{2}H NMR spectra of phospholipids in the presence of amphibian antimicrobial peptides such as aurein 1.1, citropin 1.1, and maculatin 1.1 [16], as well as the peptides nisin produced by *Lactococcus lactis* [19] and LL-37 found in humans [26], indicate that these peptides induce disorder in the lipid acyl chains.

Another interesting aspect of ^{2}H NMR spectroscopy is the study of deuterated lipid polar headgroups. In particular, DMPC deuterated on the choline headgroup at positions α and β is known to act as a "molecular voltmeter," sensing the accumulation of charges at the surface of the bilayer [27,28]. An example of this phenomenon is observed with the antibacterial peptide PGLa in interaction with DMPC-d$_4$ membranes, for which a decrease (increase) of the quadrupolar splitting for the α (β) deuterons reflects a change of conformation of the choline headgroup known as a tilt of the $^-$P–N$^+$ dipole induced by the presence of positive charges [29]. From the analysis of these ^{2}H NMR spectra, Wieprecht *et al.* have concluded that the peptide PGLa is located at the surface of the bilayer and is intercalated between the polar headgroups, resulting in a change of conformation of these headgroups [29].

Study of Antimicrobial Peptides in Membranes

Solid-state NMR is also a very useful technique to characterize the structure and dynamics of peptides that are immobilized on the relevant NMR time scale. Anisotropic interactions that dominate the solid-state NMR spectra result in orientation-dependent shifts and splittings of the peptide resonances. The main NMR parameters of interest are therefore the ^{15}N and ^{13}C chemical shifts and CSA, and the dipolar couplings between ^{1}H, ^{13}C, and ^{15}N. The goal of this section is to demonstrate how these parameters are exploited to obtain information on the structure and dynamics of antimicrobial peptides in interaction with lipids.

Dynamics of Antimicrobial Peptides

The study of the dynamics of antimicrobial peptides incorporated into lipid membranes is in general performed by the analysis of the spinning sideband intensity in MAS ^{13}C or ^{15}N spectra or of the CSA in static spectra. Buffy *et al.* have investigated by MAS the dynamics of the 18-residue antimicrobial peptide protegrin (PG-1) [30] and have demonstrated that the dynamics differs depending on the lipid composition. For example, the intensity of the spinning sidebands in ^{13}C NMR MAS spectra of the ^{13}C labeled peptide is less important in dilauroylphosphatidylcholine (DLPC) bilayers compared to palmitoyloleoyl-phosphatidylcholine (POPC) bilayers, indicating a more rigid peptide in thicker lipid bilayers. A similar result was obtained from the analysis of the $^{13}C_\alpha$–H_α dipolar coupling for the Leu5 residue, which is 11.9 kHz in POPC and 2.0 kHz in DLPC. Yamaguchi *et al.* have also investigated the PG-1 dynamics in DLPC bilayers by static ^{15}N NMR spectroscopy [21]. A decrease of the ^{15}N CSA observed for PG-1 in lipid bilayers indicates increased motion compared to the static peptide. Similar studies have also been performed with the cyclic antimicrobial peptide RTD-1 by Buffy *et al.* and the analysis of the spinning sidebands in ^{15}N and ^{13}C MAS spectra for the solid peptide and the peptide incorporated into DLPC bilayers demonstrated that the peptide is immobilized in bilayers [22].

Membrane Orientation and Topology of Antimicrobial Peptides

The determination of the membrane orientation of antimicrobial peptides is in general performed using samples oriented with their normal parallel to the external magnetic field B_0. The technique most frequently used to obtain these samples is the mechanical alignment of the lipids between glass plates [31] but the use of lanthanide-doped bicelles [32] is also possible. These experiments are performed with peptides either selectively or uniformly labeled with ^{15}N and/or ^{13}C.

Membrane Orientation from 1D Spectra

For helicoidal antimicrobial peptides selectively ^{15}N labeled at one position in the amino acid sequence, the membrane orientation can be determined from the chemical shift obtained in samples oriented in the magnetic field B_0. More specifically, for a α-helical peptide, the σ_{33} element of the ^{15}N CSA tensor is aligned along the NH bond, and the NH bond vector is almost parallel to the helix axis. It is therefore possible to estimate the peptide orientation by the analysis of the ^{15}N chemical shift [33], as illustrated in Figure 2. The situation is, however, more complex for peptides in β-sheet conformation since the

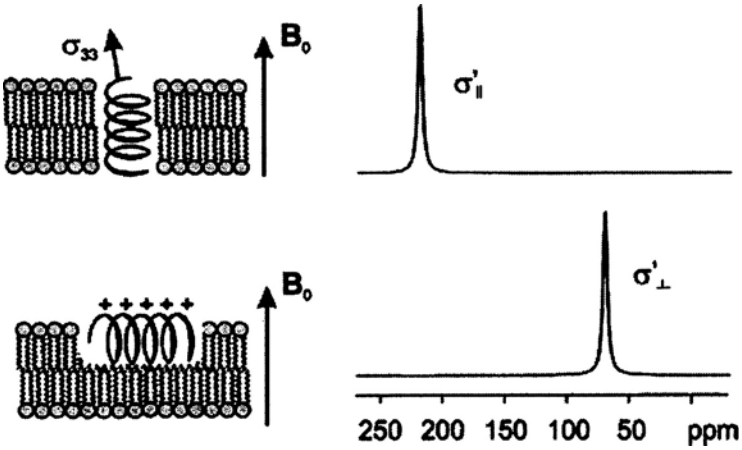

Fig. 2. Top: Simulated proton-decoupled ^{15}N solid-state NMR spectrum of a transmembrane peptide as well as a sketch of the situation. Bottom: Same as top for a peptide oriented parallel to the membrane surface. Adapted from Ref. [33] and reproduced with permissions.

membrane orientation has to be determined from both the ^{13}C and ^{15}N chemical shifts of the carbonyl and amide groups, respectively. However, since the majority of antimicrobial peptides present a helicoidal structure, these will be discussed in the present review. For more information about β-sheet peptides, the reader is referred to the references of Buffy *et al.* [22] and Yamaguchi *et al.* [21].

In addition to their study of β-sheet peptides such as protegrins PG-1, Yamaguchi *et al.* have investigated the 18-residue antimicrobial peptide ovispirin, which presents a large spectrum of activity [34]. By selectively ^{15}N labeling the peptide at residues Leu3, Ile6, Ile11, and Gly18, they have demonstrated that ovispirin adopts a surface orientation in bilayers of POPC and palmitoyl-oleoyl-phosphatidylglycerol (POPG) (3:1), except for a small portion of the C-terminal region of the helix which appears to deviate from the surface of the bilayer. In addition, the analysis of the ^{15}N CSA of the peptide incorporated into a non-oriented POPC/POPG system indicates that ovispirin undergoes uniaxial rotational diffusion around the bilayer normal. This is reflected in the ^{15}N spectra by a decrease of the CSA compared to that of a powder spectrum, namely a decrease from 150 to 75 ppm. Using a similar approach, Marassi *et al.* have determined the membrane orientation of the peptide cecropin A incorporated into DMPC/DMPG (4:1) membranes [35]. The oriented and non-oriented ^{15}N NMR spectra of cecropin A selectively labeled at residues Val11 and Ala27 indicate that the peptide is oriented perpendicular to the membrane normal and is immobile relative to the NMR time scale.

The last example presented here is the study of the membrane orientation of the 21-residue antimicrobial peptide PGLa by Bechinger *et al.* [36]. Several peptides selectively ^{15}N labeled at residues Ala3, Ala10, Ala14, Val16, and Ala20 have been synthesized and incorporated into bilayers of palmitoyl-oleoyl-phosphatidylethanolamine (POPE) and POPG (3:1) bilayers. This multiple labeling scheme has allowed the determination, via the chemical shift values, of both the orientation and dynamics of these residues along the peptide backbone. The ^{15}N NMR spectra of the peptide incorporated into bilayers oriented between glass plates have demonstrated, as for the peptides described above, a surface orientation for residues Ala10 to Ala20, while residue Ala3 has an isotropic chemical shift characteristic of a higher degree of liberty in the N-terminal region. The conclusion regarding the dynamics of several residues is also confirmed by the ^{15}N NMR spectra of non-oriented samples in which an increase of the CSA is observed from the N-terminal to the C-terminal regions.

Although it is possible, as shown by the examples presented above, to estimate the membrane orientation of antimicrobial peptides from 1D ^{15}N NMR spectra, this approach does not allow the determination of the peptide tilt angle with great precision with peptides singly labeled at one amino acid residue. This type of analysis can however be carried out using peptides ^{15}N labeled at multiple sites on a single peptide, as discussed in the next section.

The PISEMA Approach

The polarization inversion spin-exchange at the magic-angle (PISEMA) experiment combines the measurement of both the ^{15}N CSA and the dipolar coupling between the ^{15}N and ^{1}H nuclei of the amide group. In the 2D PISEMA spectrum of a helicoidal peptide uniformly ^{15}N labeled, the resonances form a regular pattern called PISA wheel from which it is possible to extract both the tilt (as illustrated in Figure 3) and rotation angle of the peptide [37–39]. This approach also requires the use of oriented samples in the magnetic field.

One of the antimicrobial peptides most studied using the PISEMA approach is magainin, a 23-residue

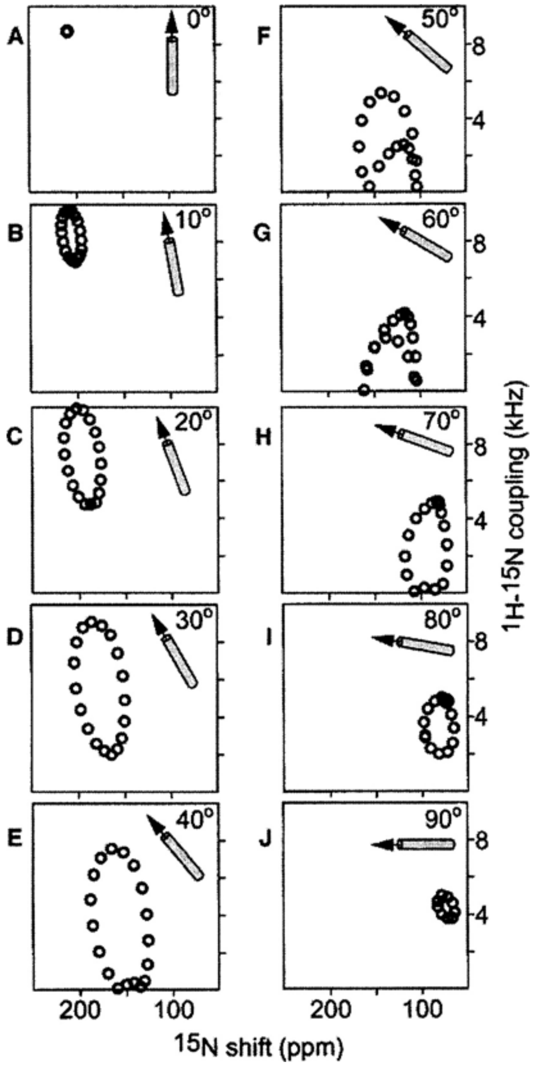

Fig. 3. PISEMA spectra calculated for a 19-residue α-helix with 3.6 residues per turn and uniform dihedral angles ($\phi = -65$, $\psi = -40$) at various helix tilt angles relative to the bilayer normal. A. 0°, B. 10°, C. 20°, D. 30°, E. 40°, F. 50°, G. 60°, H. 70°, I. 80°, J. 90°. The principal values and molecular orientation of the ^{15}N chemical shift tensor ($\sigma_{11} = 64$ ppm; $\sigma_{22} = 77$ ppm; $\sigma_{33} = 217$ ppm; $\sigma_{33}\ \angle\mathrm{NH} = 17°$) and the NH bond distance (1.07Å) were as previously determined. Adapted from Ref. [68] and reproduced with permissions.

peptide of amphibian origin. Previous experiments had demonstrated that magainin adopts a surface orientation in lipid bilayers [40]. However, the rotation angle could not be determined from 1D ^{15}N NMR spectra. Using the PISEMA approach, Marassi *et al.* have confirmed that magainin is oriented perpendicular to the membrane normal and have determined the polarity of the α-helix, namely a helix oriented in such way that residues Phe5, Phe12, and Phe16 are at the apolar/polar interface, with charged residues such as lysines exposed to the hydrophilic side of the bilayer [41]. In addition, the observation in the PISEMA spectrum of well-resolved single resonances from individual backbone amide sites indicates that magainin binds tightly to the membrane surface with a unique orientation. Another very interesting example demonstrating the potential of the PISEMA approach in the structural study of peptides is related to a peptide from a fragment of the C-terminal region of colicin B, a channel bacterial toxin [42]. More specifically, Lambotte *et al.* have determined, using the PISEMA approach, the mode of insertion of colicin B in POPC/POPG (4:1) bilayers [42]. The detailed analysis of the PISEMA spectra indicates regions characteristic of both transmembrane and in-plane helices. They have therefore concluded that colicin B preferentially adopts an "umbrella" type conformation in lipid bilayers. Another peptide from the same family as colicin B, namely colicin E1, has also been studied by the PISEMA approach [43].

^{1}H Spin Diffusion

The ^{1}H spin diffusion 2D NMR technique under MAS has been used to investigate the approximate location of peptides or proteins in lipid bilayers [44]. ^{1}H magnetization is transferred from mobile lipids to the rigid peptide via distance-dependent ^{1}H–^{1}H dipolar couplings. The 2D peak intensities as a function of the spin-diffusion mixing time yield a magnetization transfer curve that reflects the proximity of the lipid protons to the peptide protons since the rate of spin diffusion is greater in rigid media such as peptides compared to that in mobile media such as the lipids. The membrane topology of the bacterial peptide colicin Ia in interaction with POPC/POPG (3:1) bilayers has been estimated from ^{1}H spin diffusion by Huster *et al.* [45]. Previous studies on this system had revealed that colicin Ia is incorporated in the bilayer, without any information, however, on its degree of insertion. By selectively labeling the peptide with ^{13}C on the α-carbon of the Ala13 residue, these authors have observed a fast magnetization transfer between C_αAla13 and the lipid terminal CH_3 groups, estimating from simulation a distance of 2–4 Å between these two moieties. Magnetization transfers have also been observed between C_αAla13 and other regions of the lipid, namely the acyl chain CH_2 groups and the lipid polar headgroup. This model of interaction is in agreement with the "umbrella" model, which can explain the contact of the peptide with both the lipid polar headgroup and acyl chains.

The membrane topology of another antimicrobial peptide, protegrin PG-1, has also been investigated by ^{1}H spin diffusion by Buffy *et al.* [46]. When incorporated into POPC bilayers, they have determined that PG-1, like colicin Ia, is in contact with both the lipid polar headgroup and the acyl chains. However, the proposed mode of interaction is different, being more similar to the toroidal model where the PG-1 aggregates only need to span one monolayer to create the pore. The degree of penetration of PG-1 has also been determined by the same research group in DLPC bilayers using the paramagnetic ion Mn^{2+} [46]. By comparing the T_2 relaxation enhancement of PG-1 carbons to that of the lipid carbons, the relative depth of PG-1 with respect to the lipid moieties can be determined. The results obtained by this technique demonstrate that PG-1 is completely inserted in the bilayer and tilted from the bilayer normal, with Val16 as the most deeply embedded residue and Gly2 as the closest to the membrane surface phosphate group. The proposed mode of interaction is the "snorkel" model, where the peptide hydrophobic residues are incorporated into the bilayer while the polar residues remain in contact with the aqueous phase.

Secondary Structure of Antimicrobial Peptides

It is well recognized that the majority of antimicrobial peptides adopt a random conformation in solution and defined secondary structures, such as α-helices and β-sheets, only upon interaction with the membrane. It is therefore very interesting to study the secondary structure of antimicrobial peptides incorporated into membranes. The next section will thus cover some experiments that provide information on the conformation of antimicrobial peptides.

^{13}C Isotropic Chemical Shifts

One of the simplest approach to determine the secondary structure of a specifically ^{13}C labeled residue in an antimicrobial peptide consists in measuring its isotropic chemical shift in MAS spectra. In particular, the values of the carbonyl and C_α chemical shifts for several amino acids are dependent on the peptide secondary structure [47]. For example, Naito *et al.* have investigated the structure of melittin, a peptide that possesses both hemolytic and antimicrobial activities, in interaction with DMPC membranes [48]. Isotropic chemical shifts of 173.2 and 15.8 ppm have been obtained for melittin labeled at residues [1-^{13}C]Gly3 and [3-^{13}C]Ala15, confirming the α-helicoidal structure for this peptide. The helicoidal structure of the human peptide LL-37 has also been determined from the isotropic chemical shifts of 175.8 and 53.5 ppm for the [^{13}C=O]Leu31 and [$^{13}C_\alpha$]Ala13 residues [20].

Internuclear Distances

The two techniques that are most often used for the measurement of hetero- and homonuclear distances in solid-state MAS NMR spectra of antimicrobial peptides are the rotational echo double resonance (REDOR) and rotational resonance (RR) techniques [49–51]. The REDOR technique is based on the dephasing of the magnetization of the observed nucleus (typically ^{13}C) due to the coupling with a second nuclear spin (typically ^{15}N). The difference in the intensity of the spectra obtained with and without the ^{15}N pulses depends solely on the ^{13}C-^{15}N dipolar coupling, and this coupling is related to the heteronuclear distance between the nuclei. From the dephased $^{13}C\{^{15}N\}$ NMR spectra, a dephasing curve is obtained as a function of mixing time, from which the distance can be extracted. In addition, as shown in the examples discussed below, the REDOR technique can also be used to remove the natural abundance contribution of the lipid carbons in ^{13}C NMR spectra.

The first example discussed here is related to the 33-residue antimicrobial peptide pardaxin investigated by Porcelli *et al.* [52]. The structure of this peptide, a bend-helix-bend-helix conformation, has first been determined in sodium dodecylphosphocholine (DPC) micelles by ^{1}H solution NMR. The REDOR technique was then used to confirm the helicoidal structure in the C-terminal region of this peptide selectively ^{13}C and ^{15}N labeled at residues Leu18 and Leu19 incorporated into DMPC, POPC, and POPE/POPG (3:1) multilamellar vesicles [52]. More specifically, the $^{13}C\{^{15}N\}$ REDOR dephased spectra of pardaxin consist of a single peak with a frequency value of approximately 176 ppm, consistent with the helical conformation of this C-terminal segment. Another example of structural studies of antimicrobial peptides by REDOR is related to the synthetic peptide K3, a 21-residue analog of the natural peptide magainin, in interaction with dipalmitoylphosphatidylcholine/dipalmitoylphosphatidylglycerol (DPPC/DPPG) (1:1) bilayers [53]. By analyzing the isotropic chemical shifts in the REDOR spectra of residues [1-^{13}C]Ala17 and [3-^{13}C]Ala3 dephased by residues [^{15}N]Gly18 and [^{15}N]Gly4, they have concluded that the isotropic chemical shifts of 177 and 16 ppm are only consistent with a single α-helical structure for the K3 peptide.

The RR method is based on the fast magnetization exchange between two spins when the sample spinning speed (ν_r) is equal to the frequency separation ($\Delta\nu$) of the two resonances for the two spins, i.e. when $\Delta\nu = n\nu_r$, where $n = 1, 2, 3$, etc. The reintroduction of the dipolar coupling gives rise to magnetization exchange between the two spins, and a magnetization exchange curve as a function of mixing time is obtained and fitted to a specific homonuclear distance between these two spins.

The R^2 technique has been used in the last few years for the structural study of antimicrobial peptides incorporated into membranes. In particular, Lam *et al.* have illustrated the potential of the technique for structural study of the antimicrobial peptide melittin in interaction with

DMPC membranes [54]. Several peptides labeled at different positions along the amino acid sequence have been synthesized and for example, a distance of (2.5 ± 0.2) Å has been obtained between residues [^{13}C=O]Gly3 and [$^{13}C_{\alpha}$]Ala4. As expected, this homonuclear distance is consistent with a α-helical structure.

Another interesting example is the structural study of gramicidin S, a bacterial antimicrobial peptide [55]. In this case, homonuclear distances between two ^{19}F nuclei have been measured from static spectra using a modified Carr-Purcell-Meiboom-Gill (CPMG) sequence. The conformation of gramicidin S had previously been determined as a cyclic antiparallel β-sheet peptide by ^{1}H solution NMR and X-ray crystallography and by studying gramicidin S in which the Leu3 and Leu8 residues have been replaced by the non-natural amino acid 4F-phenylglycine (4F-Phg). ^{19}F has been shown to be a useful probe for the structural study of antimicrobial peptides [55].

Torsion Angles

To complement the measurement of internuclear distances in the structural study of antimicrobial peptides, a variety of experiments have recently been developed to determine the torsion angles (ϕ and ψ) between peptide planes in peptides and proteins. Even though these techniques have been mostly applied so far to peptides with only a few amino acid residues and that the application of these techniques to antimicrobial peptides is still at an early stage, the results obtained are really promising. The basic principle in the measurement of torsion angles lies in the correlation between the orientation of two anisotropic tensors, such as two dipolar tensors, two CSA tensors, or one CSA and one dipolar tensors. Since most experiments require the use of MAS, the interactions averaged out by MAS are reintroduced via specific pulse sequences, as is the case for the internuclear distance measurement techniques described above.

Several research groups have used the mono and tripeptides N-acetyl-ᴅ, ʟ-valine (NAV) and N-formyl-[U-^{13}C, ^{15}N]Met-Leu-Phe (MLF) as model peptides for the development of torsion angle measurement experiments since the crystalline structure of these peptides has been determined by X-ray crystallography. For example, Ladizhansky *et al.* have determined the torsion angle ψ for the tripeptide MLF with a HCCN dipolar correlation MAS experiment that measures ψ in the angular range of -20° to -70°, characteristic of α-helix [56]. Hong *et al.* have used the monopeptide NAV to determine the torsion angle ϕ via the correlation of the ^{15}N chemical shift and C_{α}–H_{α} dipolar coupling tensor orientations under MAS [57]. They have shown that the technique exhibits the highest sensitivity to ϕ angles typical of β-sheet conformations ($\phi \approx -140^{\circ}$). This angle has also been determined by the measurement of the relative orientation of the N–H_N and C_{α}–H_{α} bonds, which is manifested in the rotational sideband spectrum of the sum and difference of the two corresponding dipolar couplings, and they obtained a ϕ angle of -135° [58]. Both techniques used on the monopeptide NAV are in good agreement with the angle of -136.5° determined by X-ray diffraction. It has also been shown that the pair of torsion angles (ϕ,ψ) can be determined simultaneously by 2D spin diffusion solid-state NMR experiments under off MAS [59–61] or using the DOQSY approach [62,63].

Recently, Gabrys *et al.* have used melittin to demonstrate the validity of a new technique to measure torsion angles in larger peptides [64]. The principle of their method lies on 2D slow-spinning, rotor-synchronized MAS exchange spectroscopy (SSRS-MASE), in which the relative CSA tensor orientation is extracted from the intensity of the off-diagonal crosspeaks on the 2D spectrum, since these intensities are related to the magnetization transfer between the two coupled sites. The (ϕ,ψ) torsion angles can be extracted after simulation of the experimental spectrum. Their results confirm once again that melittin adopts a helicoidal structure when incorporated into lipid bilayers.

Conclusions

Solid-state NMR is a powerful technique to investigate the mutual interactions between peptides and membranes, as well as the conformation adopted by these peptides upon binding to the bilayer. Up to now, little is known about the detailed mechanisms of action of antimicrobial peptides but new methods are continually being developed to better understand these mechanisms and to develop novel peptides having the desired selectivity toward bacterial cells [65]. The goal of this chapter was to present an overview of different solid-state NMR methods that have been developed to investigate the interactions and structure of antimicrobial peptides in membranes. These methods have been illustrated with a few examples on most commonly studied antimicrobial peptides. For more exhaustive reviews, the readers are referred to recent papers by Bechinger [9] and Strandberg *et al.* [66].

Anisotropic Chemical Shift Perturbation Induced by Ions in Conducting Channels

Jun Hu, Eduard Chekmenev, and Timothy A. Cross
[1]*Department of Chemistry and Biochemistry, Institute of Molecular Biophysics and National High Magnetic Field Laboratory,*
Florida State University, Tallahassee, FL 32310, USA

Anisotropic chemical shifts observed from solid-state NMR spectroscopy of uniformly aligned samples can be influenced by three primary factors: a change in orientation of the nuclear site, a change in dynamics, or a change in the chemical shift tensor element magnitudes or orientation to the molecular frame. These features are particularly attractive for characterizing the influence of ions in ion conducting channels. Cation binding results in far more subtle effects than had previously been imagined. Prior to the analysis of the first solid-state NMR characterizations of ion binding [1,2] the experimental data were primarily in the form of a few water-soluble protein structures in the Protein Data Bank to which monovalent ions were bound [e.g. 3,4]. Such binding sites showed optimized solvation for the ions associated with strong binding. Computational modeling efforts on ion channels, for the most part, also showed substantial structural deformation upon ion binding [5–7]. We now realize that much better models for how ions interact with channels can be realized from the characterization of substrate binding to enzymes, for which we have a great deal of information represented in every biochemistry textbook. A delicate balance of molecular interactions and thermodynamic parameters has evolved for enzymes, so that substrates are attracted to the active sites of proteins while not compromising the primary function of these proteins to conduct chemistry on the substrates and to release the products efficiently. Similarly, ions must be attracted to the channel and yet the primary function of these proteins is to facilitate the transfer of ions from one side of the membrane to the other.

Here, we describe how this can be done through a model system, the monovalent cation channel gramicidin A, produced by *Bacillus brevis*, to lyse cells in its environment and from the lysate the bacillus harvests amino acids following the additional export of proteases. This unique polypeptide has an alternating sequence of D and L amino acid residues that forms a β-strand with all of its side chains on one side of the strand resulting in a helical conformation with an aqueous pore approximately 4.5 Å in diameter. The high-resolution structure has been fully characterized using solid-state NMR orientational restraints from uniformly aligned samples in lipid bilayers (PDB # 1 mag) [8,9]. Analysis of the refined structure illustrates the unique high-resolution detail of this time averaged structure [10]. This polypeptide spans the lipid bilayer as a symmetric dimer [11], the amino-termini of which are formylated at the bilayer center. The approximate location of two symmetric ion binding sites in the vicinity of the monolayer interfacial region was initially characterized by X-ray diffraction [12]. Gramicidin shares a number of important features with the more recently characterized K^+ channels [13,14]. In particular, it is the polypeptide backbone and the carbonyl oxygens that provide much of the solvation environment following ion dehydration in the ion binding site of gramicidin A and in the selectivity filter of the KcsA channel. However, in KcsA the ion binding sites are considerably closer together (approximately 7 Å for KcsA [15] and approximately 20 Å for gramicidin A) permitting stronger ion binding and a much higher degree of ion selectivity. Nevertheless, the principles gleaned from studies of gramicidin appear to have very general applicability.

Solid-state NMR of uniformly aligned samples leads to high-resolution spectra. The frequencies from chemical shift, dipolar and quadrupolar interactions can be used as structural restraints by interpreting the frequencies within the context of the appropriate motionally averaged spin interaction tensor [16–18]. Here, we primarily describe the use of ^{15}N NMR spectroscopy of the amide nitrogen sites in the polypeptide backbone of gramicidin A in hydrated liquid crystalline preparations. These tensor element magnitudes in both static and liquid crystalline environments have been characterized for each of the amide sites [8,19] and many of the tensor orientations to the molecular frame have also been characterized [19,20]. These ^{15}N anisotropic chemical shifts represented some of the data used for solving the 3D structure in the absence of ions. The anisotropic shifts in the cation binding region change upon the introduction of ions [21,22] (Figure 1). The influence of the ions is surprisingly small compared to the 40–50 ppm anisotropic shifts calculated [23] from the structural changes predicted in the first molecular dynamics study of gramicidin ion binding [5]. Consequently, it

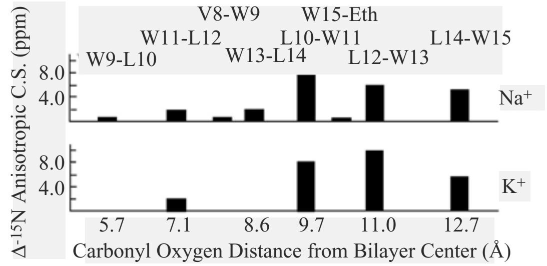

Fig. 1. Change in anisotropic chemical shift upon binding ions to the gramicidin channel (>80% double occupancy based on known binding constants [34, 35]) as a function of carbonyl oxygen distance from the bilayer center.

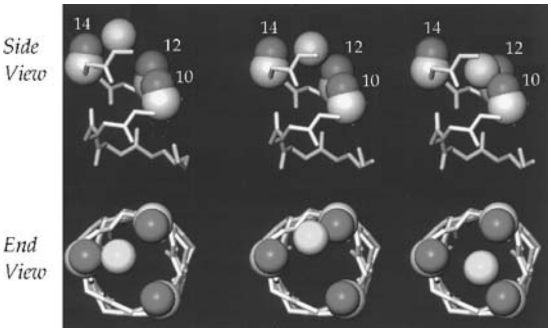

Fig. 2. Van der Waals surfaces are shown for the carbonyl groups of Leucine 10, 12, and 14, as well as for a K$^+$ ion interacting with these carbonyls. Ions are not able to interact with all three carbonyl oxygens at one time. (See also Plate 33 on page XXX in the Color Plate Section.)

appears as if the structural changes are likely to be small. In addition, the ion's influence is focused on three amide nitrogens that are in peptide planes having their carbonyl oxygens exposed at the end of the channel. If the cation interaction with the carbonyl oxygens was similar throughout the channel then the magnitude of the anisotropic chemical shift change would reflect the time the ions are positioned in the vicinity of each carbonyl oxygen and hence these sites with a significant change in anisotropic chemical shift reflect the cation binding sites.

This assumption is defendable, because we observe small anisotropic chemical shifts for sites throughout the gramicidin structure with a wide variety of ions. However, these chemical shift perturbations are all less than or equal to 2 ppm whether they are in the vicinity of the three exposed carbonyls or nearer the bilayer center. In other words, there is no rational to think that the cation binding site extends further toward the bilayer center than the Leu$_{10}$ carbonyl (9.7 Å). Even the Trp$_{15}$ carbonyl is unaffected despite its distance of 10.3 Å from the bilayer center. Indeed, for an optimal interaction between a cation and a carbonyl oxygen the ion should be on the axis or near to the axis of the dipolar vector. For the Leu$_{10}$ carbonyls (and similarly for Leu$_{12}$ and Leu$_{14}$ carbonyls) with its dipole oriented towards the aqueous environment the ion would be positioned at least an angström further away from the bilayer center (10.7 Å). However, for the Trp$_{15}$ carbonyl the dipole is oriented toward the hydrophobic interstices of the bilayer and this would suggest that for the ion to have a significant interaction with this site it would need to be at least another angström further into the channel (9.3 Å). This easily accounts for the strong chemical shift perturbation in the Leu$_{10}$ carbonyl peptide plane and the very weak perturbation in the Trp$_{15}$ carbonyl peptide plane.

Since the structure is known to high resolution and since the structure does not change substantially upon ion binding as indicated above, it can be preliminarily concluded that the ions are not interacting with all three of these carbonyl groups at the same time (Figure 2). In other words the carbonyl oxygens are not rotating in toward the channel axis and toward the cation to the extent necessary for the ion to be solvated by multiple carbonyls simultaneously. There are numerous important conclusions that follow from this unique solid-state NMR result, but first we should inspect some of our assumptions.

Upon binding monovalent ions the shift in the amide ^{15}N chemical shifts could be the result of a change in structure, dynamics, or tensor. By using three separate tensors in a single peptide plane and assuming simply a change in orientation of the peptide plane: data from the carbonyl carbon (^{13}C chemical shift) [1] suggest a change in orientation of 9°; the ^{15}N chemical shift, a change of 7° and the ^{15}N–^{2}H dipolar interaction, a change of 2° [24] (Figure 3). Such a discrepancy in the results suggests that the time averaged structural deformation

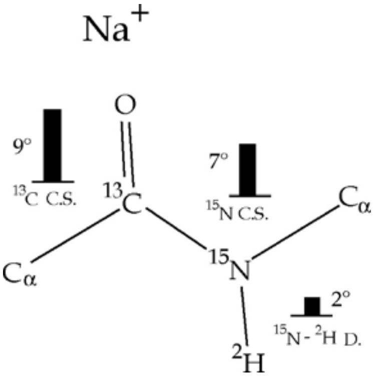

Fig. 3. Interpretation of the anisotropic spin interactions in the Leu$_{12}$-Trp$_{13}$ peptide plane upon binding Na$^+$ (>80% double occupancy).

is indeed small. Furthermore all of the spin interactions tend toward isotropic values making it difficult to distinguish between increased dynamics or an increased tilt angle of the peptide plane with respect to the magnetic field direction, which would similarly cause all of the spin interactions to shift toward isotropic values. In either event the effect is small as dictated by the ^{15}N–^{2}H dipolar interaction which shows a very small change in magnitude. The chemical shift tensors are highly susceptible to changes in electronic distribution and could have altered tensors. Indeed, temperature dependent studies of flash frozen samples of ion bound gramicidin in lipid bilayers using thin films and liquid propane showed a significant 5.5 ppm change in the ^{15}N chemical shift anisotropy [24] that could account for much of the observed anisotropic chemical shift perturbation induced by ion binding. This result confirms the above conclusion that the structural deformations are small; not only are the anisotropic ^{15}N chemical shift changes small, but also the majority of the shift can be accounted for by changes to the chemical shift tensor. In addition, this result documents significant polarizability effects. It appears that for a given peptide plane that the carbonyl ^{13}C chemical shift tensor is affected to the greatest extent and the ^{15}N tensor, which is further removed from the carbonyl oxygen and the greatest electron density changes, is affected to a lesser extent. Clearly, these polarizability effects are significant for ion binding sites and should not be ignored in molecular dynamics calculations of the selectivity filter and ion binding regions of channels. Furthermore, these results suggest that direct observations of the carbonyl oxygens by ^{17}O NMR spectroscopy would be both desirable and very informative.

Now that it is confirmed that much of the anisotropic chemical shift perturbation is due to changes in the chemical shift tensor we can continue to pursue our interpretation of these shifts. The unavoidable conclusion that the ion binding site involves the carbonyls of Leucine 10, 12, and 14 and that the ion does not interact with these sites simultaneously means that the ion maintains considerable entropy while in the binding site. Consequently, there is less enthalpy of solvation that has to be provided by the channel upon binding the ion. This is a unique finding for a cation binding site. All previous monovalent cation binding sites involved a coordination environment that approximated an ideal geometry, thereby the ion was held rigidly in the protein environment.

The dynamics within the binding site suggests a complication that has been previously overlooked. Although single occupancy and double occupancy have been taken into account for the interpretation of the ion induced structural deviations, the partial occupancy for each carbonyl in a given binding site has not been considered. Based on the size of the chemical shift perturbation in Figure 1 for the three carbonyl sites it is possible to estimate the fractional time the ion is associated with each carbonyl. For K^+ the percentages are 33/42/25 for Leucine 10, 12, and 14, respectively. Note that the distribution is different for different ions. For Na^+ the percentages are 38/32/29. Even though the time averaged conformational change has been shown to be small (i.e. just a few degrees), the structural deformation when the ion is interacting with a specific site could be as high as 10°. Although this is very small compared to some initial estimates [e.g. 5], it is more consistent with both the measured dynamics of these sites [25] and the recent molecular dynamics [e.g. 26]. While these deformations are now significant, they are not large enough to position the carbonyls in such a fashion that multiple carbonyls can provide significant solvation energy simultaneously.

These three carbonyls at the entrance of the channel coupled with an ion that maintains mobility between these sites sets up the possibility for stepwise dehydration of the ion as it enters the channel. Indeed, the number of waters that one can place into the ion's primary hydration sphere when interacting with the Leu_{14} carbonyl is 5; that for Leu_{12} is 4 or 5 and that for Leu_{10} is only 3. The result for Leu_{10} is consistent with the fact that when the ion is passing through the bulk of the channel it is in a single file arrangement with a column of water molecules and consequently there are two waters of hydration during this phase of ion transport. Consequently, in the binding process there appears to be a stepwise dehydration process and the binding site is characterized as that portion of the channel where the ion can have more than two waters of hydration in the primary hydration shell. Once the hydration has been reduced to two then it is possible for the ion to pass through the channel. Such a stepwise dehydration process provides an incremental mechanism to achieve this energetically costly dehydration goal as previously suggested by several computational studies [27–29]. The incremental increase in interaction energy for binding the cation as it is dehydrated and steps from carbonyls 14 to 10 is thought to come from the decreased enthalpy of solvation for the carbonyls in this sequence as the environment becomes more hydrophobic and from the weak interaction with the ethanolamine blocking group at the carboxy terminus of the polypeptide [21].

Olah *et al.* [12] measured a separation distance for two thallium ions bound to gramicidin at 19.2 Å. Here, we find that the distance between binding sites is dependent on the specific cation and that the distances are significantly longer than that measured by X-ray diffraction. While Li^+ is predominately associated with the Leu_{10} carbonyl, K^+ with Leu_{12}, Cs^+ is predominately associated with Leu_{14}. A weighted average of the carbonyl positions results in a binding site separation of 21.6 Å for Li^+, 22.0 Å for K^+, and 23.0 Å for Cs^+. However, the ion positions when they are polarizing the amide planes have an average position representing an ion binding site separation that maybe larger by nearly 2 Å. These ion binding site separations

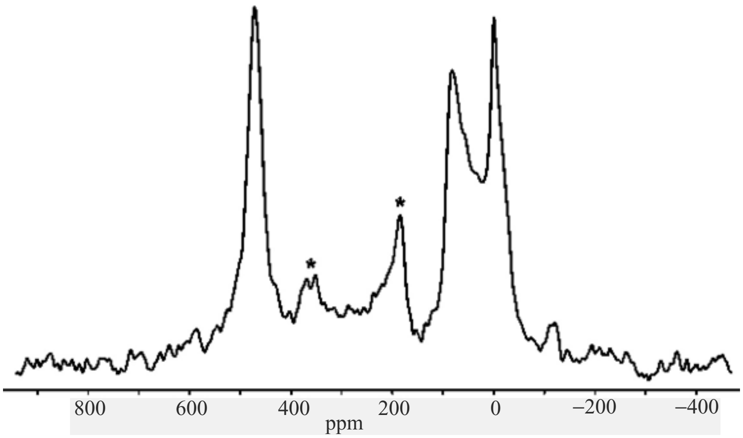

Fig. 4. ^{17}O ^{1}H decoupled spectrum of ^{17}O-Leu$_{10}$-gramicidin A in uniformly aligned DMPC lipid bilayers acquired at 21.2 T (5 mg of peptide of 57% ^{17}O enriched, 1:16 peptide-to-lipid molar ratio, 70k transients at 40 °C). Starred signals represent residual powder pattern intensity from unaligned regions of the sample.

are far greater than those observed in the KcsA selectivity filter where ion binding sites are less than 7 Å apart [15]. The need for such close proximity of the binding sites for KcsA is likely associated with the strength of ion binding. Increased selectivity may require increased binding energy and ion binding to a second site is just one mechanism for compensating for the increased free energy of the ion bound in the first site.

Solid-state NMR spectroscopy of cation binding to gramicidin has illustrated how channels can attract monovalent cations, avoid excessively strong binding, and efficiently conduct ions across membranes. Indeed, this process is similar to an enzyme catalyzed processes in which substrate is bound with care so that the enzyme–substrate complex does not have too low a value of free energy, because the goal is to reduce the ΔG associated with the difference in free energy between the enzyme–substrate complex and the enzyme–transition state complex. Here the ion is bound in a shallow potential energy well in which the ion maintains considerable entropy prior to removal of the last water before entering the single file region of the channel. In the channel region, the ion and water molecules must move through the narrow pore in a correlated fashion, since the ion cannot pass around the water molecules. Furthermore, there is published evidence that these correlated motions in the pore extend to the atoms lining the pore [25]. Motions of the peptide plane have frequency components in the 10 ns time frame—the same time frame based on single channel conductance measurements and calculated for ion transitions along the pore [6,25,30,31]. These peptide plane motions are highly overdamped presumably due to correlated motions between the covalently linked peptide planes.

The ^{15}N anisotropic chemical shifts are relatively small and error bars are on the order of ±1 ppm. The effect is small because of the considerable distance between the polarizing ion and the ^{15}N site. The carbonyl carbon position is closer to the polarizing ion, but while ^{13}C spectroscopy has also been used, its substantial natural abundance background in lipid bilayer preparations generates an additional major challenge. The ideal site to study would be the carbonyl oxygen that is in direct contact with the polarizing ion, but high-resolution ^{17}O NMR has been very difficult to observe due to the quadrupolar nucleus and associated second-order broadening that severely compromises this spectroscopy even at high field strengths.

Recently, progress has been made in the ^{17}O spectroscopy of gramicidin A in aligned bilayers at ultrahigh field using the National High Magnetic Field Laboratory 105 mm bore 900 MHz spectrometer. Figure 4 displays, to our knowledge, the first spectrum of a single site ^{17}O labeled macromolecule. While the ^{17}O line width, 30 ppm, is significantly wider than that of ^{15}N spectra of oriented samples, the carbonyl ^{17}O chemical shielding anisotropy is larger than that of amide ^{15}N by a similar factor, resulting in nearly identical effective spectral resolution. Moreover, carbonyl ^{17}O anisotropic chemical shift and quadrupole coupling is considerably more sensitive to the intermolecular interactions [32,33]. Thus, we speculate that the anisotropic chemical shift and quadrupole coupling effects induced by ion binding would be considerably greater than the line width in aligned samples. Our preliminary spectrum obtained for gramicidin A in oriented lipid bilayers shows the feasibility and practical utility of ^{17}O spectroscopy. Notably, unlike in ^{13}C spectroscopy, the anisotropic ^{17}O resonance at 471 ppm from the single site labeled gramicidin A backbone is well separated from the background contribution from water, 0 ppm, and DMPC, 82 ppm. This observation significantly increases the potential of ^{17}O spectroscopy. Because of its intrinsic sensitivity to electrostatic interactions,

^{17}O NMR has a very bright future for studying the structural and dynamic effects of ion binding.

NMR Studies of Ion-Transporting Biological Channels

James F. Hinton

Department of Chemistry/Biochemistry, University of Arkansas, Fayetteville, AR 72701, USA

A human being has about one hundred thousand million cells. For the various types of cells to properly function, channels, valves, and gates are required. Channels are used to transport ions and small molecules, such as water, through cell membranes.

All of the transporters are integral membrane proteins that contain several α-helical segments that weave back and forth across membranes. Most of the transporters are also glycoproteins with carbohydrate groups directed toward the cell exterior. Proteins that form ion-transporting channels are quite common among eukaryotes. The majority of these channels transport positive ions, such as Na^+, K^+, and Ca^{+2}. However, Cl^- channels have been observed. The cation channels function in a selective or selective nonspecific manner. For example, a channel may transport K^+ ions more efficiently than Na^+ ions but both cations move through the channel. A channel may transport one cation (K^+) but not another (Na^+).

The mechanism for selectively transporting ions through a channel is complex. It may involve a number of factors. The shape, size, and polar nature of the channel surface, the size and charge of the ions, the thermodynamic driving force for the partial dehydration of the ion at the channel entrance and the subsequent binding of the ion to the channel entrance and the interaction of the ion with the polar groups that line the channel. All of these factors play a role in transport and determining the selectivity filter of a channel.

Most ion channels operate in a gated mode. Conformational changes produced by ligand binding, mechanical stress, or voltage change open and close the channel for ion transport. The ligand-gated channel opens and closes in response to the binding of specific molecular species. Hormones and molecules released by nerve cells as neurotransmitters act as control molecules that open and close ligand-gated channels. Voltage-gated channels open and close in response to changes in membrane voltage or electrical potential. The mechanosensitive-gated channel functions by mechanical stresses on the membrane producing conformational changes, which open and close the channel. Gating can be very rapid. Ion transport rates can change from essentially zero to millions of ions per second in a few milliseconds.

The significance of these types of channels was verified by the award of the 2003 Nobel Prize in Chemistry to Peter Agre and Roderick MacKinnon for seminal studies on water and ion channels, respectively. The operation of these channels, like so many other processes occurring in cells, involves proteins. Although significant information was known about which proteins formed certain channels and how these channels function, only recently has a three-dimensional structure been obtained for a few channels, making it possible to begin to relate structure to function. A major reason for this is that proteins embedded into membrane bilayers are poor candidates for X-ray crystallography. Currently, these proteins are too large to be studied by conventional NMR techniques. It is hoped that the next generation of ultrahigh magnetic field NMR spectrometers combined with new solution and solid-state experiments will extend the size of proteins that might be amenable for NMR studies. However, if or until that becomes a reality, other strategies must be employed to investigate the structure–function relationship of ion channel proteins.

One strategy is to use small peptides that form channels in membranes and membrane mimics or to use segments of protein channels that are associated with channel formation. Channel-forming peptides, considered to be minimal models for the pore-forming structure of protein channels can be classified in three categories: (1) minimally designed synthetic peptides, (2) naturally occurring channel-forming peptides, and (3) peptides that mimic structural elements predicted to form the channel lining of authentic protein channels. An understanding of how a channel in one of these categories is formed and how its structure affects the function of ion transport requires knowledge of many facets of this relationship. One must understand the interaction between the model channel and the membrane environment, which ultimately determines the folded structure that forms the channel. The structure of the channel in a membrane environment must be obtained. Ion binding thermodynamic parameters, kinetic activation energy parameters for the transport process, and channel conductance studies are necessary in order to relate the structure of the channel to its function.

There are relatively few physical techniques available for the characterization of the interaction of ions with molecular systems capable of forming channels. However, NMR spectroscopy has proven to be a very powerful technique used to determine, for example; the

three-dimensional structure of the model channel, the thermodynamic parameters for incorporating the channel-forming system into a membrane environment, the thermodynamic parameters for ion binding with the channel, the kinetic activation parameters for ion transport, and the internal motion properties of the channel.

Because of limited space, this is not an extensive review. An extensive review, "NMR Studies of Ion-transporting Biological Channels," has been recently published [1]. The reader is directed to this review for a much more in-depth discussion of the subject.

A number of naturally occurring peptide channels have been investigated using NMR techniques. The gramicidin family of linear polypeptides represents a biologically viable channel system of related peptides in which specific changes in amino acid composition can be correlated with cation binding selectivity and transport. This relatively small molecule (15 amino acid residues) is probably the best-characterized cation channel, structurally and functionally, and has been the principal proving ground for many ideas concerning the molecular nature of cation transport across membranes. High resolution, two-dimensional ^{1}H [2–5] and ^{15}N, ^{13}C, ^{1}H, and ^{2}H solid-state NMR spectroscopy [6–9] have been used to determine the structure of gramicidin A and a number of its analogs incorporated into micelles and bilayers, respectively. The gramicidin channel is a dimer formed by the formyl-to-formyl association of two single-stranded, right-handed, $\beta^{6.3}$ helical monomers [2,10]. The dimer, which spans the lipid bilayer or is incorporated into micelles, is about 26 Å long with a diameter of about 4 Å.

Since the movement of ions through a channel involves (i) diffusion of the ion through the aqueous environment to reach the channel entrance, (ii) association of the ion with the channel at the entrance, (iii) transport through the channel, (iv) dissociation from the channel, and (v) diffusion away from the channel, the thermodynamic binding constant for the association process and the kinetic activation enthalpy for the transport process are very important quantities to be determined for the gramicidin analogs. The position of the binding "pocket" for monovalent cations has been determined for gramicidin A and the Phe-15 gramicidin A analog incorporated into SDS micelles using the NOESY11 NMR technique [11]. The binding "pocket" involves the carbonyl groups of residues 10–15. These results are in agreement with those obtained with solid-state ^{2}H and solution-state ^{13}C NMR experiments [12–14].

To obtain a quantitative measure of cation binding to the gramicidin channel, one must determine the enthalpy and the entropy for the binding process, not just the equilibrium constant at a single temperature. The thermodynamic parameters for the binding of cations to the channel have been obtained using the ^{205}Tl NMR-competitive binding method [15]. This method involves the measurement of the ^{205}Tl^{+} chemical shift as a function of the Tl^{+} thermodynamic activity in the presence of a constant amount of gramicidin incorporated into lipid vesicles. The equilibrium binding constant is calculated from the chemical shift–activity relationship. The equilibrium binding constant, determined as a function of temperature, is then used to obtain the enthalpy and the entropy for the binding of the Tl^{+} ion to the channel entrance. This procedure is repeated for the system that also contains a cation (e.g. Li^{+}, Na^{+}, or K^{+}) that competes with the Tl^{+} ion for the same binding site. The change in the chemical shift of the ^{205}Tl^{+} ion is then used to calculate the enthalpy and the entropy of binding for the competing cation. The binding constant and the enthalpy of binding for monovalent cations was found to increase in the order: $Li^{+} > Na^{+} > K^{+} > Tl^{+}$. The binding constants determined for the alkali cations are in agreement with those obtained with ^{13}C NMR spectroscopy of ^{13}CO labeled gramicidin A [13]. The binding constants for divalent cations were found to be much larger than those for the monovalent cations. This binding study of the gramicidin channel explains the selectivity of transport for the monovalent cations and why the divalent cations are not transported.

The kinetic activation enthalpy for the transport of Li^{+}, Na^{+}, and K^{+} has been determined for gramicidin A and its analogs using the magnetization inversion transfer (MIT) technique [16]. If a membrane impermeable chemical shift reagent, such as $[Dy(P_3O_{10})_2]^{-7}$ is added to an aqueous salt solution of large unilamellar vesicles with incorporated gramicidin, the internal and external pools of the NMR active cations (^{7}Li^{+}; ^{23}Na^{+} or ^{39}K^{+}) can be distinguished by there individual NMR signals. The MIT experiment allows one to obtain the kinetic rate constant for the transfer of magnetization for one cation aqueous pool to the other. When the MIT experiment is performed as a function of temperature, the rate constants can then be used to determine the activation enthalpy for the transport process. The activation enthalpy of transport through the gramicidin A channel was found to increase in the order of cations: ^{39}K^{+} (4.2 kcal/mol^{-}), ^{23}Na^{+} (5.4 kcal/mol^{-}), and ^{7}Li^{+} (7.2 kcal/mol^{-}).

The dynamic nature of the gramicidin channel has been the subject of considerable interest. For example, the ^{15}N spin-lattice relaxation time of the nitrogen atom at the Leu-4 position has been used to investigate the local dynamics about the Ala-3/Leu-4 linkage [17,18]. The NMR results of the experiments suggest a correlation between the local dynamics and ion transport through the channel. The backbone dynamics of gramicidin A in bilayers have been studied using low temperature solid-state ^{15}N NMR spectroscopy [19]. A ^{1}H T_1 and T_2 study of the tryptophan indole NH of gramicidin analogs incorporated into SDS micelles showed a systematic decrease in the overall motion of the indole ring from the

Trp-15 (at the aqueous interface) to Trp-9 (at the interior of the micelles) for all analogs.

There are other applications of NMR spectroscopy for studying various aspects of the gramicidin channel and the interaction of the channel with a membrane environment. Solid-state NMR has been used to investigate the closed state of the gramicidin channel in lipid bilayers [20]. The kinetic activation parameters for the incorporation of gramicidin analogs into vesicles as a channel have been determined using ^{23}Na NMR spectroscopy [5, 21]. The differential photochemical degradation of the four tryptophan residues in gramicidin A has been studied using ^{1}H two-dimensional NMR spectroscopy [22].

Another type of small, naturally occurring peptide, the peptaibols, has been used as an ion channel model. These channels consist of a bundle of transmembrane helices surrounding a central core. Alamethicin, a 20-residue linear peptide, is the most thoroughly studied member of this class of model channels. A number of NMR studies of alamethicin in SDS micelles [23] and in methanol and aqueous methanol solution [24] have been conducted to determine the conformation of the monomers within the bundle. It appears that the N-terminal region is of an α-helical nature with several 3.0_{10} segments in the C-terminal region. Solid-state ^{15}N NMR results were found to be consistent with an α-helical conformation inserted along the bilayer normal [25]. NMR studies of other peptaibols also indicate the characteristic α-helical conformation.

Other naturally occurring peptides, such as melittin, magainin, cecropin, and pardaxin, form bundles that produce a central channel. There have been many NMR studies of melittin in solution, in micelles, in bilayers, and interacting with lipid membranes [26–29]. The structure of the monomer appears to be that of an α-helix. NMR investigations of magainin [30,31], cecropin [32,33], and pardaxin [34, 35] show that, in general, these peptides also form α-helical monomers that assemble into a structure that has a central pore or channel.

Ligand-gated ion channels provide efficient communication between cells of the central nervous system. At the molecular biochemical level, the nicotinic acetylcholine receptor is one of the best-characterized membrane proteins and serves as a paradigm for a family of ligand-gated ion channels [36]. Of the transmembrane segments, M1, M2, M3, and M4, five M2 helices form the central ion channel or pore. Solid-state ^{15}N NMR experiments of the labeled M2 segment in bilayers have shown that the helical segment is perpendicular to the plane of the bilayer [37]. The M2 protein from the influenza A protein functions as an ion channel. Solid-state ^{15}N NMR results with the M2 protein from the influenza A virus suggest that this tetrameric protein is in a left-handed, four-helix bundle [38,39]. Peptide mimics of protein channels have been used to investigate structure and function using a variety of NMR techniques [40,41].

Membrane Proteins

Part I

Site-Directed NMR Studies on Membrane Proteins

Hazime Saitô

Department of Life Science, Himeji Institute of Technology, Harima Science Garden City, Hyogo 678-1297, Japan and Center for Quantum Life Sciences, Hiroshima University, Higashi-Hiroshima 739-8526, Japan

Introduction

Integral membrane proteins, traversing the membrane once or several times as α-helices, play crucial roles in maintaining various activities of cells such as transport of appropriate molecules into or out of the cell, catalysis of chemical reaction, and receiving and transducing chemical signals from the cell environment. Naturally, biological activity of such proteins may depend upon their conformations and dynamics regulated by specific lipid–protein and/or protein–protein interactions as structural determinants, as studied by analysis of 2D assembly of bacteriorhodopsin (bR) as a typical membrane protein [1]. bR is active as a proton pump and considered as a prototype of a variety of G-protein coupled receptors, consisting of seven transmembrane α-helices.

Interestingly, the bR structure is far from static at *ambient temperature* in spite of currently available 3D structural models revealed by crystallography at low temperature but flexible even in the 2D crystal, especially at the loops and N- or C-terminal residues fully exposed to aqueous phase, and undergoing fluctuation motions with correlation times of the order of 10^{-4}–10^{-5} and 10^{-8} s, respectively, as revealed by recent site-directed solid-state ^{13}C NMR [2–6].

Well-resolved ^{13}C NMR signals are fully visible from 2D crystalline ^{13}C-labeled [3-^{13}C]Ala-[2,3,7] or [1-^{13}C]Val-labeled bR [3,5] recorded by *both* cross-polarization-magic angle spinning (CP-MAS) and dipolar decoupled-magic angle spinning (DD-MAS) techniques. Inherent motional fluctuation of the transmembrane α-helices of bR monomer, however, turns out to be accelerated by two orders of magnitude in the lipid bilayer in the absence of specific protein–protein interactions, from their correlation times of the order of 10^{-2} s in 2D crystal [2,3,8] to 10^{-4}–10^{-5} s, [9–13] in the monomer. Accordingly, ^{13}C NMR signals from several residues in the transmembrane α-helices and loops could be suppressed due to the failure of attempted peak-narrowing caused by interference of the motional fluctuation frequency with the frequency of proton decoupling or MAS [2,3,14–16], although the functional unit responsible for the photocycle is the monomer itself rather than the trimeric form found in the 2D crystal [17,18]. In this case, uniform ^{13}C-labeling is not always favorable for solid-state NMR, because ^{13}C NMR study of densely ^{13}C-labeled proteins such as [1,2,3-$^{13}C_3$]Ala-labeled bR could be substantially broadened in the presence of such intermediate and slow motions, due to the accelerated relaxation rate through a number of homonuclear ^{13}C–^{13}C dipolar interactions and scalar J couplings [16].

We demonstrate here how the site-directed ^{13}C NMR approach is useful to reveal conformational features of *intact* membrane proteins with emphasis on their surface structures and dynamics at *ambient temperature*, as revealed by ^{13}C NMR studies on bR from the 2D crystal and monomer and various membrane proteins active as signal transducers and enzyme, expressed from *E. coli* and present as monomer in lipid bilayers.

Conformation-Dependent ^{13}C Chemical Shifts

It has been demonstrated that C_α and C=O ^{13}C chemical shifts of a variety of polypeptides taking the α-helix form are displaced to high frequencies by 3.5–8.0 ppm with respect to those of the β-sheet form, while the C_β signals of peptides taking the α-helix form are displaced to low frequencies by 3.4–5.2 ppm as compared with those of the β-sheet form [2,3,19]. In addition, it is possible to distinguish even the following six kinds of local secondary structures, right-handed and left-handed α-helices, α_{II}-helix, collagen-like triple helix, silk I and β-sheet forms, besides random coil form, with reference to the conformation-dependent ^{13}C chemical shifts of Ala residues (Table 1). ^{13}C NMR peaks from the α-helices in membrane proteins, however, are more widely spread than the expected values of the conformation-dependent displacement of the peaks from solid polypeptides. In fact, several ^{13}C NMR peaks from the α-helical residues resonate at their lowest (C_β) and highest (C_α and C=O peaks) boundary peak positions with those of random coil form in the presence of intermediate or low frequency motions, but their peak positions are distinct from those of the loop and β-sheet form [2,3,10]. In such case, the observed distribution of the chemical shifts may deviate greatly from their expected peak positions from the distribution of the torsion angles

Graham A. Webb (ed.), Modern Magnetic Resonance, 291–297.

determined by X-ray diffraction [20]. Nevertheless, the conformation-dependent displacement of ^{13}C peaks are very useful as a structural constraint to predict the local structure of membrane proteins. A possibility of the conformation-dependent ^{15}N chemical shifts, however, may be obscured, because ^{15}N chemical shifts are influenced by both the local conformation and the primary structure or probably by the higher order structure [21].

Site-Directed Assignment of ^{13}C NMR Signals

Figure 1 illustrates the ^{13}C DD-MAS and CP-MAS NMR spectra of fully hydrated [3-^{13}C]Ala-labeled bR in 2D crystal (MW 26 kDa) at ambient temperature [2,3]. Twelve Ala C_β ^{13}C NMR peaks are resolved in the CP-MAS NMR (bottom) among 22 Ala residues present in the transmembrane α-helices and loops. The three intense ^{13}C NMR signals from membrane surface (gray; top) are noteworthy in the DD-MAS NMR spectrum (consisting of contribution from total 29 Ala residues) and are unambiguously assigned to Ala 228 and 233 (C-terminal α-helix), Ala 240, 244–246 (C-terminal tail taking random coil), and Ala 235 (corner at the C-terminal α-helix) from the upper to the lower field with reference to the conformation-dependent ^{13}C chemical shifts [2,3,19] together with their absence after enzymatic cleavage by papain [22]. Naturally, these ^{13}C NMR signals are suppressed in the CP-MAS NMR, because the C-terminal α-helix and its tail undergo fluctuation motions with correlation times of the order of 10^{-6} and 10^{-8}s, respectively [10]. The assigned peaks indicated at the individual peaks are obtained in view of selectively reduced ^{13}C NMR peak intensity of relevant mutant in which an individual Ala residue is replaced by other amino acid residue (for instance, A196G, A126V, A215G, etc.) as compared with that of wild type as illustrated in Figure 2 [3,10] provided that global conformational change is not induced as in D85N [23]. Such a ^{13}C NMR peak from the transmembrane α-helices can be identified as a single Ala residue by the difference ^{13}C NMR spectrum between a wild type and a mutant, together with suppressed signals from residues located near the surface (within ca. 8.7 Å) by accelerated transverse relaxation due to surface-bound Mn^{2+} [20]. Site-specific assignment of ^{13}C NMR signals has been attempted for [1-^{13}C]Val- [3,5], Pro- [24], Trp-, and Ile-[5] labeled bR.

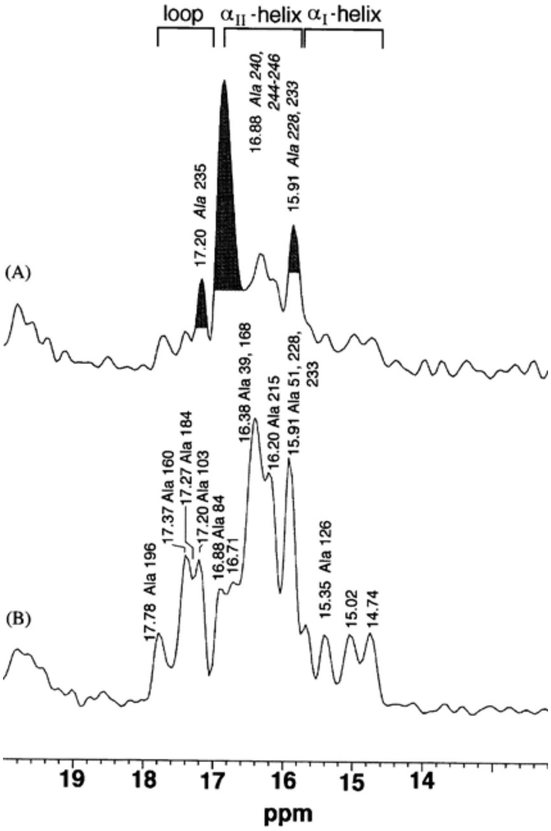

Fig. 1. ^{13}C DD-MAS (A) and CP-MAS (B) NMR spectra of [3-^{13}C]Ala-labeled bacteriorhodopsin. The ^{13}C NMR signals from the C-terminal residues are in gray.

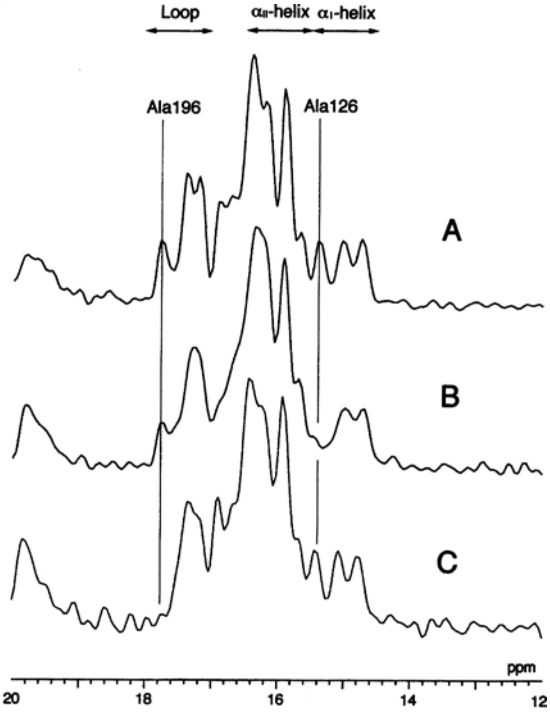

Fig. 2. Comparison of the ^{13}C CP-MAS NMR spectra of [3-^{13}C]Ala-labeled bacteriorhodopsin (A) and A126G (B) and A196G mutants (C).

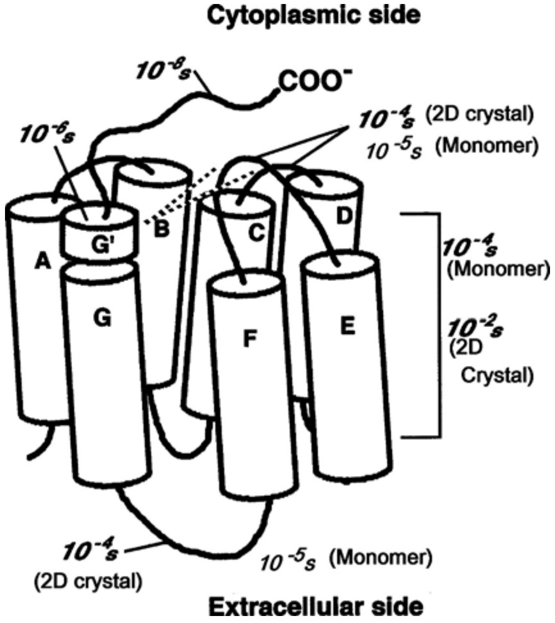

Fig. 3. Schematic representation of the location of the C-terminal α-helix (helix G′ protruding from the membrane surface), its interaction with the C-D and E-F loops (dotted lines) leading to the cytoplasmic surface complex and their correlation times. Note that the correlation times for the transmembrane α-helices differ substantially between preparations of 2D crystal or monomer.

Dynamic Aspect of Membrane Proteins

Surprisingly, ^{13}C NMR signals of bR labeled with certain [1-^{13}C] amino acid residues are not always fully visible from the loops and transmembrane α-helices by both CP-MAS and DD-MAS techniques, even if 2D crystalline preparations were examined [5,16]. In contrast, ^{13}C NMR signals from the N- and C-terminal regions with the correlation time shorter than 10^{-8} s can be observed by DD-MAS NMR only [2,3,5]. Indeed, ^{13}C NMR signals of [1-^{13}C]Gly-, Ala-, Leu-, Phe-, and Trp-labeled bR are partially or almost completely suppressed from residues located at the membrane surfaces, and the signals of which can be conveniently estimated by means of accelerated transverse relaxation effect from the surface-bound Mn^{2+} ions [5]. Indeed, the relative proportions of ^{13}C-labeled residues from the negatively charged surface residues (within 8.7 Å) from fully visible ^{13}C NMR peaks of [3-^{13}C]Ala-, [1-^{13}C]Val-, and Ile-bR [5,20] were consistent with the expected numbers of such residues available from the secondary structure. In contrast, we found that the relative contributions of the surface areas estimated by this procedure are substantially lower than the expected numbers of residues from the secondary structure for ^{13}C NMR spectra of [1-^{13}C]Gly-, Ala-, Leu-, Phe-, and Trp-bR from 2D crystalline purple membranes [5]. This means that these ^{13}C NMR signals from the surface area are *partially or completely suppressed* as a result of failure of the attempted peak-narrowing by interference of incoherent low frequency fluctuation motion (10^4 Hz) with the coherent frequency of MAS [15].

This kind of peak suppression for fully hydrated bR can be utilized as an invaluable means to evaluate *in situ* protein dynamics with the local correlation time of the order of 10^{-4} s in the 2D crystal as schematically illustrated in Figure 3, although this phenomenon is obviously a serious disadvantage as viewed from choice of a suitable ^{13}C-labeled amino acid residue. One should also anticipate that ^{13}C NMR signals of fully hydrated, *monomeric* [1-^{13}C]Gly-, Ala-, Leu-, Phe-, and Trp-labeled membrane proteins [5,9–13] in lipid bilayers are almost completely suppressed, because even the transmembrane α-helices are able to acquire accelerated fluctuation motions in the absence of specific protein–protein interactions essential for trimeric structure in the 2D crystals (Figure 3). This is because the lowest energy minimum for Gly and the others in the conformation map may be shallow and the backbone dynamics of the last four amino acid residues represented by the C_α–$C_\beta H_2$–Z system could be coupled with a possible rotational motion of the χ_1 angle around the C_α–C_β bond. On the other hand, such a conformational space leading to fluctuation motion may be limited to a very narrow area for Val or Ile residues with a bulky side chain at C_α. For [3-^{13}C]Ala-labeled bR in either 2D crystal or monomeric state in lipid bilayer, peak suppression could occur when incoherent fluctuation motion is interfered with frequency of proton decoupling (correlation time being ca. 10^{-5} s) [14].

Obviously, intermediate or slow fluctuation motions with correlation times in the order of 10^{-4}–10^{-5} s may be well related to individual biological functions, because flexibility in the loops and/or transmembrane α-helices may be essential for initiating transport of proton or ion, receiving external signals, binding substrate, etc. for their respective biological functions such as proton pump, signal transduction, enzymatic activity, etc. In spite of 2D crystalline bR, the fluctuation frequency is spontaneously increased from 10^2 Hz in the ground state to the order of 10^4 Hz at the M-like state as a result of a modified retinal–protein interaction owing to proton transfer from the Schiff base to Asp 85 [23].

Surface Structures

The surface structure of bR is still obscured, or inconsistent, among a variety of the 3D structures so far revealed by cryoelectron microscopy and X-ray diffraction studies at low temperature [25–27]. This arises because it can be easily altered by a variety of intrinsic or environmental factors such as the manner of crystallization either in the 2D or in the 3D crystals, temperature, pH, ionic strength, crystallographic contact, etc [2,3]. Instead, the ^{13}C NMR approach proved to be a very suitable means to reveal its surface structure in relation to biological activity at ambient temperature. In particular, ^{13}C NMR studies revealed that the C-terminal residues, 226–235, participated in the formation of the C-terminal α-helix as viewed from their peak positions [16,22], with reference to the conformation-dependent ^{13}C chemical shifts [2,3,19]. Only a part of this α-helix, however, was visible by X-ray diffraction [26], owing to the presence of motions with correlation times in the order of 10^{-6} s detected at ambient temperature, as judged from the carbon spin–lattice relaxation times, T_1^{C}, and spin–spin relaxation times, T_2^{C}, under CP-MAS conditions [16].

Yonebayashi *et al*. examined the ^{13}C NMR spectra of [3-^{13}C]Ala-labeled bR and its mutants while varying a variety of environmental or intrinsic factors such as ionic strength, temperature, pH, truncation of the C-terminal α-helix, and site-directed mutation at cytoplasmic loops [28]. For instance, increased ionic strength from 10 to 100 mM NaCl causes simultaneous changes of the high frequency displacement of Ala 103 signal of the C-D loop and the reduced peak intensity of the C-terminal α-helix [28]. This finding together with other similar changes caused by temperature and pH variations leads to the conclusion that the cytoplasmic loops and the C-terminal α-helix are not present independently but are held together to form *cytoplasmic surface complex* stabilized by salt bridges and/or cation-mediated linkages of a variety of side chains as schematically indicated by dotted lines in Figure 3. Indeed, ^{13}C NMR signals from such loops are suppressed by accelerated fluctuation motion with a correlation time of the order of 10^{-5} s and the ^{13}C chemical shift of the C-terminal α-helix was displaced to low frequency, when blue membranes were prepared by either complete removal of surface-bound cations (deionized blue) or neutralization of surface charge by lowered pH to 1.2 (acid blue) [28,29]. Further, partial neutralization of Glu and Asp residues at the extracellular side such as E194Q/E204Q (2 Glu), E9Q/E194Q/E204Q (3 Glu), and E9Q/E74Q/E194Q/E204Q (4 Glu) caused global fluctuation motions at these loop regions as well as the disorganized trimeric form [30]. The cytoplasmic surface complex in which the C-terminal α-helix is probably tilted toward the direction of the B- and F-helices seems to prevent unnecessary fluctuations of the helices for efficient proton uptake during the photocycle [28]. It appears that such surface structure is disrupted at a low temperature or in the M-like state. This view is consistent with the previous data for "the proton binding cluster" consisting of Asp 104, Glu 160, and Glu 234.

Site-Directed ^{13}C NMR on Membrane Proteins Present as Monomers

Most of reconstituted membrane proteins may be present as monomer in lipid bilayers at ambient temperature in the absence of certain endogeneous lipid molecules essential for specific lipid–protein and protein–protein interactions, as manifested for bR in the 2D crystalline assembly as purple membrane [31,32]. Therefore, it seems to be very important to clarify how the present site-directed ^{13}C NMR approach is useful to reveal conformation and dynamics of reconstituted membrane proteins as *Pharaonis* phoborhodopsin (*p*pR; sensory rhodopsin II), its cognate transducer (*p*HtrII), and diacylglycerol kinase (DGK) which are overexpressed by *E. coli* [11–13]. In such cases, use of proteins labeled by [3-^{13}C]Ala is more preferable than [1-^{13}C]Val, because ^{13}C NMR signals of the latter preparations were substantially suppressed in a similar

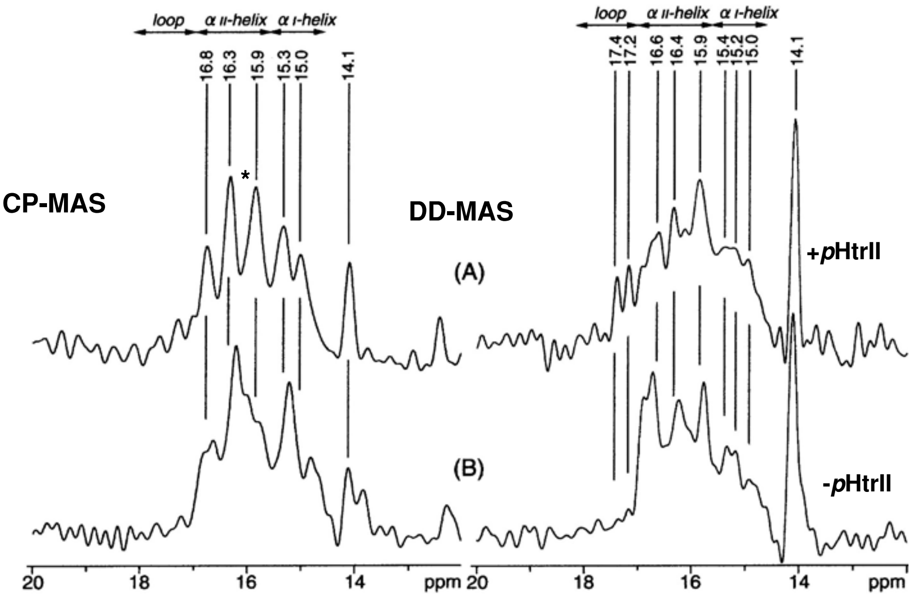

Fig. 4. Comparison of the ^{13}C CP-MAS (left) and DD-MAS (right) NMR spectra of [3-^{13}C]Ala-labeled phoborhodopsin (*p*pR) in the presence (A) or absence (B) of its truncated transducer, *p*HtrII (1–159). The asterisked peak of the CP-MAS NMR spectrum in the upper trace indicates the peak of the C-terminal α-helix.

manner as encountered for monomeric bR as pointed out already [11,13].

*p*pR and *p*HtrII

*p*pR is a retinal protein as a photoreceptor from *N. pharaonis*, consisting of seven transmembrane α-helices as in bR. Its cognate transducer *p*HtrII consists of two transmembrane α-helices and yields signaling for negative phototaxis activated by receiving incoming light by *p*pR through tightly formed complex with *p*pR. Spreads of the ^{13}C chemical shifts for reconstituted [3-^{13}C]Ala-labeled *p*pR in egg PC bilayers and their relative peak intensities (Figure 4) are very similar to those of bR because of taking similar secondary structures for both proteins, in spite of their sequence homology of 27% [11]. The intense ^{13}C NMR peak at 15.9 ppm, ascribable to the C-terminal α-helix protruding from the membrane surface as found for bR on the basis of the conformation-dependent ^{13}C chemical shifts described already, is clearly visible in the DD-MAS spectrum (Figure 4B, right) but almost completely suppressed (Figure 4B, left) in the CP-MAS NMR because of fluctuation motion with a frequency of 10^5 Hz [6,11]. This peak, however, is made visible by the CP-MAS spectrum (Figure 4A, left: asterisked peak) by the complex formation with *p*HtrII (1–159) due to the lowered fluctuation frequency in the C-terminal α-helix (10^4 Hz). This finding indicates that mutual interactions among the extended TM1- and TM2-helices of *p*HtrII (1–159) beyond the surface and the C-terminal α-helix of *p*pR play an important role for stabilization of the *p*pR–*p*HtrII complex.

The intense high frequency α_{II}-helical ^{13}C DD-MAS NMR peaks of [3-^{13}C]Ala-labeled *p*HtrII (1–159) resonate at 16.6 and 16.3 ppm [12] and ascribed to the coiled-coil portion protruding from the membrane surface, with reference to the conformation-dependent displacement of peaks [2,3,19]. These peaks were almost completely suppressed by CP-MAS NMR regardless of the presence or absence of *p*pR or by DD-MAS NMR in the absence of *p*pR. Surprisingly, this is caused by increased fluctuation frequency in the C-terminal α-helix from 10^5 Hz in the uncomplexed state to $>10^6$ Hz in the complexed state. This means that the transducers alone are in an aggregated or clustered state but the *p*pR–*p*HTrII complex is not aggregated.

Diacylglycerol Kinase

DGK from *E. coli* is a small, 121 amino acid, membrane-bound enzyme to catalyze the conversion of diacylglycerol and MgATP to phosphatic acid and MgADP. It is believed to be assembled into a trimer to be active as a catalytic unit, each consisting of three transmembrane α-helices, together with additional two amphipathic α-helices located at the membrane surface [33]. Yamaguchi *et al.* recorded ^{13}C NMR spectra of [3-^{13}C]Ala-, [1-^{13}C]Val-labeled *E. coli* DGK reconstituted in POPC and DPPC bilayers using CP-MAS and DD-MAS methods [13]. Surprisingly, ^{13}C NMR spectra of [3-^{13}C]Ala-labeled DGK in lipid bilayer were broadened to yield rather featureless peaks at the physiological temperature of the liquid crystalline phase. It is also noted that ^{13}C NMR spectra of [1-^{13}C]Val-labeled DGK were completely suppressed at temperatures corresponding to the liquid crystalline phase. Such a suppression of peaks is obviously caused by interference of motional frequency with the frequency of the MAS or proton decoupling (10^4–10^5 Hz), under the physiological condition exhibiting enzymatic activity. In the gel phase lipid, however, up to six distinct ^{13}C NMR signals were well resolved due to lowered fluctuation frequency ($<10^5$ Hz) for the transmembrane α-helices, the amphipathic α-helices and loops. The fact that the enzymatic activity is low under conditions where motion is restricted and high when conformational fluctuation can occur suggests that acquisition of low frequency backbone motions, on the microsecond to millisecond timescale, may facilitate the efficient enzymatic activity of DGK. Clearly, the present observations demonstrate that site-directed ^{13}C NMR approach is very useful for probing the conformation and dynamics of DGK reconstituted in a membrane environment under physiological condition.

Concluding Remarks

It should be anticipated that ^{13}C NMR spectral feature of *fully hydrated* membrane proteins at ambient temperature strongly depends upon sample preparations (either 2D crystals or monomers), a variety of ^{13}C-labeled amino acid residues ([3-^{13}C]Ala-, [1-^{13}C]Val-, Gly- or Leu-, etc.), lipid phase (liquid crystalline or gel phase), etc. in view of their intrinsic flexibility. In particular, well-resolved, fully visible ^{13}C NMR signals of membrane proteins are available from 2D crystalline preparations, as manifested from site-directed ^{13}C NMR studies on [3-^{13}C]Ala- and/or [1-^{13}C]Val-labeled bR recorded by both CP-MAS and DD-MAS methods. In contrast, ^{13}C NMR signals from several residues located at the surfaces of such preparations are partially or almost completely suppressed when they are labeled with [1-^{13}C]Gly, Ala, Leu, Phe, or Trp, as a result of failure of the attempted peak-narrowing by interference of low frequency fluctuation motions with the coherent frequency of MAS, because backbone dynamics in these systems could be coupled with a possible rotational motion of the χ_1 angle around the C_α–C_β bond, as represented schematically by the C_α–$C_\beta H_2$–Z system, where Z is H, isopropyl, phenyl, or indole. Further, ^{13}C NMR studies on [3-^{13}C]Ala-labeled membrane proteins such as *p*pR, *p*HtrII, *p*pR–*p*HtrII complex, and DGK reconstituted in lipid bilayers as *monomers* are also very useful to analyze their conformations and dynamics at ambient temperature, although the absence of several ^{13}C NMR signals from residues located at the surfaces such as loops should be taken into account. In addition, one should anticipate that ^{13}C NMR signals of fully hydrated, monomeric [1-^{13}C]Gly, Ala, Leu, Phe, or Trp-labeled membrane proteins in lipid bilayers are almost completely suppressed at liquid crystalline phase. Nevertheless, it is emphasized that the present site-directed ^{13}C NMR approach turns out to be an unrivaled means to be able to provide an invaluable insight into their conformation and dynamics which are essential for respective proteins to achieve their own biological functions.

The inside of living cells is separated from the external environment and divided into functionally distinctive compartments by a variety of lipid membranes such as the plasma membrane, the endoplasmic reticulum membrane, the nuclear membrane, etc. Naturally, a number of important cellular functions depend on translocation of materials and transduction of signals between those compartments as results of regulated transports of proteins and small molecules between the membranes of the compartments. In fact, a number of proteins involved in the important cellular functions such as cellular signal transduction, regulation of the cytoskeleton, and regulation of the membrane structure have been known to interact with the membrane surfaces as parts of their functions. Although many of those proteins are classified as water-soluble proteins, important parts of their physiological functions are related to their transient membrane-binding states. In order to understand structure—function relationship of those membrane-binding proteins, the protein structures at the water-lipid bilayer interface should be investigated in detail and compared with those in the aqueous phase, since structural changes accompanying the translocation of the proteins from the aqueous phase to the membrane surface would alter the functions of the proteins at the membrane surfaces where they play important physiological roles.

Phospholipase C-δ1 (PLC-δ1), schematically shown in Figure 1, is a protein involved in the phospholipid signal transduction pathway of higher organisms. PLC-δ1 hydrolyzes phosphatidylinositol 4,5-bisphosphate (PIP_2) in the cellular membrane as a response to an increase in the intracellular Ca^{2+} concentration induced by stimulations of the cell to produce the second messengers D-*myo*-inositol 1,4,5-trisphosphate (IP_3) and diacylglycerol [1, 2]. Among three membrane-binding sites of PLC-δ1 shown by triangles in Figure 1, a specific binding site for PIP_2 and IP_3 located at the N-terminal PH domain have been proposed to regulate the membrane localization of PLC-δ1 [3]. In the living cell, a release of PLC-δ1 from the plasma membrane induced by the decrease in PIP_2 and the increase in IP_3 provides a negative feedback system for a regulation of the hydrolysis of PIP_2 at the membrane surface by PLC-δ1. The structure of PLC-δ1 during the hydrolysis reaction at the plasma membrane surface is expected to be characterized by several factors, such as membrane-binding affinities of the membrane-binding sites, structures of the individual domains, orientations of the domains at the membrane plane, interactions between the domains, and dynamics of the protein structure at rather mobile membrane environments. In order to understand the physiological function of PLC-δ1, methods to obtain information about those factors at the membrane surface are needed. The X-ray diffraction analysis is hard to be applied to a structural study of the transient membrane-binding state of PLC-δ1, since the diffraction methods require an isolation and a crystallization of the protein. Using solution NMR methods, transient NOE (TRNOE) measurement [4–8] and the measurement of protein–micelle complex system [9] have been applied to the peripheral membrane proteins and the membrane-binding peptides to provide structural information at the membrane surface. The TRNOE measurement makes it possible to detect the NOE information corresponding to the structures of peptides at various membrane surfaces by solution NMR, when the structures undergo a rapid exchange between the membrane-bound state and the aqueous solution state. TRNOE is an effective method to investigate the structural state of peptides or proteins that weakly bind to the membranes. If the membrane-binding state has a long lifetime, such as in the case of the high affinity membrane binding of PLC-δ1, it is difficult to apply TRNOE, since the lifetime of the exchange is required to be short as compared with the longitudinal relaxation time of the observed nuclei in the target molecules. The protein–micelle complex system makes it possible to investigate the protein structure at the interface between the aqueous phase and the hydrophobic core of the micelle by solution NMR due to short rotational correlation time of the micelle. By using this approach, the membrane insertion and the structural change of the FYVE domain of human early endosome antigen 1 protein at the membrane surface have been investigated [9]. The micelle system is effective to reproduce the membrane surface environment close proximity of the peripheral membrane protein.

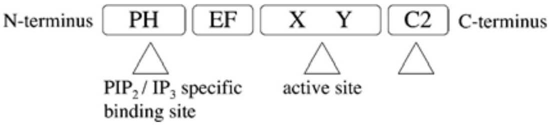

Fig. 1. A schematic representation of a domain arrangement of ratPLC-δ1. Proposed membrane binding sites are indicated by triangles.

A limitation of the system, however, is the difficulty in reproduction of several properties of the lipid bilayer, such as membrane curvature, lateral pressure, membrane mobility, and a local lipid composition. Among those properties, the local lipid composition is particularly important because of a growing number of evidence for the physiological importance of the lipid microdomain [10–13].

An advantage of an application of high-resolution solid-state NMR to study structure of lipid binding protein is that solid-state NMR can provide direct information on protein structure at the surface of the lipid vesicle suspended in an aqueous buffer under various conditions mimicking physiological conditions by changing temperature, vesicle size, buffer composition and the lipid composition of the membrane.

Dynamic Structure of the Membrane-Binding Proteins at the Membrane Surface

The structure, orientation and mobility of membrane-binding proteins or their domains are expected to be altered at the membrane surface due to the unique anisotropic environment of the water-lipid bilayer interface. The peripheral membrane proteins at the membrane surface would interact with the "interface region" between the aqueous phase and the hydrophobic layer of the membrane. The interface region consists of the polar head groups of the lipid molecules and occupies a 15 angstroms thickness of the single leaflet of the lipid bilayer [14]. Since the interface region possesses low dielectric constant ($\varepsilon = 10 \sim 30$) [15], and contains a number of electrically charged groups, the structure, orientation, and mobility of a membrane-binding protein that penetrates into the interface region are expected to be altered due to modification of hydrophobic and electrostatic interactions with the lipid head groups. In fact, membrane-binding peptides forming amphipathic α-helices are proposed to be located at the membrane interface, aligning its α-helical axis parallel with the membrane surface and facing its hydrophobic side of the α-helix the hydrophobic inner layer of the membrane [14, 16]. A membrane-binding domain of colicine, a bacterial toxin, has been proposed to undergo a drastic conformational alteration during its contact with the membrane surface [17–19]. The conformational changes were suggested to include reorientations of the amphipathic α-helices at the membrane surface and an insertion of the hydrophobic α-helix into the inner layer of the membrane.

A study of the lateral-pressure dependency of the PLC-δ1 lipid hydrolysis activity has suggested that parts of the PLC-δ1 molecule penetrate into the membrane during the hydrolysis [20]. If PLC-δ1 penetrates into the interface or the inner hydrophobic regions of the membrane, the conformation, orientation, and mobility of the PLC-δ1 can also be altered due to the changes of the dielectric constant or the electrostatic interactions. An application of the solid-state ^{13}C NMR to PLC-δ1-lipid vesicle complexes provides a suitable method to investigate those alterations at the membrane surface. An important advantage of this approach is that an aqueous suspension of the protein–lipid vesicle complexes assures dynamic structures analogous to the membranes under the physiological condition. Lipid molecules in a lipid bilayer surrounded by an aqueous solution at ambient temperature are known to undergo rapid rotational and translational diffusions within a membrane plane and fluctuations of the molecular structure [21]. These fluctuations are expected to affect the structure and dynamics of membrane-binding proteins at the membrane surface. The solid-state NMR studies of a transmembrane protein, bacteriorhodopsin, have shown the presence of internal motion of the protein relates to the depth in the membrane [22]. The characteristic motional frequencies for the transmembrane α-helices, the hydrophilic N- and C-termini protruded from the membrane surface, and the termini of the α-helices and loops located at the interface region have been reported to be $\sim 10^2$, $>10^5$ and $\sim 10^4$ Hz, respectively [22]. The protein structures including those fluctuations related to the flexible nature of the membrane would be important to understand functions of the membrane-binding proteins under the physiological conditions.

A solid-state NMR study of protein–lipid vesicle complexes provides information about the dynamic structures of the membrane-binding proteins characteristic to those of the anisotropic environments of the water-lipid bilayer interfaces under the physiological conditions. If the three dimensional structures of proteins in crystal or in solution are solved by X-ray diffraction studies or by solution NMR studies, as for the case of PLC-δ1, the information provided by solid-state NMR studies can be interpreted in detail by taking these high-resolution structural models into account.

Application of the Solid-State NMR on the PLC-δ1 PH Domain [23]

As shown in Figure 1, rat PLC-δ1 is a 85 kDa protein consists of functionally and structurally distinguishable five domains; N-terminal PH domain, EF-hand domain, X domain, Y domain, and C-terminal C2 domain [24].

Among these domains, the PH, EF-hand, and C2 domains are common structural modules of proteins included in the cellular signal transduction systems [25]. The X and Y domains form an active site of phospholipase activity of PLC-δ1. Inter-domain and membrane–domain interactions of these proteins provide intracellular cross-talking networks that support traffics of information in the living cells. The PH domain motif is a small and stable structure which consists of about 110 amino acid residues, and found in over 150 proteins involved in the cellular signal transduction pathway and the cytoskeltal reorganization [26, 27]. A number of the PH domains are suggested to mediate protein–lipid interactions by selective bindings to phosphorylated-inositol groups of inositol-phospholipids such as PIP_2 [28–31]. Proteins such as the heterotrimeric G-protein and the protein kinase C are also reported to be specific ligands of some PH domains [29]. As mentioned above, the N-terminal PH domain of PLC-δ1 is known to have high affinities to PIP_2 and IP_3, and regulates the membrane localization and the activity of PLC-δ1 [32, 33]. By applying solid-state ^{13}C NMR, structural alterations of the PH domain of PLC-δ1 during the membrane localization could directly be detected. Since the three dimansional structure of the PLC-δ1 PH domain-IP_3 complex have been determined by an X-ray diffraction study [24], the structure of the water-soluble PH domain-IP_3 complex could be utilized as a template to interpret the structural changes detected by solid-state NMR during the membrane localization of the PH domain.

Figure 2 shows the solid-state ^{13}C NMR spectra of the ^{13}C-labelled methyl groups of alanine residues introduced into the PLC-δ1 PH domain. Figure 2A and B show the spectra of the complex of the PH domain and the phosphatidylcholine (PC) vesicles containing 5% of PIP_2 measured by the cross polarization-magic angle spinning (CP-MAS) technique and the dipolar decoupled-magic angle spinning (DD-MAS) method, respectively. Vertical bars at the bottom of the spectra indicate the chemical shifts of the ^{13}C NMR signals of Ala residues in the PH domain–IP_3 complex in solution. In order to reproduce the dynamic property of the plasma membrane under the physiological condition, the lipid vesicles are suspended in buffers at neutral pH, and enclosed in the air-tight solid-state NMR rotor to prevent an evaporation of water.

The PLC-δ1 PH domain contains five Ala residues, Ala21, Ala88, Ala112, Ala116, and Ala118, as shown in the Figure 3A. Assignments of the signals in the solid-state NMR spectra to the individual Ala residues could be determined by site-specific replacements of the alanine residues by other amino acid residues, provided that no conformational changes are induced by resplacement of alanine with glycine, valine, or leucine. The assignment of the peaks was carried out by detecting the disappearance of a signal induced by a replacement of each alanine residue. The assignments of the Ala signals of the PLC-δ1 PH domain are shown at the top of the spectra in Figure 2.

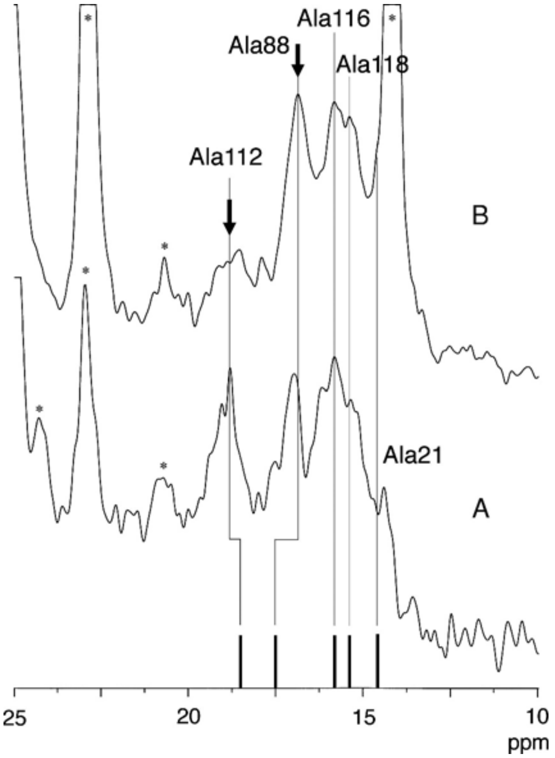

Fig. 2. High-resolution solid-state NMR spectra of the [3-^{13}C]Ala labeled PLC-δ1 PH domains forming complex with PC/PIP_2 vesicles obtained by (A) the CPMAS and (B) the DDMAS method. Assignments of the individual signals are shown at the top of the spectra. The vertical bars at the bottom of the spectra indicate the chemical shifts of the [3-^{13}C]Ala signals for the PLC-δ1 PH domain-IP_3 complex in solution.

The three dimensional structure of the PLC-δ1 PH domain, forming complex with IP_3, consists of β sandwich core containing seven β-strands, three α-helices located at the N-terminus, C-terminus, and the loop between β5- and β6-strands (β5/β6 loop), and loops connecting the β-strands (Figure 3A) as determined by an X-ray diffraction study [24]. The β1/β2, β3/β4, and β6/β7 loops form the specific ligand-binding site. The chemical shift displacements of the methyl carbons of the Ala residues in the PLC-δ1 PH domain shown in Figure 2 reflect the presence of a variety of torsion angles of the Ala residues in these higher-order structures. The conformation-dependent ^{13}C chemical shifts of Ala C_β carbons have been investigated and reported by solid-state NMR studies on polypeptides and structural proteins [34–36] and by the quantum mechanical calculations of model peptides [34–37]. Ala21 located at the N-terminal α-helix, and Ala116 and Ala118 located at the C-terminal

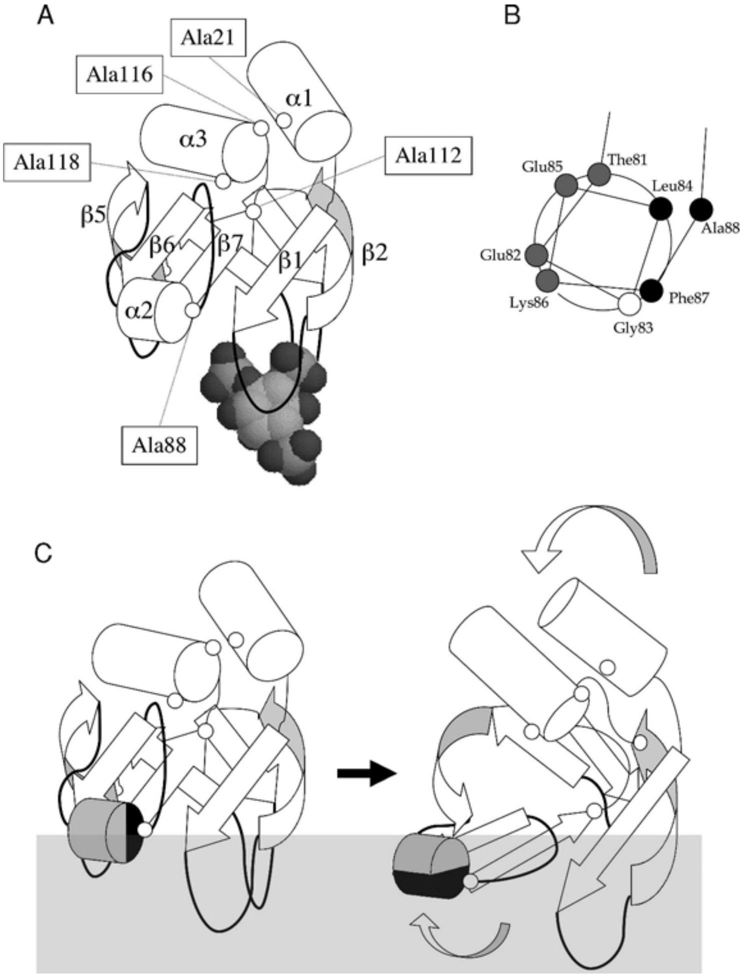

Fig. 3. (A) A schematic representation of the three-dimensional structure of the PLC-δ1 PH domain [24]. The α-helices and β-sheets are indicated by cylinders and arrows, respectively. Ala residues are indicated by open circles. IP_3 is shown by a cpk model. (B) The amphipathic α2-helix viewed from the C-terminus. Hydrophilic and hydrophobic residues are shown by grey and black circles, respectively. (C) A model of the conformational change of the PLC-δ1 PH domain induced at the membrane surface.

α-helix in the model structure are resonated between 14.8 and 16.1 ppm. Since the chemical shifts of these residues are identical to the chemical shifts of the PH domain forming complex with IP_3, it can be concluded that the conformations of the N- and C-terminal α-helices forming the hydrophilic face of the domain located at the opposite side of the membrane-binding surface do not change during the membrane localization. In contrast, significant changes in the chemical shifts of Ala88 and Ala112 as shown by arrows and kinked lines in Figure 2 indicate that the conformations of C-termini of the α2-helix and β7-strand are altered by the membrane localization of the PH domain. Changes of the chemical shift of Ala88, which is included in the α2-helix and that of Ala112, which is located at the C-terminus of the β7-strand flanking with the C-terminus of the β5/β6 loop, indicate the conformational changes of the α2-helix and the β5/β6 loop at the membrane surface. As shown in Figure 3B, the α2-helix has an highly amphipathic structure. In the model structure of the PH domain-IP_3 complex, the α2-helix faces its hydrophobic surface to the hydrophobic surface of the β-sandwich core consists of β5-, β6-, and β7-strands. Considering the proposed orientation of the amphipathic α-helical peptides at the interface region of the lipid bilayer, the α2-helix is expected to be located at the interface region of the membrane, facing the hydrophilic surface to the aqueous phase and the hydrophobic surface to the hydrophobic core of the lipid bilayer. The expected conformational changes of the α2-helix and the β5/β6 loop at the membrane interface are likely to provide more typical α-helix and β-sheet structures for Ala88 and Ala112, respectively. The structural changes include formations of the typical α-helix and β-sheet type hydrogen bonds of the residues that are missing in the model structure of the PH domain-IP_3 complex. These conformational changes are consistent with the directions of the chemical shift displacements of Ala88 and Ala112 induced by the formation of the PH domain–vesicle complexes. A model of the conformational changes of the PLC-δ1 PH domain at the membrane surface expected from the solid-state NMR study is illustrated in Figure 3C.

The structure of the PH domain at the membrane surface is also found to be remarkably affected by the lipid composition of the membrane. For instance, the above-mentioned conformational alteration of the PLC-δ1 PH domain induced at the surface of the PC/PIP_2 membrane are found to be suppressed at the negatively charged membrane surface containing acidic phospholipids, such as phosphatidylserine (PS). The solid-state NMR spectra of the PH domain binding to the PC/PS/PIP_2 membrane indicate that the conformation of the PH domain is identical to that of the PH domain forming a complex with IP_3 in solution. Moreover, a drastic increase in the mobility of the PH domain at the surface of the PC/PS/PIP_2 membrane is also detected from the changes of the relaxation parameters of the solid-state NMR spectroscopy. That the structure and the mobility of the PLC-δ1 PH domain depend on lipid composition of the target membrane may provide molecular mechanisms for the regulation of the PLC-δ1 function; changes in the local lipid composition in response to a variety of physiological reactions in the cell [38–40].

Modification of the protein structure and dynamics induced at the water-lipid bilayer interface as observed for the PLC-δ1 PH domain would also occur for other lipid-binding domains and proteins that are localized at the surfaces of the cellular membranes. The high-resolution solid-state NMR provides an unique method to investigate structural characteristics of the membrane-binding proteins that take part in important cellular functions mediated by changes in the structure, composition, and dynamics of the intracellular and plasma membranes.

Solid-State NMR of Membrane-Active Proteins and Peptides

John D. Gehman and Frances Separovic
School of Chemistry, University of Melbourne, Melbourne, VIC 3010 Australia

Membranes are commonly perceived as little more than a simple canonical bilayer formed by the obvious orientation-preference of the constituent amphiphilic lipid molecules. Hydrophilic head groups, such as the zwitterionic phosphatidylcholine (PC), line the interface with aqueous environments on both sides of the membrane, while the aliphatic fatty acid chains of varying lengths and degree of unsaturation meet tail-to-tail to fill the region flanked by the head groups. The common perception of membrane-associated peptides and proteins is that they generally span the membrane with simple secondary structures, usually α-helices, but include the occasional β-sheet structure. These secondary structures are frequently regarded as trivial anchors to be removed so that the more interesting soluble domains may be studied by conventional approaches.

The classic "fluid-mosaic" model [1] suggests that membranes are simply a two-dimensional analog of a solution: lipids and membrane-associated protein rotate about single axes (normal to the bilayer surface) and translate across the membrane plane in a similar way to water and soluble proteins in three-dimensional solution. As well, study of membrane-associated proteins typically focuses almost exclusively on the protein—the membrane lipid is the negative space, akin to the buffer in which soluble protein is studied, while all the light is cast upon the protein.

Closer inspection of membrane structure, however, suggests that a more balanced view of membranes and membrane-associated protein is often necessary and more rewarding. Lipids have complex phases and phase transitions which depend upon particular lipid properties, temperature, hydration levels, and, especially relevant—the protein composition of the mixture. For those lipids commonly employed in model membrane studies, longer-chain fatty acids tend to persist in the lamellar gel-phase L_β as temperature is increased, particularly at low hydration levels. Conversely, shorter fatty acid chains and higher hydration levels tend to allow transition to the lamellar liquid crystalline phase L_α at lower temperatures. Higher temperatures and different lipid geometries than those typically employed for model membrane studies, lead to additional phase transitions into cubic (Q_{I} and Q_{II}) and hexagonal phases (H_{I} and H_{II}) [2].

Membrane-associated peptides and proteins include cell signaling receptors, immune response factors, ion channels, cell adhesion elements, toxins, and metabolic and photosynthetic components, many of which are also exploited by viruses to recognize and gain entry into cells. The literature is replete with hyperbole of the suitability of solid-state NMR for study of proteins in membrane environment: solid-state NMR does not require long-range ordering of molecules as is required for crystal diffraction work, and is not subject to the same hydrodynamic restraints that liquid-state NMR requires of molecules in solution. These are actually strengths rather than mere lack of weakness: less stringent sample structure allows protein *and* lipid molecules to be studied under conditions much closer to their natural membrane environments, and being independent of rapid global molecular rotation reintroduces the sensitivity of orientation-dependent parameters to local molecular structure and motion.

This sensitivity is based in large part upon the $(3\cos^2\theta - 1)$ dependence, which is treated under perturbation theory as first order corrections (H') to the Zeeman energy Hamiltonian ($H_z = \Delta m_z \gamma B_0$). θ is the angle subtended by the relevant vector within the sample and the applied magnetic field $\vec{B}_0$, and $(3\cos^2\theta - 1)$ is also known as the proportional Legendre polynomial $P_2(\theta)$ or the spherical harmonic function Y_0^2 :

$$H_T \approx H_z + H'\left(Y_0^2\right).$$

Conveniently for NMR studies of phospholipid membranes, ^{31}P is 100% naturally abundant, is more sensitive than carbon, and phospholipids typically have just one ^{31}P nucleus per molecule in the head group. Also advantageous is the infinitesimal natural abundance of ^{2}H, as small amounts of ^{2}H-enriched lipids may be selectively added to a sample and observed against virtually zero background. Together, wideline ^{31}P and ^{2}H NMR can be used to report on relative motional differences or changes in conformation of the hydrophilic head group at the aqueous interface and the hydrophobic aliphatic tails within the lipid bilayer, respectively, upon addition of protein

Graham A. Webb (ed.), Modern Magnetic Resonance, 305–311.
© 2008 *Springer.*

and other lipid components. At an extreme, changes in sample composition actually introduce new lipid phases that may compromise protein conformation and dynamics and/or may be relevant to the function of the protein being explored (as is the case for cytolytic toxins).

Similarly, despite relatively low intensity, selective enrichment of ^{13}C and ^{15}N in protein can be used against otherwise very low natural abundance to permit measurement of several structural aspects of membrane proteins: ^{13}C and ^{15}N NMR can help to define protein structure as well as orientation within the membrane.

Chemical Shift Anisotropy (CSA)

For spin $I = 1/2$ nuclei, which include ^{31}P, ^{1}H, ^{13}C, and ^{15}N, Y_0^2 modulates the interaction (H_σ) between the applied magnetic field and the anisotropic chemical shift tensor, specifically the anisotropic component. Each individual nucleus may be thought of as an individual crystallite, and each crystallite is most simply described by its principal axis system (PAS)—the orientation in which the chemical shift anisotropy (CSA) tensor is diagonal, with characteristic components σ_x^{PAS}, σ_y^{PAS}, σ_z^{PAS} · Each crystallite contributes signal intensity to the powder spectrum at frequency ν_σ according to its orientation relative to $\vec{B}_0$, which in the laboratory frame is simply $(0,0,B_0)$. The frequency at which a given crystallite contributes to the spectrum is given by [3]

$$\nu_\sigma = \gamma B_0 \left(\sigma_x^{\mathrm{PAS}} \cos^2\alpha \sin^2\beta + \sigma_y^{\mathrm{PAS}} \sin^2\alpha \sin^2\beta + \sigma_z^{\mathrm{PAS}} \cos^2\beta\right)$$

where, for all basis set vector lengths normalized to unity and expressed in laboratory frame coordinates, β is the angle between the PAS z-axis and $\vec{B}_0$

$$\beta = \cos^{-1}\left(\vec{z}^{\mathrm{PAS}} \cdot \vec{B}_0\right),$$

and, provided $\beta \neq 0$, α is the angle between the PAS y-axis and the vector orthogonal to both the PAS z-axis and $\vec{B}_0$. The direction of rotation by α is fixed by forcing the rotation axis to point in the same direction as the PAS $+z$-axis:

$$\alpha_{(\beta\neq 0)} = \cos^{-1}\left(\vec{y}^{\mathrm{PAS}} \cdot \frac{\left(\vec{z}^{\mathrm{PAS}} \times \vec{B}_0\right)}{\sin\beta}\right) = \sin^{-1}\left(\left|\vec{y}^{\mathrm{PAS}} \times \frac{\left(\vec{z}^{\mathrm{PAS}} \times \vec{B}_0\right)}{\sin\beta}\right|\right),$$

which simplifies to

$$\alpha_{(\beta\neq 0)} = \cos^{-1}\left(\frac{\vec{x}^{\mathrm{PAS}} \cdot \vec{B}_0}{\sin\beta}\right) = \sin^{-1}\left(\frac{\vec{y}^{\mathrm{PAS}} \cdot \vec{B}_0}{\sin\beta}\right).$$

α, β, and (although irrelevant here) γ are also commonly known as the Euler angles [4]. For the simple case considered here in which the PAS axis system is transformed directly to the laboratory frame, β and the Y_0^2 angle θ are the same.

When all individual crystallites are ordered identically, as in a macroscopic crystal, a single peak for each resonance is observed according to the orientation of the crystal relative to the magnetic field (e.g. Jones *et al.* [5]). More commonly, when crystallites are distributed randomly over all orientations, as for a powdered sample, a characteristic powder pattern is observed in which the discontinuities in the lineshape reveal the three PAS components. When the individual crystallite experiences rapid motion, whether by experimental mechanical spinning, or by molecular motion within the sample, time-averaged chemical shift values are observed. For the common case when the sample is mechanically spun about 54.74° (the "magic angle," where $Y_0^2 = 0$), the anisotropic component of the chemical shift tensor averages to zero, and the time-averaged value observed is the isotropic chemical shift; local magnetic environmental differences aside, this is the same value observed in solution NMR. When the orientation of the crystallite varies owing to molecular motion, as for a lipid rotating and translating within a model membrane, averaging of the CSA will depend on the range, axes, and frequency of motion.

The ^{31}P CSA of the head group at the rigid-lattice limit is realized with anhydrous gel-phase lipid samples, which have principal tensor values of approximately −98, −35, and 133 ppm (in traceless form[1]) for PC [6], a lipid head group class most commonly used in model membranes. Hydration of the lipid permits head group rotation about the glycerol-carbon/phosphate-oxygen and phosphate-oxygen/phosphorous bonds, and the static CSA is partially averaged to apparent principal tensor values of approximately −82, −27, and 109 ppm (in traceless form) for PC [6] (Figure 1).

Further deviations from this lineshape are indicative of the lipid phase. Above the gel-phase transition temperature, lipids experience rapid axial rotation as well

---

[1] Traceless form expresses principal chemical shift tensor values such that their average, the isotropic chemical shift, is zero. Adding the isotropic chemical shift to these principal CSA values gives reference-specific chemical shift values.

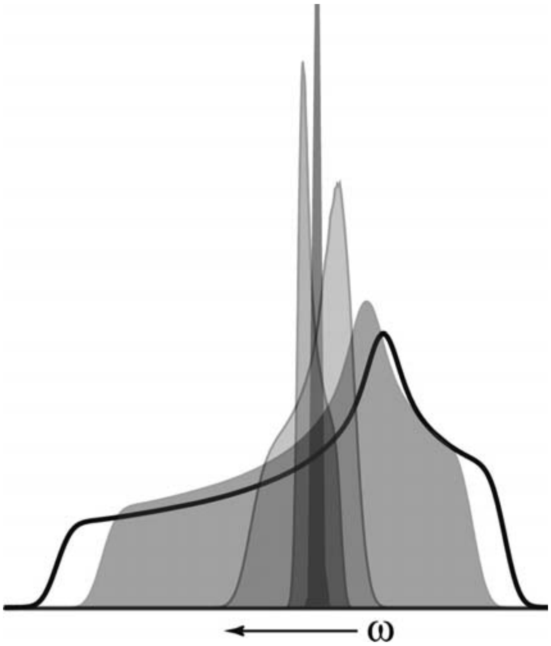

Fig. 1. Simulated lineshapes for static ^{31}P NMR of various lipid phases, in order of decreasing linewidth: static limit, monohydrated, liquid lamellar, hexagonal, and isotropic. Relatively intensities are only qualitatively correct. (See also Plate 34 on page XXXI in the Color Plate Section.)

as translational motion across the lipid surface. In the liquid crystalline lamellar phase of unoriented samples, though the bilayer normal vectors would be distributed randomly just as for regular powder samples, lateral translation of lipid molecules on the NMR timescale causes negligible deviation in lipid long-axis orientation. Hence in this phase the effect of rapid axial rotation alone is observed, where the ^{31}P CSA tensor is motionally averaged so that it appears axially symmetric, and only two different principal tensor values are needed, labeled $\sigma_{\perp}$ and $\sigma_{||}$ with reference to the axis of rotation about the bilayer normal.

Translational diffusion of lipids in the hexagonal phase, however, *does* serve to reorient the lipid rotation axis on the NMR timescale, and hence a further averaging of the CSA tensor is observed, which is generally manifest as a narrowing and reversal of the asymmetric liquid crystalline or bilayer phase lineshape.

Finally, a number of other phases where lipids rapidly reorient on the NMR timescale yields a symmetric and relatively narrow peak about a single principal value—the isotropic chemical shift. Most relevant for biological work are micellar and small vesicle phases, where the entire lipid structure is small enough to rotate quickly; indeed it is these phases that are used for solution NMR experiments of lipid-associated proteins.

^{31}P wideline NMR alone can provide a simple diagnostic, which may, for example, indicate whether temperature, hydration, or lipid characteristics and membrane composition need to be adjusted to maintain lamellar phase or vesicle structure upon addition of protein [7,8].

Another aspect of the CSA property of nuclei is explored by using aligned membrane samples. Lipid bilayers can be formed with parallel surfaces by layering hydrated phospholipids between glass plates. Similar to NMR of single crystals, by forcing a common orientation relative to the applied magnetic field $\vec{B}_0$, a single chemical shift value may be observed. While this can be useful for lipid samples using ^{31}P [9], it is particularly useful for the determination of backbone orientation using carbonyl ^{13}C and amide ^{15}N chemical shifts of membrane-associated peptides and protein. The principal ^{13}C CSA values for peptide backbone carbonyl are approximately -75, -3, and 78 ppm (in traceless form), with the intermediate -3 ppm value being the most variable and aligned approximately 10° off the ^{13}C=O bond (on the opposite side of the ^{13}C–N peptide bond) in the peptide plane, and with the 78 ppm axis perpendicular to the peptide plane [10–13]. Hence, when a given carbonyl orientation and membrane bilayer normal vector orientation are such that the peptide plane is perpendicular to $\vec{B}_0$, a maximum chemical shift value is observed. Other orientations yield Y_0^2-attenuated chemical shift values. This property can be combined together with consideration of molecular motion and secondary structure to help discriminate between different possible models for peptide and protein association with lipid bilayers, as applied to gramicidin A [14,15] (Figure 2) and melittin [16].

Similarly, principal shift tensor values for ^{15}N peptide backbone amides are approximately -60, -41, and 101 ppm (in traceless form), with the 101-ppm component lying 15°–20° off the ^{15}N–H bond vector and in the peptide plane [13,17,18]. When the fixed relationship between a particular backbone ^{15}N amide and an oriented membrane is such that the ^{15}N–H bond vector lies approximately parallel to $\vec{B}_0$, a maximum of chemical shift is observed. From a collection of other chemical shift observations the orientation of each ^{15}N–H bond vector can be deduced from the chemical shift as a function of the angle of the oriented bilayer normal to $\vec{B}_0$. This information can be used similarly to the above, for example, to determine whether an α-helix inserts into membranes (where ^{15}N–H bond vectors lie parallel to bilayer normal vectors), or lies parallel to the bilayer surface on membranes [9,19].

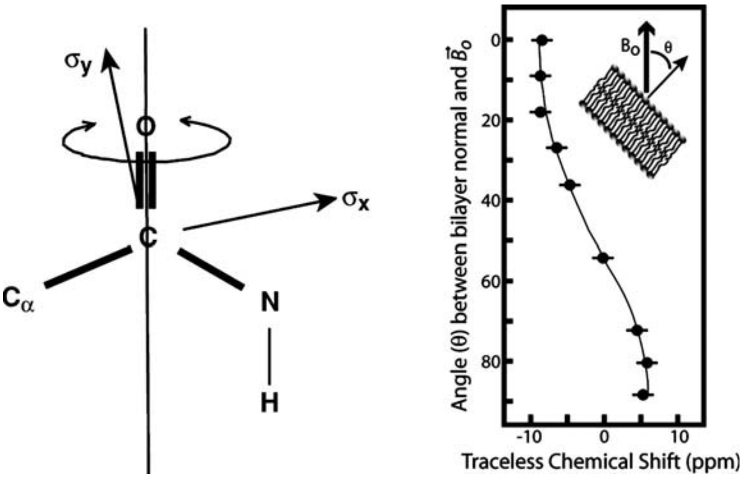

Fig. 2. (Left) Representation of the Ala^3 carbonyl orientation of gramicidin A in a $\beta^{6.3}$-helical structure for the molecular and PAS frame relative to an axis of rotation parallel to the lipid bilayer normal. Expected CSA with fast axial rotation in this orientation is −17 ppm. (Right) Measurement of carbonyl chemical shift for Ala^3 as a function of the angle of the bilayer normal to $\vec{B}_0$. The experimental CSA is approximately −16 ppm. (Adapted from Cornell *et al.* [14].)

Quadrupolar Coupling

Spin $I > {}^1/_2$ nuclei have an additional interaction (H_Q) with the nuclear electric field gradient, manifest as a nonzero quadrupole moment

$$H' \approx H_\sigma + H_Q.$$

In the case of the spin $I = 1$ nucleus ^{2}H bound to carbon, simplifications can be made of the anisotropic properties involved such that

$$\Delta \nu_Q(\text{kHz}) = 127.5 \cdot (3\cos^2\theta - 1),$$

where the underlying tensor is oriented such that θ is the angle between the applied magnetic field and the C–^{2}H bond vector [20], and rapid axial rotation about the C–^{2}H bond reduces the static coupling constant by a factor of two, so that the quadrupolar splitting magnitude varies between 127.5 and −63.75 kHz at 0° and 90°, respectively [2]. Owing to a probability distribution of θ proportional to $\sin\theta$, the $\theta = 90°$ orientation is most probable, and $\theta = 0°$ is least probable. Hence, the characteristic powder pattern—a "Pake" pattern [21]—of a static ensemble of C–^{2}H bond vectors is symmetric, according to $\nu = \nu_\sigma \pm {}^1/_2\Delta\nu_Q$. The lineshape has greater intensity where the quadrupolar splitting is reduced (the "90° edge"), lower intensity where the quadrupolar splitting is greatest, and the intensity overlaps at ν_σ for both $\Delta m_I = +1 - 0$ and $\Delta m_I = 0 - (^-1)$ transitions at $\theta = 54.74°$.

As for ^{31}P chemical shift, molecular motion which is rapid on a timescale relative to the quadrupole splitting causes variations in the angle θ and serves to time-average the quadrupolar splitting constant to a smaller-magnitude effective splitting at each orientation. In the fatty acid chains of membrane lipids, carbon–carbon bond rotation is the principal molecular motion, and serves to attenuate the maximum potential splitting. Such an attenuation is attributed to disorder among the lipid tails, and is characterized in practice by an order parameter S, which is proportional to Y_0^2 for the *apparent* quadrupole splitting,

$$S = \tfrac{1}{2}\langle 3\cos^2\theta - 1\rangle,$$

expressed to indicate that the splitting is a time-averaged value [22].

A fully deuterated fatty acid acyl chain produces a spectrum that is a sum of Pake patterns, one for each C–^{2}H position along the chain (e.g. Separovic and Gawrisch [23], Figure 3A). With sufficient resolution, the signal from each carbon position can be distinguished at the most intense portion of the lineshape at $\theta = 90°$. These complex spectra may be simplified by "de-Pake-ing" [24]—a numerical procedure for deriving the spectrum for a single angle θ from the powder pattern (Figure 3B). While strict interpretation of spectra can be difficult without systematically deuterating each position individually [25], it is generally assumed that for the typically resolved 90° intensities, the outermost to innermost intensity of the ^{2}H spectrum corresponds to the sequential chain positions from the first CD$_2$ positions after the carbonyl ester to the terminal methyl group deuterons. This indicates that the chain positions closest to the bilayer interface are most ordered, as they contribute the intensity at the wings of the spectrum with greatest quadrupole splitting. Positions become less ordered with subsequent steps further down the acyl chain [25]. Increasing disorder at each chain position causes the chain to protrude

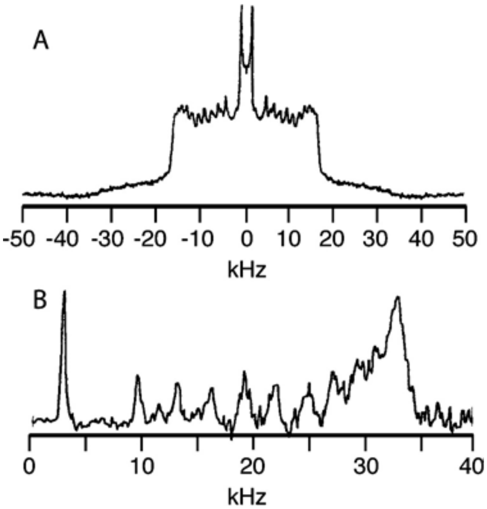

Fig. 3. ^{2}H spectrum of ($^2H_{31}$)-palmitoyl-oleoyl-PC (single-chain deuterated POPC) and natural abundance dioleoyl-phosphatidylethanolamine (DOPE) (5:1 molar ratio) bilayers: (A) powder pattern from unoriented dispersion; and (B) de-Paked half spectra, calculated for 0° orientation from A. (Adapted from Separovic and Gawrisch [23].)

less far from the membrane interface than it would in an extended conformation. Therein, greater acyl chain order can be interpreted as an increase in membrane thickness [23,26]. Hence, changes in quadrupolar splittings can indicate changes in membrane structure and dynamics upon addition of peptide or protein.

^{31}P and ^{2}H NMR of Lipids

Numerous examples demonstrate that together ^{31}P and ^{2}H NMR can provide important insight into membrane structure given the independent reporting of the relative motion and phase state of the head groups and hydrophobic tails. At one extreme, we have shown that Core Peptide from a transmembrane sequence of T-cell antigen receptor, known to be inhibitory of immune response, impacts upon ^{31}P and ^{2}H spectra of lipid bilayers only at unreasonably high peptide concentrations, supporting the supposition that its activity must be other than a consequence of membrane disruption [27].

At another extreme, the sphingomyelin-dependent cytolytic sea anemone protein equinatoxin II (EqtII) was shown to cause significant changes in model membranes at very low concentrations [28]. In this study, PC lipid head group motion increased upon addition of either 10% sphingomyelin *or* 0.1% cytolytic EqtII protein, but appeared similar to PC alone when *both* are added to model membranes (although the lipid phase transition temperatures increase). ^{2}H spectra of a deuterated PC for the same samples show a similar trend: overall linewidth (demarcated by the 0° edges of the highest ordered carbons of the acyl chain) decreases, reflecting greater disorder upon addition of sphingomyelin or EqtII individually, but higher order is observed when both are added. These two observations (together with relaxation data) were interpreted as suggesting that EqtII and sphingomyelin significantly impact membrane dynamics independently, but when combined tend to preferentially segregate out together from bulk PC lipid, leaving the PC dominated ^{31}P signal and ^{2}H signal to appear similar to pure PC. A higher protein concentration (0.4%) and higher temperature were also shown to promote an additional phase with an isotropic spectral component in both ^{31}P and ^{2}H spectra. These are likely to be very small unilamellar vesicles as seen by cryo-electron microscopy, and are sphingomyelin-enriched as shown by magic-angle spinning ^{31}P spectra of phases separated by centrifugation.

Lying between these extreme effects is the example of the αM1 transmembrane helix of nicotinic acetylcholine receptor added to PC bilayers. ^{31}P NMR [8] was used to show that high protein concentration and longer incubation times promoted the formation of an isotropic lipid phase. Of the conceivable lipid phases possibly giving rise to an isotropic signal, it was deduced that smaller, more rapidly tumbling vesicles were formed since ^{2}H NMR spectra did not show spectral averaging of the lipids. Furthermore, slightly higher order of the acyl chains, indicated by larger quadrupolar splittings, suggested a greater average membrane thickness. Addition of cholesterol prevented formation of the ^{31}P isotropic phase, while addition of the anesthetic halothane promoted conformational changes in the polypeptide due to changes in bilayer properties.

Dipolar (Re)-Coupling

Magnetically active nuclei also directly interact with one another in a distance-dependent manner, a property that can be exploited for structure determination of membrane protein complexes. The most significant terms in the dipolar coupling Hamiltonian are also a function of Y_0^2. These are: (i) the zero-frequency term, "I_zS_z" in product-operator parlance,which expresses the direct impact of the spin state of one nucleus upon another and (ii) the difference frequency/zero quantum term, "$I_+S_- + I_-S_+$", which drives mutual antiparallel "spin flips" between nuclei. While the I_zS_z term is significant for all nuclear pairs, the $I_+S_- + I_-S_+$ term is significant only for nuclear pairs for which the orientation-dependent resonance frequency difference $\Delta\omega$ is sufficiently small, principally homonuclei in a typical magnetic field.

Dipolar interactions usually complicate a spectrum; experiments that include sample-labeling schemes to provide for such complicating interactions are generally also spun at a speed about the magic angle that is several times faster than the strength of the dipolar interaction. The Y_0^2-dependent dipolar coupling is thus averaged to zero as for the anisotropic component of chemical shift and the first order quadrupolar coupling for spin $>{}^1\!/_2$ nuclei.

Further conjuring lies in the techniques to selectively reintroduce the dipolar coupling under magic-angle spinning conditions. One technique, rotational resonance, (RR or R^2), is so simple it may actually be achieved accidentally with an inopportune choice of magic-angle spinning speed ω_r for an isotopically (often ^{13}C) labeled sample. When the condition

$$\Delta\omega = n \times \omega_r$$

is met for small integer n and chemical shift difference $\Delta\omega = |\omega_I - \omega_S|$, the nuclear spin pair I, S are recoupled through the $I_+S_- + I_-S_+$ term, and effectually trade nuclear polarization [29] at a distance-dependent rate [30]. The technique can be employed for somewhat qualitative determination of protein complex models [31,32]. Strict analysis of the data requires attention to several complicating physical factors [30,33], and has been employed to achieve distance determinations of 2.7 ± 0.2 Å for a ^{31}P–^{31}P nuclear pair [34], as well as distances as long as 5 Å with identical or better accuracy for ^{13}C–^{13}C nuclear pairs in melittin measured in a membrane environment [7].

Conclusion

Exploitation of the $(3\cos^2\theta - 1)$ dependence of anisotropy in the chemical shift, quadrupolar and dipolar interactions with magnetically active nuclei provides a rich source of information for both proteins and, importantly, lipids in membrane systems. Solid-state NMR is well suited to measure these anisotropies, and is becoming geometrically more important as the focus of biomedical research increasingly spotlights membrane proteins. While straightforward approaches require sometimes tedious isotopic labeling of samples, and data interpretation should not be assumed to be trivial, the experiments are relatively easy to perform and do not require extraordinarily high field strengths as do many other currently emerging and increasingly important NMR approaches. Although currently evolving at an accelerated pace, existing biological solid-state NMR techniques can also give information on both the membrane and the associated protein.

Magnetic Resonance Spectroscopic Studies of the Integral Membrane Protein Phospholamban

Gary A. Lorigan
Department of Chemistry and Biochemistry, Miami University, Oxford, OH 45056, USA

Membrane proteins (which make up approximately one-third of the total number of known proteins) are responsible for many important properties and functions of biological systems: they transport ions and molecules across the membrane, they act as receptors, and they have roles in the assembly, fusion, and structure of cells and viruses. Despite the abundance and clear importance of membrane-associated molecules, very little information about these systems exists. A plethora of membrane proteins are intimately associated with cardiovascular function and disease. Structural studies of these membrane proteins represent one of the final frontiers in structural biology. X-ray crystallography is the premiere technique that is used to elucidate structural information of biologically significant protein systems. However, this technique has not been very successful in providing structural information about membrane protein systems. The hydrophobic surfaces associated with membrane-bound protein systems make the crystallization process extremely difficult. Although researchers are making progress with X-ray techniques, still only a handful of membrane protein structures have been obtained via X-ray crystallography [1–5]. Alternatively, solution NMR spectroscopy, solid-state NMR spectroscopy, and EPR spectroscopy are powerful techniques that can be used to provide structural, orientational, and dynamic information about membrane protein systems in lipid bilayers [6–10]. This short review chapter will analyze some of the magnetic resonance techniques that have been used to investigate the integral membrane protein phospholamban (PLB).

Phospholamban

The contraction/relaxation cycle intimately associated with cardiac muscle cells is regulated by cytosolic levels of Ca^{2+} ions. In order for cardiac muscle cells to relax after a contraction, Ca^{2+} ions must be rapidly transferred between the cytosol and the cardiac sarcoplasmic reticulum (SERCA) lumen. The transfer of Ca^{2+} ions is performed by the Ca-ATPase of the SERCA [11–14]. This unique pumping mechanism is activated by the cyclic AMP- and calmodulin-dependent phosphorylation of the integral membrane protein PLB [15–17]. Dephosphorylated PLB inhibits SERCA ATPase activity and stops the flow of Ca^{2+}ions. Conversely, when PLB is phosphorylated this inhibition is relieved, and Ca^{2+} ions are transferred through the membrane. This unique process controls the heartbeat of the cardiac cycle. The rate and extent of myocardial contraction is determined by the flow rate of Ca^{2+} ions into the myoplasm. Recent studies have suggested that an abnormal relaxation of cardiac muscle cells can induce heart failure, due to abnormalities in Ca^{2+} transients and decreases in Ca-ATPase concentrations [18,19]. PLB is a small (52 amino acid) type II membrane protein and shares many characteristics with some of the larger mammalian ion channels [20]. The size of PLB makes it an ideal candidate to investigate with both NMR and EPR spectroscopy. Determining the structure of PLB and its interaction with lipid bilayers is central to understanding its regulatory role.

The full three-dimensional structure of WT-PLB in either the phosphorylated or dephosphorylated states has not been determined in a phospholipid bilayer. Sequence homology studies have indicated that the protein consists of three domains: a hydrophilic amphipathic N-terminus (1–21) MDKVQYLTR SAIRRASTIEMP section, a hinge or β-sheet region QQARQNLQN (22–30), and a hydrophobic (31–52) C-terminus LFINFCLILICLLLICIIVMLL segment that spans the bilayer. WT-PLB is believed to consist of a homopentameric cluster, which retains activity when reconstituted into lipid bilayers with Ca-ATPase [21,22]. The structural characteristics of PLB have been investigated with several biophysical spectroscopic techniques including: CD spectroscopy, EPR spectroscopy, IR spectroscopy, and NMR spectroscopy in a variety of different environments (organic solvents, micelle, and phospholipid bilayer). CD and solution NMR studies carried out on the hydrophilic cytoplasmic domain of PLB in organic solvents have identified a partial α-helical structure [23–27]. The α-helical secondary structure of the cytoplasmic domain has been confirmed with CD and IR and extended further to include the transmembrane segments of PLB [28,29]. The structure of PLB may change when the full-length protein

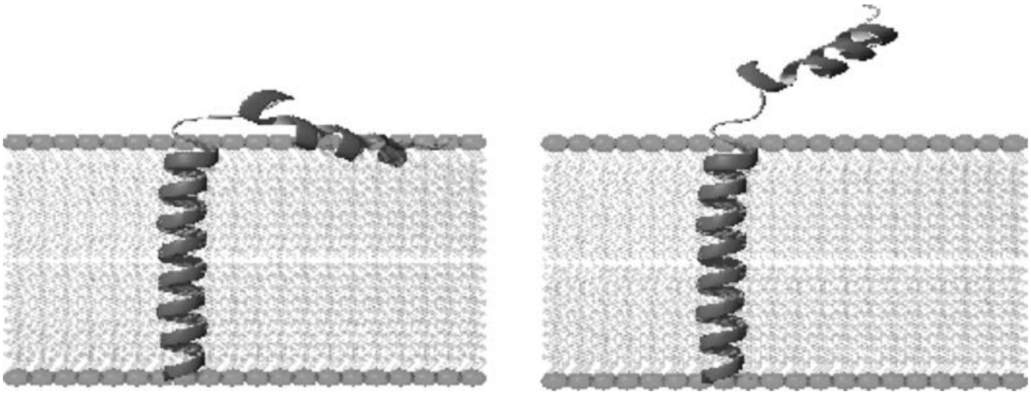

Fig. 1. (Left) Structure of PLB inserted into a phospholipid bilayer. (Right) Additional structural model of PLB inside a phospholipid bilayer. The structures are shown as monomers for clarity. WT-PLB is believed to exist as a pentamer. (See also Plate 35 on page XXXI in the Color Plate Section.)

is placed into a proper functional lipid environment such as a phospholipid lipid bilayer. Also, the structure may be modified by its interaction with Ca-ATPase which is required for regulatory function.

Two structural models have been proposed for PLB based upon FTIR, NMR, and computer data/modeling (Figure 1). Tatulian *et al.* have indicated that PLB consists of two disjointed helices: a transmembrane helix that is parallel with the bilayer normal and a tilted helix that extends outside the membrane (Figure 1 (left side)) [30]. The two helices are connected by a small intervening β-sheet/unstructured region.

Another model (not shown) proposes that PLB is a continuous α-helix in which both the transmembrane and cytosolic elements are oriented at a tilt angle of $28^\circ \pm 6^\circ$ with respect to a DMPC lipid bilayer [28]. According to this model, PLB is one long straight α-helical structure in which the hydrophobic portion is located within the membrane and the hydrophilic region lies outside the membrane. Analysis of all the different biophysical studies of WT-PLB, indicates that the structure and helix orientation of phosphorylated and dephosphorylated pentameric PLB with respect to the membrane is under debate.

Phosphorylation serves as the regulatory switch for PLB. It confers protease resistance, indicating a possible structural change in PLB [29]. Upon β-adrenergic stimulation, PLB is phosphorylated at sites Ser-16 and Thr-17 concomitant with the flow of Ca^{2+} ions [13]. Once again, a discrepancy exists in the literature as to whether a change occurs in the secondary structure of phosphorylated PLB. Specifically, fluorescence, FTIR, and solution NMR measurements have observed secondary structural changes on the full-length and segmented portions of PLB, while computer modeling and additional FTIR and CD studies have not [11,12,26,29–31]. Recent solution NMR studies on the cytoplasmic portion of PLB (residues 1–36) in trifluoroethanol have indicated that phosphorylation does not adversely affect the structure of the C-terminus between residues 21 and 36, and that phosphorylated PLB has more loose helical packing than the nonphosphorylated version of the protein.

Solid-State NMR Spectroscopic Studies of PLB

Several research groups are studying the structural and dynamic properties of PLB utilizing NMR spectroscopy [14,23,32–44]. The structural properties of PLB have been studied utilizing the rotational echo double resonance (REDOR) and the rotational resonance solid-state NMR techniques.

Solid-state NMR spectroscopic studies on PLB utilizing the rotational resonance method have indicated that the sequences Pro21-Ala24 and Leu42-Leu44 adopt an α-helical structure in pure lipid bilayers, in the presence and absence of Ca-ATPase [39]. Additional REDOR NMR experiments have revealed that the sequence Ala24-Gln26 switches from an α-helix in pure lipid membranes to a more extended structure in the presence of SERCA [39,44]. The data gleaned from this study suggest that the Ca^{2+}-ATPase has a long-range effect on the structure of PLB around residue 25, which promotes the functional association of the two proteins. Additional rotational resonance NMR data have shown that internuclear ^{13}C distances between Leu7 and Ala11 in the cytoplasmic region, between Pro21 and Ala24 in the juxtamembrane region, and between Leu42 and Cys46 in the transmembrane domain of PLB all consist of an α-helical secondary structure [41]. REDOR experiments agree that the secondary structure is α-helical in the region of Pro21 and that there are no large conformational changes upon phosphoryla-

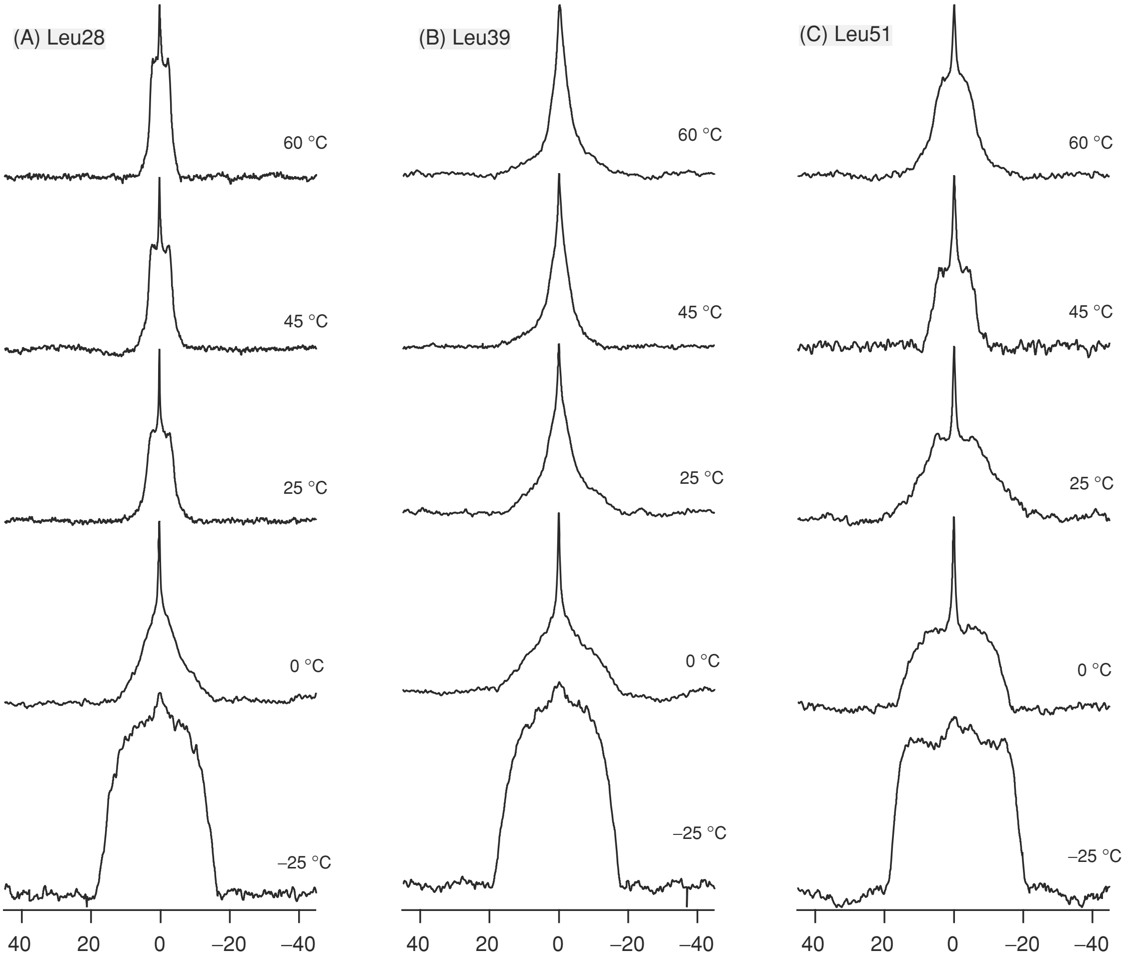

Fig. 2. ^{2}H NMR powder pattern spectra of L-leucine-5,5,5-d$_3$ incorporated at specific sites of TM-PLB and inserted into POPC phospholipid bilayers. ^{2}H NMR spectra are shown for (A) CD$_3$-Leu28 PLB, (B) CD$_3$-Leu39 PLB, and (C) CD$_3$-Leu51 PLB incorporated into POPC phospholipid bilayers at lipid/peptide molar ratios of 25:1.

tion [41]. The data indicate that PLB exists as homogenous α-helical pentamer.

Additionally, the side chain and backbone dynamic properties of PLB have been investigated utilizing solid-state NMR spectroscopy. Figure 2 shows the solid-state ^{2}H NMR powder pattern spectra of specific labeled TM-PLB (transmembrane section of PLB consisting of residues Ala24-Leu52) samples incorporated into unoriented 1-palmitoyl-2-oleoyl-phosphocholine (POPC) bilayers as a function of temperature [33]. ^{2}H solid-state NMR spectra of ^{2}H-labeled leucine (deuterated at one terminal methyl group) incorporated at different sites (CD$_3$-Leu28, CD$_3$-Leu39, and CD$_3$-Leu51) along the TM-PLB peptide exhibited line shapes characteristic of either methyl group reorientation about the C_γ–C_δ bond axis, or by additional librational motion about the C_α–C_β and C_β–C_γ bond axes. The ^{2}H NMR line shapes of all $-CD_3$ labeled leucines are very similar below 0 °C, indicating that all the residues are located inside the lipid bilayer. At higher temperatures, all three labeled leucine residues undergo rapid reorientation about the C_α–C_β, C_β–C_γ and C_γ–C_δ bond axes as indicated by ^{2}H line shape simulations and reduced quadrupolar splittings. At all the temperatures studied, the ^{2}H NMR spectra indicated that the Leu51 side chain has less motion than Leu39 or Leu28 which is attributed to its incorporation in the pentameric PLB leucine zipper motif. The unique features associated with these spectra could be explained by the condition that the Leu51 side chain is involved in the so-called "knobs-into-holes" bonding arrangement in which the side chain of Leu51 from one α-helix is locked into the groove of a second α-helix (of the pentamer) so that the two α-helices are coiled around each other. Smith and co-workers have also reported that Leu44 is buried within the core of pentameric PLB and also observed the general bell-shaped characteristics in the line shape [45]. This type of structural arrangement is believed to help stabilize the structure of the pentamer [41]. ^{31}P NMR spectra of these samples indicate that TM-PLB is incorporated into phospholipid bilayers in the liquid crystalline (L_{α}) phase [46]. Additional studies have probed the interaction of PLB with the membrane utilizing spin-label EPR spectroscopy [40]. Finally, ^{15}N solid-state NMR studies have indicated that TM-PLB is transmembrane with respect to the membrane normal [47].

Magnetic Resonance Spectroscopic Studies of the AFA-PLB Monomer

Recently, some exciting new NMR and EPR spectroscopic results have been obtained on a mutated version of PLB (AFA-PLB) that predominantly exists as a monomer [27,36,39,41,45,48,49]. AFA-PLB is obtained by mutating the three Cys residues (36, 41, and 46) to Ala, Phe, and Ala. This mutated PLB monomer has been shown to be fully functional [50]. One of the biggest breakthroughs has been the solution NMR structure of AFA-PLB by the Veglia research group. His research group has determined an "L-shaped" α-helical structure of the mutated monomeric version of PLB in dodecylphosphocholine micelles [38]. Figure 3 shows a well-resolved HSQC solution NMR spectrum of uniformly ^{15}N-labeled AFA-PLB with assignments. The spectrum was kindly provided by Dr. Gianluigi Veglia. The structure on the left hand side of Figure 1 illustrates the "L-shape" structure of AFA-PLB inserted into a phospholipid bilayer.

Additional solid-state NMR research conducted on site-specific ^{15}N-labeled AFA-PLB has shown that the monomeric form of PLB has one component that is nearly transmembrane (hydrophobic segment, residues 31–52) and the amphipathic segment lies on the surface of the membrane [51,52]. The solid-state NMR data coupled with molecular dynamic simulations estimates that the monomeric transmembrane helix makes an approximate 10° angle with respect to the bilayer normal.

NMR and EPR structural dynamic studies have indicated that PLB involves functionally important transitions among potentially multiple structural states and that the structure of PLB is affected by its phosphorylation and its interaction with Ca-ATPase [49,51]. Primarily, the Thomas lab has studied backbone dynamics with EPR spectroscopy of specific-site 2,2,6,6,-tetramethyl-piperidine-N-oxyl-4-amino-4-carboxylic acid (TOAC) attached at positions 0, 11, and 24 in the cytoplasmic domain or at position 46 in the transmembrane domain of AFA-PLB. The EPR spectrum of the AFA-PLB with a TOAC label at position 46 reveals a single broad component, indicating an ordered transmembrane helix. However, the cytoplasmic labels reveal two separate spectral EPR components. One of the components is disordered and nearly isotropic with dynamic motion on the ns timescale, while the second spectral component is more ordered and undergoing slower motion on the EPR timescale. The results indicate that the cytoplasmic domain of the AFA-PLB monomer is in dynamic equilibrium between an ordered confirmation (buried within the membrane) and a motionally dynamic form that is detached from the membrane and poised to interact with its regulatory target [50]. A model of AFA-PLB between these two states can be seen by examining the two structural

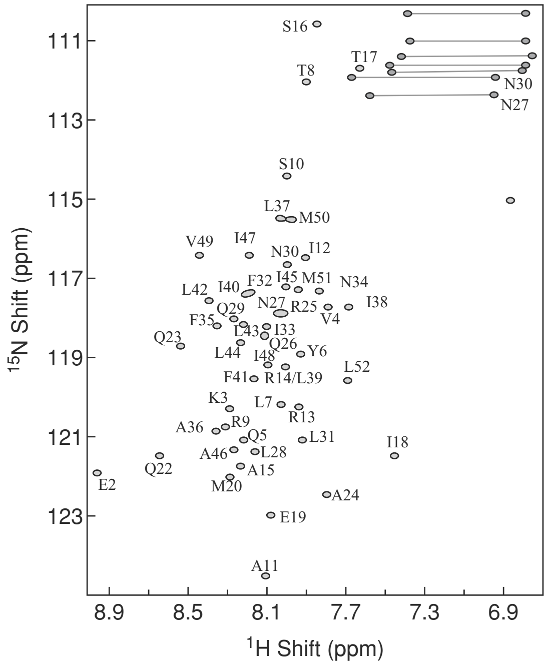

Fig. 3. HSQC solution NMR spectrum of ^{15}N-labeled AFA-PLB in dodecylphosphocholine micelles. The NMR spectrum was kindly provided by Dr. Gianluigi Veglia.

configurations of PLB located within Figure 1. This TOAC EPR spin-label method provides excellent backbone dynamic information similar to ^{15}N amide solid-state NMR dynamic studies.

Future NMR and EPR spectroscopic studies that probe the structural and dynamic properties of both the pentameric and monomeric forms of PLB and how they interact with SERCA and PKA are needed to help to better understand regulatory function.

Acknowledgments

GAL would like to acknowledge his research group and Professor Gianluigi Veglia for all of their help in preparing this review chapter. This work was supported by a National Science Foundation CAREER Award (CDE-0133433), an NIH Grant (GM60259-01), and an American Heart Association Scientist Development Grant (0130396). The 500 MHz Wide bore NMR Spectrometer was obtained from NSF Grant (#10116333).

NMR Studies of the Interactions Between Ligands and Membrane-Embedded Receptors: New Methods for Drug Discovery

David A. Middleton
Faculty of Life Sciences, University of Manchester, Sackville Street, P.O. Box 88, Manchester M60 1QD, UK

Abbreviations: REDOR, rotational echo double resonance; CP-MAS, cross-polarization magic-angle spinning; et-NOESY, exchange transferred nuclear Overhauser effect spectroscopy; STD, saturation transfer difference spectroscopy; DR, dipolar recoupling; waterLOGSY, water-ligand observation by gradient spectroscopy; MAOSS, magic angle oriented sample spinning; bR, bacteriorhodopsin; nAChR, nicotinic acetylcholine receptor.

Introduction

The interactions between ligands and their receptors lie at the heart of many of the complex cascades of cellular events responsible for life and death, disease and therapy. The outcomes of these events depend upon the selectivity and affinity of natural agonists, antagonists, modulators, and inhibitors for their physiological targets, since it is only through specific interactions that the correct biological signals are generated and processed. Similarly, the therapeutic/toxicological ratios of synthetic drug compounds often hinge on their fidelity for a specific receptor sub-type against a background of closely related receptors. Recent technological advances in drug discovery have led to the wide availability of sophisticated methods for identifying natural or synthetic ligands of specific receptors with high throughput and sensitivity. When these methods are combined with combinatorial chemistry vast numbers of compounds can be screened for ligand activity in a fraction of the time taken 20 years ago [1].

Despite this level of progress, there remains a demand for lower-throughput techniques which can examine receptor–ligand interactions beyond the phenomenological and provide mechanistic information at the molecular level. The NMR community, in particular, has risen to the challenge presented by the revolution in drug discovery and the past decade has witnessed the arrival of many exciting new methods. The versatility of NMR makes it an attractive technique capable of addressing many aspects of drug discovery from screening weak interactions of ligands through to the structural assessment of receptor–ligand complexes.

Over half of the targets for currently marketed drugs are proteins that function within the cell membrane [2] and the pipeline of drugs in clinical development suggests that this proportion will rise significantly in the future. There is, therefore, a compelling case for obtaining molecular level details about how ligands interact with membrane-embedded receptors. Nevertheless, such information remains scarce owing to the insoluble nature of proteins in a lipid membrane environment, which has hampered crystallographic studies and, until recently, has precluded analysis by NMR. Recent progress in NMR hardware and methodology development has been astonishing, however, and the first details of how ligands interact with their receptors in a membrane environment are now being revealed to resolution unattainable by diffraction techniques.

This review will give a brief account of some of the recent developments in NMR in both the solid-state and solution-state and comment on future prospects of these developments for drug discovery.

Choice of Technique

The majority of the physiological and pharmacological ligands of relevance here are water-soluble small molecules that bind reversibly to the receptor embedded in what is effectively a solid support. The affinity of the ligand for the receptor is defined by the on-rate k_{on} and off-rate k_{off} of the ligand (Figure 1). If the association of a ligand with its receptor is diffusion controlled, k_{on} is typically on the order of 10^7 M^{-1} s^{-1} and the dissociation constant ($K_\text{D} = k_{\text{off}}/k_{\text{on}}$) of the receptor–ligand complex is dependent largely on the off-rate. Low-affinity interactions ($K_\text{D} \geq 1$ mM) therefore usually involve rapid dissociation of the ligand from the binding site and the ligands are classified as weak. In such cases, solution NMR methods are advantageous because the ligand can be observed in solution whilst exploiting various physical properties of the ligand that are modulated by its transitory

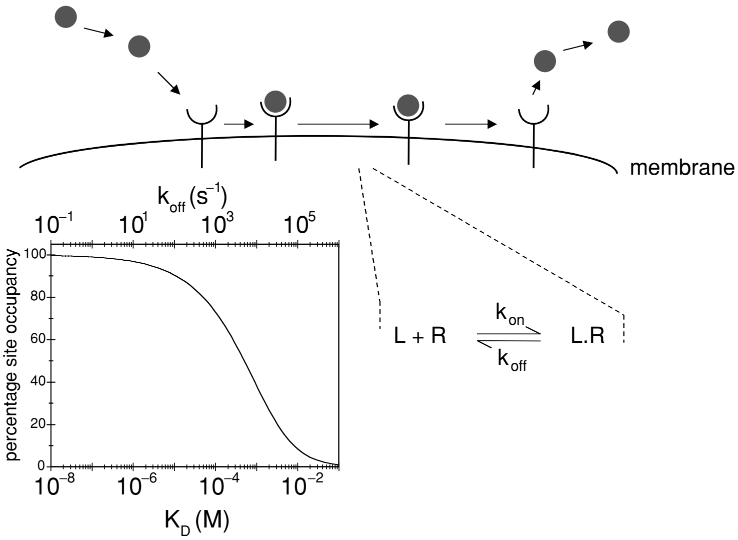

Fig. 1. A schematic representation of the time-course of the interaction between a ligand L (red circles) and a membrane-embedded receptor R (cups). The dissociation constant for the receptor–ligand complex K_D is given by the ratio of the on-rate and off-rate, k_{off}/k_{on}. The graph shows the percentage of ligand molecules that are predicted to be bound to a receptor at equilibrium over a range of K_D values, when the ligand and receptor are present in equimolar concentrations. The off-rate corresponding to each K_D value is shown on the upper axis, based on the assumption that association is diffusion limited with an on-rate of 10^7 M^{-1} s^{-1}.

association with the receptor (e.g. transferred NOEs, relaxation, or saturation). A corollary of this approach, which is implicit in the graph in Figure 1, is that the ligand must be present in large excess over the receptor in order to saturate the available binding sites. Such a large excess of ligand may promote non-specific binding, which can obscure the pharmacologically relevant interactions or lead to misinterpretation. Appropriate control experiments, usually involving competitive displacement, must therefore be designed to eliminate these effects.

Higher affinity ligands ($K_D \leq 10$ μM) usually undergo slower dissociation from their targets (Figure 1) and cannot be detected directly by conventional solution NMR methods because the resonance lines are broadened as a result of the slow tumbling of the membrane assembly. In this motional regime, solid-state NMR is a more appropriate technique for detecting and characterizing the bound ligand directly. The graph in Figure 1 implies that, by adding an equimolar concentration of high-affinity ligand to a receptor, over 90% of the ligand will be bound. The sample can be frozen to eliminate interference from molecular dynamics and very precise structural data can be extracted with appropriate solid-state NMR techniques.

Solution NMR Methods

In recent years a variety of ^{1}H NMR methods have been developed for screening weak ligand interactions with receptors as well as for determining sites of interaction, identifying ligands from compound mixtures, mapping interfacial sites and providing structural contraints [3]. Some of the most notable amongst these are saturation transfer difference (STD) spectroscopy, water-ligand observations with gradient spectroscopy (waterLOGSY), and transferred NOE methods. In the STD approach, the ^{1}H magnetization from the protein target is irradiated at low power by a shaped pulse at a frequency well away from the ligand resonance. The saturation effect is, in turn, transferred to a ligand for the duration that it is associated with the binding site within the receptor. For a ligand in fast exchange between free and bound environments, the saturation is carried with the ligand when it dissociates from the receptor into the free state. If two spectra are obtained, one with and one without saturating pulses, the peaks from the ligand can be identified from the complex spectrum of the mixture [4]. This approach has been exploited for the analysis of carbohydrates to provide details of off-rates and binding constants, map the sites of ligands forming the interface with the receptor and identify ligands from mixtures of compounds [3]. The waterLOGSY technique is similar in concept but relies on the use of water to detect receptor-bound ligands, by generating negative water-ligand NOEs after saturating the water proton magnetization [5]. The bound conformations of fast exchanging ligands (i.e. $k_{off} > 1/T_1$) have been explored using exchange-transferred NOE (et-NOESY) experiments [6]. The strong NOES that develop when the ligand is bound to the receptor are transferred with the ligand to the free state from where they are measured.

The experiments described above are valid only when the ligands bind weakly to the receptor and can be observed in solution. In the case of more tightly bound ligands, dissociation constants have been estimated indirectly with the development of relaxation based NMR experiments that measure the relaxation rates of a standard ligand of known affinity for a receptor before and after displacement with the ligand of interest [7].

The applications of these and other solution NMR methods to membrane embedded proteins have so far been limited to a few examples. Weak interactions between a cyclic peptide inhibitor of the membrane-spanning protein integrin incorporated into liposomes and living cells have been detected using STD NMR [8] and et-NOESY [9]. The latter technique was also used to determine the conformation of ligands bound to the muscarinic acetylcholine receptor and showed that the bound conformations of muscarine and methacholine were different from their conformations in solution [10]. The full potential of these methods remains to be tested, however, and it is anticipated that many more examples of applications to membrane receptor–ligand interactions will appear in the literature.

Solid-State NMR Methods

Solid-state NMR embraces a collection of diverse methods that take advantage of the spatial and dynamic properties of biomembranes to extract information about structure and dynamics. Such methods may exploit the positions of the spectral lines arising from the incomplete averaging of anisotropic interactions (chemical shielding, dipole–dipole, quadrupolar) within the membrane components. Alternatively, the technique of cross-polarization magic-angle spinning (CP-MAS) is used to eliminate or reduce the effects of restricted anisotropic motions and susceptibility effects in biomembranes to gain high-resolution spectra from which site-specific information can be gained with the appropriate pulse sequences.

Sample Requirements

In the analysis of biomembrane samples by CP-MAS NMR methods it is generally desirable that the receptor is fully functional and present in its native membrane or isolated and incorporated into a new lipid bilayer [11]. In both cases, the ligand is titrated into the hydrated membranes and the NMR sample is prepared as a gelatinous pellet by centrifugation to maximize the receptor density that can be loaded into the sample spinner. The receptor purity (and concentration) that can be achieved is often the key factor in determining which experiments are feasible. For example, Spooner *et al.* (see below) have reported various CP-MAS studies of the interactions between bacterial transport proteins and their natural substrates in native membranes in which the receptor of interest represents less than 60%, and as little as 20%, of the total membrane protein. Such studies were possible because of the excellent selectivity of the substrates for their receptors and the high expression levels of protein achieved, which alleviated the requirement for difficult and inefficient purification procedures. In cases where the ligands are less specific or the protein of interest is in low abundance, however, it may be desirable to manipulate the receptor to achieve a higher level of purity.

An alternative approach to CP-MAS involves measuring the orientation of anisotropic interactions (dipolar, chemical shielding, and quadrupolar) in the magnetic field under static (i.e. non-rotating) conditions to determine the alignment of bonds, functional groups or domains of the ligand relative to the receptor. Here, the hydrated membrane samples are laid down onto glass plates of dimensions appropriate for the NMR radiofrequency coil in such a way that the membrane components adopt a uniaxial alignment with respect to the magnetic field. Various methods for obtaining membrane alignment have been proposed, but most have achieved limited success in aligning receptors in native or reconstituted membranes. One apparently successful approach is the isopotential spin-dry ultracentrifugation technique, which produces good alignment whilst preserving biological integrity of the membrane sample [12].

A historical limitation of solid-state NMR has been its inability to exploit protons directly because the strong couplings between them lead to severe line broadening. Although new measures are being taken to eliminate proton line broadening, the observation of naturally rare nuclei (^{13}C, ^{15}N, ^{2}H, ^{19}F) in isotope enriched samples remains central to most biological solid-state NMR experiments.

Detection of Ligand Binding by CP-MAS NMR

In conventional solid-state CP-MAS NMR, Hartmann-Hahn cross-polarization serves to enhance the signal from the observed low-gamma nucleus and reduce recycle times, by transferring magnetization from protons which have higher sensitivity and more favorable T_1 relaxation times. Spooner *et al.* [13] demonstrated an alternative use for CP-MAS in which interactions between ^{13}C labeled L-glucose and the bacterial sugar transporter GalP could be detected by Hartmann-Hahn cross-polarization in partially purified *E. coli* membrane samples at 4 °C. Using CP-MAS it is possible to discriminate between free and bound substrate molecules because of the differences in the motional characteristics of substrate in the two environments. The CP-MAS method detects ligand binding only when the membrane sample is in a fluid state, allowing weak receptor–ligand interactions to be characterized under physiologically relevant conditions that are intractable to other methods of analysis. This development provided the incentive for further studies in which bacterial transporters were nitroxide spin-labeled at unique

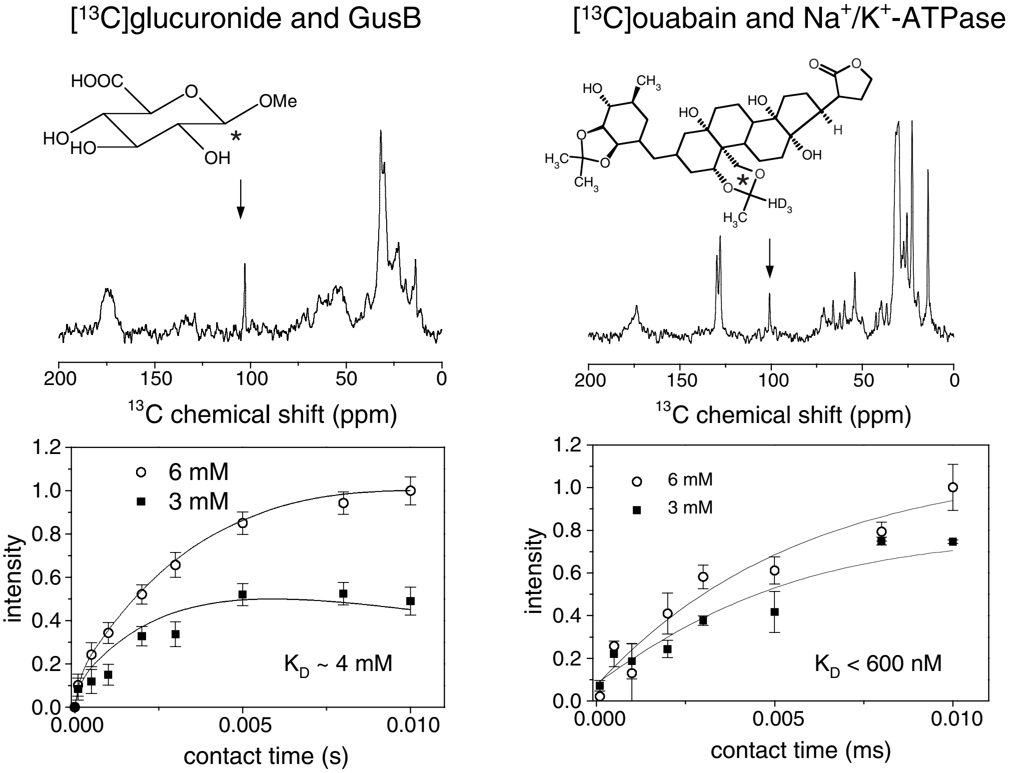

Fig. 2. A demonstration of how ^{13}C CP-MAS NMR is used to estimate the affinities of ligands for membrane-embedded receptors. Examples of spectra (top) and cross-polarization build-up curves (bottom) are shown for two cases in which the ligands have different affinities for their receptors. The spectrum and peak intensities for [^{13}C]methylglucuronide interacting with GusB in *E. coli* membranes is shown on the left. On the right are shown data for [^{13}C]acetonidoouabain interacting with Na^+/K^+-ATPase. In the graphs, the experimental peak intensity values at two ligand concentrations are shown as circles and squares and the lines represent the curves of best fit, corresponding to the K_D values shown.

cysteine residues in order to locate residues close to the substrate binding site. It was shown that the strong magnetic dipole of the electron spin broadened the peaks from the bound substrates and permitted distances between the labeled residues and the bound ligand to be estimated [14–15].

Recently, the CP-MAS approach has been extended to provide quantitative information about ligand binding affinities for receptors in fluid membranes. In this new development, peak intensities from different concentrations of an isotope labeled ligand in the presence of a membrane receptor are measured at increasing cross-polarization contact times [16]. The build up of peak intensities at different ligand concentrations is highly sensitive to binding affinity (Figure 2) and the experimental data are compared with simulated curves to extract values of K_D. One advantage of this method is that the K_D value can be checked independently by measuring the peak intensities after displacement of the labeled ligand by titration of unlabeled ligand. Another attractive feature of this method is that the cross-polarization procedure can be "tuned" to eliminate the signal from non-specifically bound ligand. To date, K_D values have been measured for the interactions of glucuronide sugars with the bacterial transport protein GusB [16], ouabain analogs with the Na^+/K^+-ATPase [17] (Figure 2) and the antidepressant drug trifluoperazine (TFP) with gastric H^+/K^+-ATPase [18]. In the latter work, the intrinsic ^{19}F signal of TFP was exploited to measure ligand binding affinities.

All of the examples highlighted above rely upon being able to resolve the peaks for the labeled ligand from the natural abundance signals from the lipids and protein. In most of the published experiments on ^{13}C labeled substrates of bacterial transporters, it is by design that the peaks from the ligand lie in a region of the spectrum (90–110 ppm) uncontaminated by background signal. To extend the applicability of the CP-MAS method beyond this rather limited situation to the many cases where the peaks from the ligand and membrane inevitably overlap, it is desirable to remove the background signal from the membranes. One recent approach has been to express a bacterial protein in ^{12}C-enriched media, thereby minimizing the background signal from ^{13}C [19]. This is a rather expensive strategy, however, that will be most suitable in cases where high expression levels of protein can be achieved.

Structural Analysis of Ligands

In the solid-state, structural information comes in the form of internuclear distances, torsional angles and bond orientations relative to a fixed reference frame. The data is extracted using variants of the CP-MAS experiment, from uniformly aligned membranes or using a combination of both methods called magic angle oriented sample spinning (MAOSS) [20]. In the case of CP-MAS, structural measurements rely upon a variety of dipolar recoupling (DR) experiments, which manipulate the nuclear spin systems to restore the weak, but structurally informative, dipolar interactions that are otherwise removed by sample rotation [21]. Many such experiments have been devised including rotational resonance NMR, which restores and measures homonuclear couplings, REDOR for heteronuclear couplings and a range of experiments to measure H–C–C–H, H–C–N–H, and N–C–C–N torsional angles [22].

Early applications of solid-state NMR to membrane protein–ligand interactions focused on the structure and orientation of the retinal chromophore within the proton pump bacteriorhodopsin (bR) of the bacterium *H. salarium*. Rotational resonance experiments on double ^{13}C labeled retinal in bR [23] confirmed the torsional angle defining the relative orientations of the β-ionone ring and the polyene chain. Deuterium NMR experiments on bR in aligned membranes revealed changes in quadrupolar tensor orientations for ^{2}H labels in a methyl group (position 19) of the retinal polyene chain after photoexcitation of bR to the M-state, which was consistent with isomerization about the C13–C14 double bond [24]. Further measurements of angles along the polyene chain using DR CP-MAS methods have resolved a slightly distorted conformation of retinal in the binding pocket and resolved ambiguities about bond configurations in the various photointermediates that were not evident from the crystal structures [25]. Recently, sophisticated multidimensional DR experiments have been devised to examine dipolar contacts between the retinal Schiff base and residues lining the binding pocket of bR [26].

Similar methods have been applied to examine the structure of the retinal chromophore in the G-protein coupled receptor (GPCR) rhodopsin during the photocycle responsible for visual signal transduction. Studies of the orientation of retinal using MAOSS revealed significant changes in the orientation of the β-ionone ring in the first stages of the photoexcitation cycle before major protein conformational changes occur [27]. More recently, Smith and co-workers used two-dimensional dipolar-assisted rotational resonance experiments to identify couplings between ^{13}C labels in retinal and labels in Tyr, Gly, Ser, and Thr residues around the binding pocket [28]. It was shown that the transition of rhodopsin to the M_{II} state involves the disruption of helix interactions in the transmembrane domain as retinal moves some 5 Å toward helix 5 and the C20 methyl group of retinal moves toward extracellular loop 2.

The studies of retinal in bR and rhodopsin are excellent demonstrations of how solid-state NMR is ideally suited to filling in details about ligand structure and orientation that are beyond the resolution of available crystal structures. A similar case is the interaction of acetylcholine with the nicotinic acetylcholine receptor (nAChR), the ligand-gated cation channel that mediates synaptic transmission. The highest resolution structure of nAChR is at about 4 Å and inadequate to visualize the positions and structure of the natural ligand in the binding sites. Solid-state NMR studies of a derivative of the natural ligand, bromoacetylcholine, bound covalently to the receptor purified from *torpedo* electroplax have helped to provide clues about how the ligand interacts with the binding pocket [reviewed in Ref. 29]. Deuterium NMR experiments on uniformly aligned membranes containing [^{2}H]bromoacetylcholine indicated that the ligand is positioned in the binding site with the quaternary ammonium group facing outwards and oriented at about 40° with respect to the membrane normal. Further, CP-MAS spectra of the bound ^{13}C labeled ligand showed an up-field perturbation in chemical shift relative to the free ligand in solution which was consistent with a ring current effect of aromatic residues that are believed to line the binding pocket.

The examples described above all benefit from the availability of receptor crystal structures of varying resolution with which to combine NMR measurements to draw conclusions about ligand binding. The following section will show examples of the less favorable, but unfortunately common, situation in which mechanistic information about ligand binding is obtained by solid-state NMR methods in the absence of any crystallographic coordinates for the receptor.

A Case Study: Solid-State NMR Investigations of Ion Pump Inhibitors

The P-type ATPases are a class of large (>100 kDa) membrane-embedded enzymes that are found in higher eukaryotic organisms and some bacteria. The specific functions of these enzymes vary from cell to cell, but all are related by their ability to couple ATP hydrolysis to vectorial ionic transport across the cell membrane [33]. Ionic transport may be electroneutral (i.e. translocation of charge-equivalent ions) or electrogenic (establishing a transmembrane potential) and is coupled to conformational changes in the enzymes that reveal, in turn, high-affinity sites for ions on opposite sides of the membrane. Two members of this family are well-established targets for drugs. The cardiac Na^+/K^+-ATPase controls the relaxation–contraction cycle of the heart and is the receptor for high-affinity cardiac glycoside inhibitors, collectively known as digitalis, which have been used for over 200 years in the treatment of congestive heart failure. The gastric H^+/K^+-ATPase is a proton pump responsible for secretion of acid into gastric glands, and is a target for drugs in the treatment of gastric ulcer disease. Reversible inhibitors of the proton pump include the aryl-substituted imidazopyridines, which are reasonably potent ($IC_{50} \sim 1\ \mu M$) but have undesirable toxicological properties.

Solid-state NMR experiments have revealed the first details about how these inhibitors interact with their targets despite high-resolution structures being unavailable for either of the two proteins. Information about the bound conformation and orientation of these drugs has given clues about how they achieve selectivity for their specific targets. Selectivity is a crucial property of these inhibitors because promiscuous binding to other ATPases could have catastrophic consequences for patients treated with these or related drugs. The NMR experiments form a component of the broader approach summarized in Figure 3 for the specific example of proton pump inhibitors. First, aryl-substituted imidazopyridines were isotope labeled at various sites with ^{13}C and ^{19}F and titrated into gastric membranes enriched in H^+/K^+-ATPase. Measurements of heteronuclear and homonuclear dipolar couplings using REDOR and rotational resonance NMR [30,31] have

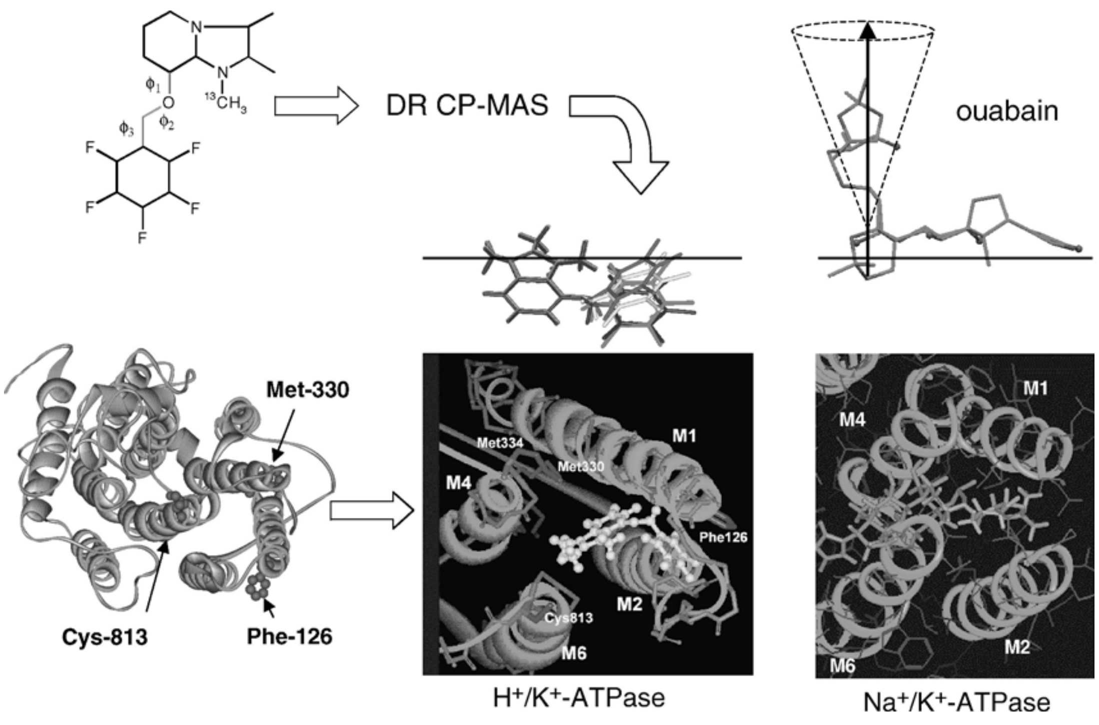

Fig. 3. An overview of the strategy for modeling an aryl-substituted imidazopyridine inhibitor in its binding site within the H^+/K^+-ATPase. The details of the strategy are described in the text. The model is shown alongside a model of ouabain in its site of action within the Na^+/K^+-ATPase, derived by a similar approach. (See also Plate 36 on page XXXI in the Color Plate Section.)

provided structural constraints defining the relative orientations of the aryl and imidazopyridine rings within the site of action, showing that the molecule is distorted from a planar configuration and exhibits a slightly curved profile.

It has been possible to produce a model describing the location of the inhibitor within the luminal face of H^+/K^+-ATPase with the aid of published site directed mutagenesis (SDM) data and coordinates from the crystal structure of the homologous Ca^{2+}-ATPase. The sequence of H^+/K^+-ATPase was threaded onto the structure of the Ca^{2+}-ATPase and the spatial disposition of residues in the proton pump, known from SDM studies to be implicated in drug binding, were predicted. The inhibitor in its curved conformation was found to fit convincingly into a putative binding site bounded by residues and beneath the luminal surface of the protein (Figure 3). By contrast, similar solid-state NMR measurements of $^{13}C/^{19}F$ labeled digitalis analogs have suggested that the recognition site of the Na^+/K^+-ATPase lies at the membrane surface [32] with the functionally-redundant sugar group of ouabain facing away from the protein (Figure 3). These distinct binding characteristics may hold the clue as to why the two inhibitors have such remarkable selectivity for these closely related proteins.

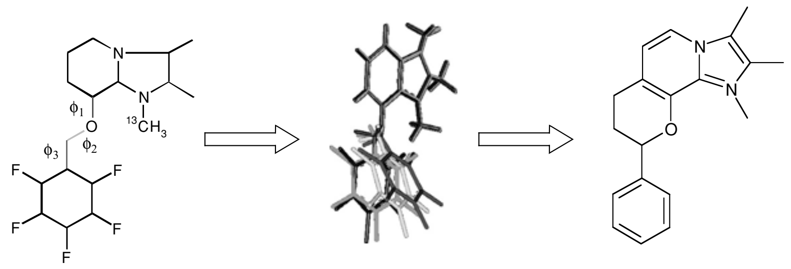
Future Prospects

The versatility of NMR in the characterization of receptor–ligand interactions, when viewed alongside the therapeutic importance of membrane-embedded proteins, suggests that this technique will continue to play a valuable role in drug discovery. This optimistic prognosis will only be realized, however, if developments in NMR hardware and methodology keep apace with the breathtaking progress seen in other aspects of the drug discovery process. With this in mind, the author speculates below on how NMR may continue to provide new and groundbreaking information about membrane receptor–ligand interactions.

(i) Solution state NMR remains underdeveloped as a technique for characterizing receptor–ligand interactions in biomembranes, yet many of the experiments are in place and simply await validation with the appropriate membrane samples. There is a clear opportunity to take advantage of the tremendous improvements in the sensitivity of solution NMR instrumentation in order to compensate for the often low quantities of membrane receptors that can be obtained.

(ii) The examples of work on bR, rhodopsin, and the gastric proton pump inhibitors given in this brief review are good demonstrations of how solid-state NMR can provide precise structural constraints for ligands bound to receptors. If such information were obtained for current drug targets, this could help to guide medicinal chemistry toward structures with higher affinity or selectivity for their receptors. This approach has already been used with some success in the case of the aryl-substituted imidazopyridine inhibitors of the gastric proton pump (Figure 4, bottom). By chemically restraining the aryl group in a configuration close to that seen for the flexible parent inhibitor in the binding site, the new compound inhibited the pump with almost 100-fold higher potency.

(iii) The major proportion of membrane-embedded drug targets are GPCRs [2], but NMR studies of their interactions with ligands have so far been limited to a few well-chosen cases. The NMR studies of retinal in the GPCR rhodopsin have shown that structural details can be obtained with high precision, but rhodopsin is a unique case amongst this class of proteins and the retinal chromophore is not typical of a GPCR agonist or antagonist of interest in pharmaceutical research. Recently Baldus and co-workers used



flexible, IC_{50} = 10 µM NMR conformation Constrained, IC_{50} = 100 nM

Fig. 4. An example of how the structure of a receptor-bound ligand can provide information of relevance to drug discovery (refer to the text for details). (See also Plate 37 on page XXXII in the Color Plate Section.)

solid-state NMR to solve the structure of a fragment of the neurotensin peptide when bound to its receptor [34]. This approach is potentially very useful, as determining the pharmacophore structure of a natural peptide ligand could help to predict small molecule antagonists.

In all three cases above, the future role of NMR in the analysis of membrane receptor–ligand interactions will be intimately linked to improvements in the methods for producing useful quantities of functional receptors in a suitable form for NMR studies.

Photosynthetic Antennae and Reaction Centers

H.J.M. de Groot
Leiden Institute of Chemistry, Gorlaeus Laboratories, NL2300 RA Leiden, The Netherlands

Introduction

In photosynthesis, light energy conversion proceeds in two steps [1]. First excitons are generated in antenna systems and subsequently charge separation takes place in reaction centers (RCs, Figure 1). To gain insight into the structural and functional properties of such active elements in photosynthesis, solid-state NMR is increasingly important. Here a number of examples of recent investigations are summarized, first structure–function studies of antennae and RCs, and second structure determination, including methodology development. To resolve molecular electron pumping mechanisms in bacterial RCs and to study the electronic structure of light-harvesting (LH) proteins, both global and specific assays of cofactors and protein side chains have been performed. Novel techniques allow a determination of structural models for self-assembled chlorophyll preparations *in vitro* and for the natural chlorosome antenna system. Finally, it is possible to perform sequence specific assignments of uniformly labeled complexes and to observe intermediate states in light-triggered reactions, produced by illumination of frozen samples in the spectrometer.

Structure–Function Studies of Antenna Systems and RCs

The electronic ground states of the bacteriochlorophyll (BChl) *a* type B800 and type B850 (BChl molecules absorbing around 800 or 850 nm) in the LH2 complex of *Rhodopseudomonas acidophila* strain 10050 have recently been characterized by magic angle spinning (MAS) dipolar ^{13}C–^{13}C correlation NMR spectroscopy [2]. Extensive sets of isotropic ^{13}C NMR chemical shifts were obtained for the BChl in the LH2. Density functional theory calculations were performed to analyze the data in detail. By correction for the ring current shifts, the ^{13}C shift effects due to the interactions with the protein matrix can be resolved. The shift effects for the B800 and B850 are similar, and are attributed to a weak nonlinear dielectric response of the protein environment to the cofactor binding, in contrast with local effects due to interaction with specific amino acid (AA) residues. In addition, the polarization of the electronic ground states induced by the protein environment is comparable for both cofactors and corresponds with a red shift of $\sim$30 nm relative to the monomeric BChl in solution. According to the NMR, the electronic coupling between the B850 cofactors due to macrocycle overlap is the predominant mechanism responsible for the color difference between the B800 and B850 cofactors.

In another study, photosynthetic RCs of *Rhodobacter sphaeroides* R26 were reconstituted at the Q_A site with ubiquinone-10, selectively ^{13}C-enriched on positions 1, 2, 3, 4, and 3-Me [3]. RCs dispersed in LDAO detergent were studied with ^{13}C CP/MAS NMR spectroscopy at temperatures between 180 and 240 K, while RCs precipitated by removal of the detergent were investigated at ambient temperature and at temperatures down to 180 K. Electrostatic charge differences in Q_A induced by polarization from the protein are small, less than 0.02 electronic equivalent for any of the labeled positions. The 4-carbonyl signal indicates a rigid environment for this functionality, which contrasts with previous studies with FTIR that provided evidence for a strong perturbation and possibly dynamic disorder of this quinone functionality [4]. The Q_A site is slightly heterogeneous on the scale of the NMR as the observed line widths of the labels are between 150 and 300 Hz and inhomogeneous broadening is observed for the signals of positions 1, 2, and 3 upon cooling. For the 4-carbonyl only at sample temperatures below -255 K, a CP/MAS response can be observed at 183 ppm. The data indicate a difference between the dark adapted state monitored by NMR and the light adapted form that is probed by optical investigations.

Various ^{15}N and ^{13}C CP/MAS NMR methods have been used to analyze BChl–histidine interactions and the electronic structure of histidine residues in RCs and antenna complexes [5,6]. For the LH2 complex of *R. acidophila*, the histidines were selectively labeled at both or one of the two nitrogen sites of the imidazole ring. The resonances of histidine nitrogens that are interacting with B850 BChl *a* have been assigned. Specific ^{15}N labeling confirmed that it is the τ-nitrogen of α-His30 and β-His31 that are ligated to Mg^{2+} of BChl cofactors. The π-nitrogens of these Mg^{2+}-bound histidines were

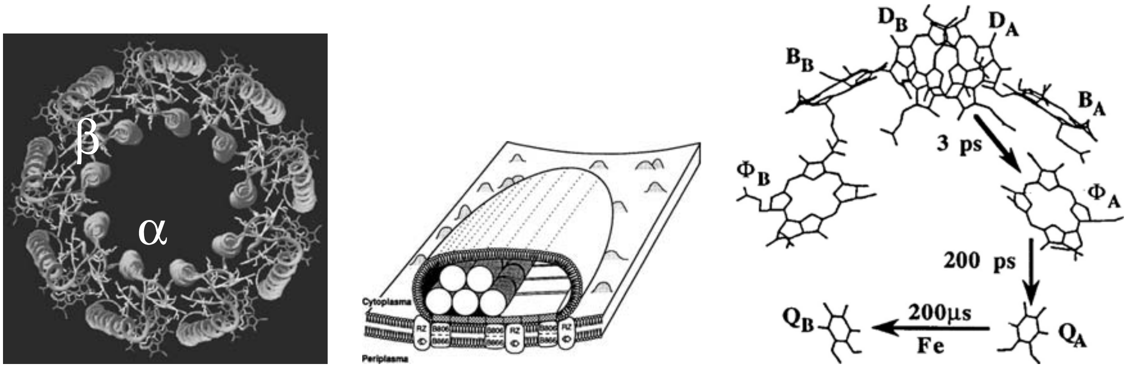

Fig. 1. Self-organized photosynthetic complexes, which play key roles in the photosynthetic process. *Left*: Top view on the LH2 LH membrane protein complex. This 9-mer contains two α-helical segments in every monomeric unit. The transmembrane helices embed the BChl that performs the LH function. *Center*: Chlorosomes are oblong bodies inside a protein free antenna system that currently serves as one possible paradigm for light concentration in artificial photosynthesis research. With solid-state NMR it was possible to show that a chlorosome antenna contains tubular bilayers of self-aggregated BChl. *Right*: Photo excitations are transferred to a RC, which is brought into an excited state. Electron transport (ET) occurs from the special pair (D_A/D_B) and via two additional chlorophyll molecules (B_A/B_B), to a pheophytin (Φ_A), and finally the quinones (Q_A, Q_B) as indicated by the arrows. (See also Plate 38 on page XXXII in the Color Plate Section.)

found to be protonated and may be involved in hydrogen bond interactions. Comparison of the 2-D MAS NMR homonuclear (^{13}C–^{13}C) dipolar correlation spectrum of [^{13}C,^{15}N]-histidines in the LH2 complex with model systems in the solid state reveals two different classes of electronic structures for the histidines in the LH2. In terms of the ^{13}C isotropic shifts, one corresponds to the neutral form of histidine and the other resembles a positively charged histidine species [5,7]. ^{15}N–^{13}C double-CP/MAS NMR data provide evidence that the electronic structure of the histidines in the neutral BChl *a*/His complexes resembles the positive charge character form. While the isotropic shift of the ^{15}N ligated to the Mg^{2+} confirms a partial positive charge transfer, its anisotropy is essentially of the lone pair type. This provides evidence that the hybridization structure corresponding to the neutral form of the imidazole is capable of "buffering" a significant amount of positive charge.

To study the active chlorophyll and pheophytin cofactors involved in the primary processes in photosynthesis, and their environment in the protein, photochemically induced dynamic nuclear polarization (photo-CIDNP) is the method of choice. The unmatched sensitivity of the photo-CIDNP allows the detection of signals at natural abundance of the ^{13}C [8]. Recently we have reported photo-CIDNP for the RCs of plant photosystems I and II (PS I, II) [9,10]. The light-enhanced NMR provides information on the electronic structure of the primary electron donors. The radical cation response from the bacterial RC shows at least four emissive center bands, indicating a symmetric spin density distribution over the entire BChl macrocycle. In contrast, the data for the PS II reveal a pronounced asymmetry of the electronic spin density distribution within the $P680^{\bullet +}$ (chlorophyll molecules absorbing around 680 nm). PS II shows only a single broad and intense emissive signal and the spin density appears shifted compared to monomeric chlorophyll in solution. It leads to a first hypothesis as to how the planet can provide itself with the chemical potential to split water and generate an oxygen atmosphere using the Chl *a* macroaromatic cycle: a local electrostatic field can polarize the electronic charge and associated spin density and increase the redox potential of P680 by stabilizing the highest occupied molecular orbital, without a major change of color.

In addition, RCs of wild-type *R. sphaeroides* were selectively ^{13}C-isotope labeled in BChl and bacteriopheophytin (Bphe), and ^{13}C solid-state CP/MAS NMR and photo-CIDNP were used to provide insight into the electronic structure of the primary electron donor and acceptor on the atomic and molecular levels [11,12]. The first 2-D photo-CIDNP ^{13}C–^{13}C solid-state MAS NMR spectra reveal that negative polarization of the two BChl rings of the primary donor is involved in ground state tuning of the oxidation potential of these cofactors in the protein via local electrostatic interactions (Figure 2). In particular, the ^{13}C shifts show moderate differences in the electronic structure between the two BChl molecules of the special pair in the electronic ground state, which can be attributed to hydrogen bonding of one of the BChl molecules. The major fraction of the electron spin density is strongly delocalized over the two BChl molecules of the

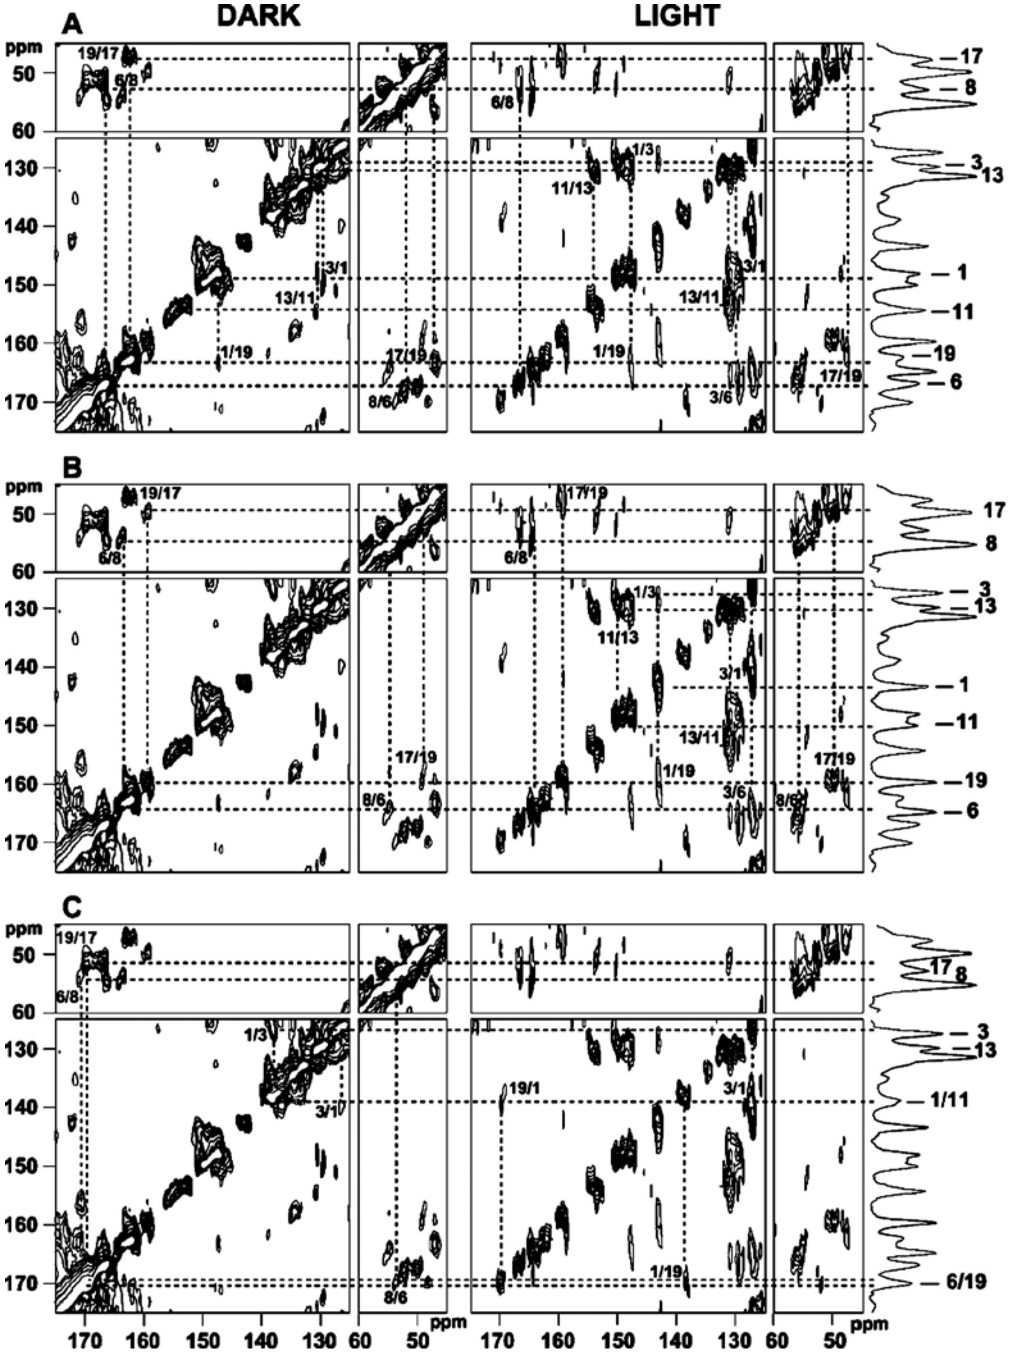

Fig. 2. Contour plot of the "dark" 2-D RFDR CP/MAS spectrum (left) and the 2-D RFDR photo-CIDNP spectrum (right) of RCs containing ^{13}C labels in the cofactors. The data were recorded at ~220 K with 12 and 5 kHz spinning frequencies and ~5 ms RFDR mixing. The assignments of the correlations of the two BChl of the special pair (A, B), and the BPhe (C) are indicated with the dashed lines.

special pair and the photochemically active BPhe. A small fraction of the π-spin density is distributed over a fourth component, which is assigned to the accessory BChl. Comparison of the photo-CIDNP data with "dark" NMR spectra obtained in ultrahigh field indicates that putative structural changes of the special pair during the primary process of photosynthesis should be reversed upon charge recombination on the timescale of the photo-CIDNP experiment.

MAS NMR Structure Determination: Chlorosomes and LH2

The structure of photosynthetic membrane proteins and other membrane associated assemblies represents a solid matrix that is essential to the mechanism of biological function. In recent years MAS NMR has been used to gain in-depth understanding the structure of photosynthetic energy conversion systems.

In photosynthesis, light is collected by LH antenna complexes that generally contain 50–200 chlorophylls in well-defined membrane bound protein structures. Photosynthetic green sulfur bacteria, however, contain chlorosomes (Figure 1). These are unique antenna systems among photosynthetic organisms since their LH pigments are organized without proteins. Already at an early stage the chlorosome of the green bacterium *Chlorobium tepidum* was studied by 1-D MAS NMR methods [13]. With 2-D correlation spectroscopy, it was shown that the BChl are self-organized into supramolecular aggregates by coordinative bonding and π–π stacking interactions [14]. Homo- and heteronuclear MAS NMR, along with comparison of BChls with different side chains lead to a model for the structure with two concentric tubes for the aggregated BChl in chlorosomes (Figure 3) [15]. Heteronuclear 2-D and 3-D MAS NMR dipolar correlation spectroscopy was applied to determine solid-state ^{1}H shifts for aggregated BChl *c* in uniformly ^{13}C-enriched chlorosomes. A complete assignment of 29 different observable resonances of the 61 protons of the aggregated BChl *c* in the intact chlorosomes was obtained. The 21-H, 32-H, and 31-H resonances are shifted upfield by -2.2, -1, and -3.3 ppm, respectively, relative to monomeric BChl *c* in solution, revealing parallel stacking of the BChl in the antenna.

Although the resonances are inhomogeneously broadened and reveal considerable global structural heterogeneity, the 5-CH and the 7-Me responses are doubled, which provide evidence for the existence of at least two relatively well-defined structurally different arrangements. *Ab initio* quantum chemical modeling studies were performed to refine a model for the self-assembled BChl *c* with two different types of BChl stacks. The BChl in the stacks can adopt either *anti*- or *syn*-configuration of the coordinative bond, where *anti* and *syn* designate the relative orientation of the Mg–OH bond relative to the direction of the 17–17^{1} bond. Based on the NMR data, a bilayer model for the tubular supra-structure of sheets of BChl *c* was proposed, from a homology modeling approach (Figure 2).

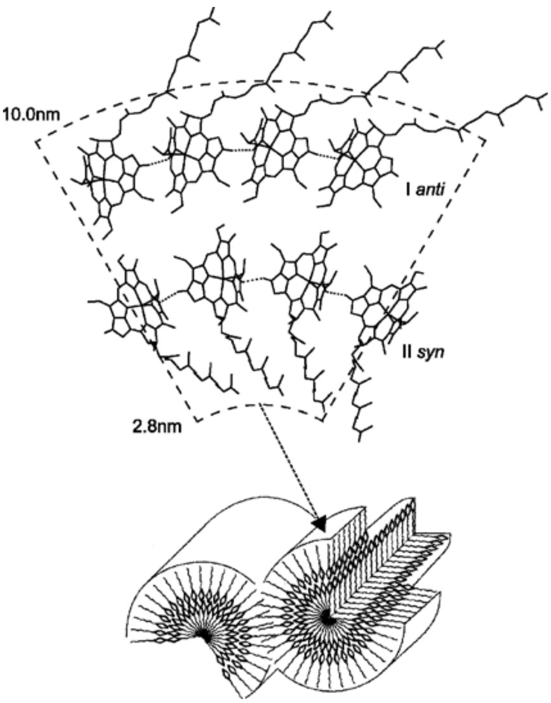

Fig. 3. The structure model of the chlorosomal antennae in *Chlorobium tepidum* derived from MAS NMR, consisting of bilayers of self-assembled BChl *c*.

As a spin-off mainly from the investigations into chlorosome LH antenna structures and ligand–protein interactions for membrane proteins, the construction and use of novel ultrahigh field (750 MHz) MAS NMR equipment was recently demonstrated [16]. The new technology represents a twofold increase of field strength with respect to previous practice, since biological MAS NMR was and is still often performed at 300–400 MHz ^{1}H frequency. The higher field increases the sensitivity by $\sim$60% and improves the range and resolution considerably [17].

To confront the new technique with real biomolecular targets from research in molecular structural biology and to explore the range of the new technology for structure determination of membrane proteins, the sequence specific assignments for the transmembrane

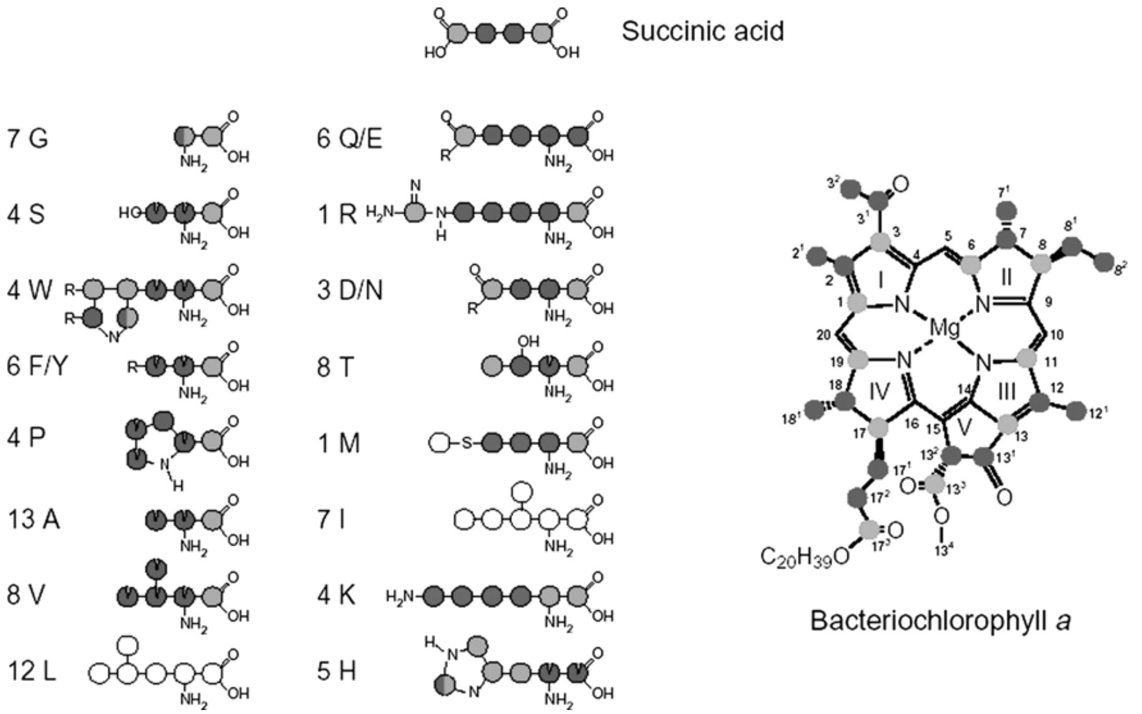

Fig. 4. ^{13}C-isotope enrichment of the residues and BChl *a* cofactors in LH2. The green color shows the labeling pattern that is obtained by growing on [1,4-^{13}C]-succinic acid, while the labeling pattern obtained by growing on [2,3-^{13}C]-succinic acid is indicated in red. The small sections indicate a partial scrambling of isotopes. Ile and Leu are labeled due to the uptake from an AA nutrient source. (See also Plate 39 on page XXXII in the Color Plate Section.)

helices in the monomeric unit of the LH2 were recently obtained [18,19]. Here MAS NMR was used in combination with extensive and selective biosynthetic isotope labeling methods. For both the residues of the protein and for the cofactors distinct labeling patterns have been deduced with 2-D proton-driven spin diffusion (PDSD) solid-state NMR correlation spectroscopy for samples prepared from [1,4-^{13}C]-succinic acid, [2,3-^{13}C]-succinic or AA labeled media (Figure 4) [20]. All residues, except isoleucine and leucine, have been labeled almost homogeneously by the succinic acid precursor. Carbonyl carbons in the protein backbone were labeled by [1,4-^{13}C]-succinic acid, while the Cα and Cβ carbons of the residues were labeled by [2,3-^{13}C]-succinic acid. Leucine and isoleucine residues were labeled using a uniformly labeled AA mixture in the medium. The pattern labeling yields an increase of the resolution and less spectral crowding.

The partial labeling technique in combination with conventional solid-state NMR methods at ultrahigh magnetic fields provides an attractive route to resolve chemical shifts for a helical transmembrane protein structures. Assignments have been performed on the basis of 2-D PDSD ^{13}C–^{13}C correlation experiments with mixing times of 20 and 500 ms and band selective ^{13}C–^{15}N correlation spectroscopy on a series of site-specific biosynthetically labeled samples (Figure 5) [19]. The decreased line width and the reduced number of correlation signals of the selectively labeled samples with respect to the uniformly labeled samples enable to resolve the narrowly distributed correlation signals of the backbone carbons and nitrogens involved in the long α-helical transmembrane segments. Correlations between nearby residues and between residues and the labeled BChl *a* cofactors, provided by the ^{13}C–^{13}C correlation experiments using a 500 ms spin diffusion period, are used resolve the NMR responses for many residues in the protein complex. In this way it is demonstrated that MAS NMR methods combined with site-specific biosynthetic isotope labeling can be used for sequence specific assignment of a transmembrane protein complex.

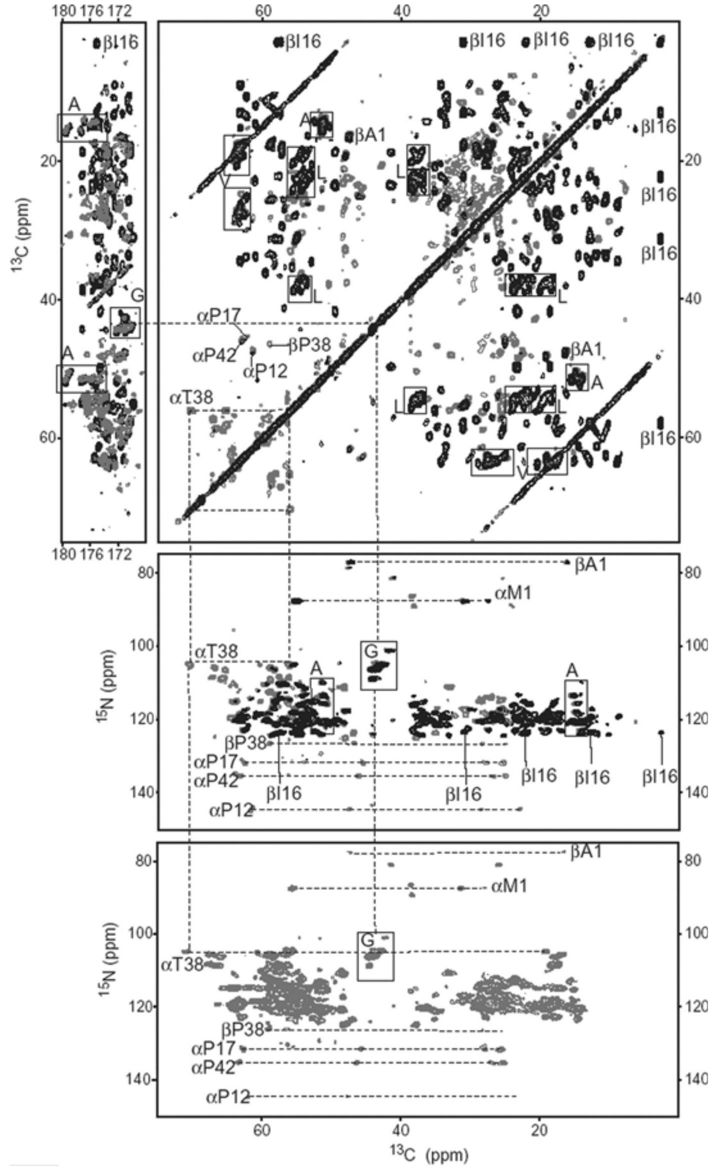

Fig. 5. In the upper panels two regions from homonuclear ^{13}C–^{13}C PDSD50 correlation spectra collected from 2,3-LH2 (red) and AA-LH2 (black) are shown. The region shown in the upper left panel contains cross peaks involving the aliphatic carbons and carbonyl carbons, while the upper right panel shows correlations between aliphatic carbons, present in the side chains of the AAs. In the left part, a few responses are observed for 2,3-LH2, belonging to H, Q, and E residues. The responses from AA-LH2 in the carbonyl area are from I, L, A, G, and V residues. The blue-coded spectrum in the carbonyl region comprises carbonyl responses from 1,2,3,4-LH2. In the upper right panel the aliphatic responses are shown. The dashed lines indicate correlations involving the αT38 and 4P residues for the 2,3-LH2, and correlations involving βI16 for the AA-LH2. The residues that are labeled via both nutrient sources are also indicated. In the middle pane, the aliphatic region of the NCACX spectra of 2,3-LH2 (red) and AA-LH2 (black) are shown. The data are aligned with the PDSD50 spectrum and correlations involving αT38, βI16, and the 4P residues are indicated with dashed lines for the two different samples. The responses of the G residues are indicated with a rectangular box. The NCA signals are aligned with the carbonyl area of the PDSD50 spectrum. Finally, in the lower panel the NCACX spectrum of a 1,2,3,4-LH2 sample is shown. (See also Plate 40 on page XXXIII in the Color Plate Section.)

Insight into Membrane Protein Structure from High-Resolution NMR

Philip L. Yeagle and Arlene Albert
Department of Molecular and Cell Biology, University of Connecticut, Storrs, CT 06269, USA

Introduction

Since α-helices and turns (helix-turn-helix motif) are stabilized by short-range interactions, and since many membrane proteins are built around (transmembrane) helical bundles, much of the secondary structure of such membrane proteins can be captured in peptide fragments. Furthermore, if sufficient long-range point-to-point experimental distance constraints are available from the intact protein, a structure for the whole protein can be assembled from the structures of the peptide fragments. In this review, we will describe the basis for the first statement and give some examples of the second. The review will conclude with a brief look at the future of high-resolution NMR in the study of the structural biology of intact membrane proteins in detergent micelles.

Membrane Protein Structure—Current Status

Our understanding of the structure of integral membrane proteins lags considerably our understanding of soluble protein structure. Less than 0.5% of the structures in the PDB represent integral membrane proteins, whereas genomic analysis indicates that 25–40% of proteins encoded by most genomes are membrane proteins [1]. Clearly there is a huge deficit of structural information on membrane proteins.

The major source of this knowledge deficit lies in the difficulties in applying the most productive techniques in protein structure determination to membrane proteins. X-ray crystallography requires crystallization of membrane proteins and to date only about 80 structures of membrane proteins have been published using this approach in large part because of difficulties in crystallization. Membrane proteins have extensive hydrophobic surfaces and therefore are insoluble in water. Because of this insolubility, many of the standard techniques for crystallization will not work on membrane proteins.

Powerful NMR techniques have been developed and exploited to determine structures of a variety of soluble proteins. These techniques in general require that the protein under study be stable and active in aqueous solution. Integral membrane proteins are not soluble in aqueous solution. These membrane proteins must be solubilized in detergent micelles. The protein-detergent micelles tend to be large, with molecular weights in excess of 50 kDa. The long rotational correlation times of such structures enhance dipolar and chemical shift anisotropy interactions and consequently broaden resonances, which inhibits the acquisition of high-resolution spectra. At this writing, structures from only one family of membrane proteins have been reported using high-resolution NMR data [2,3]. These structures are of porins, β-barrel proteins from the outer membrane of *E. coli*. Structures of the larger families of membrane proteins consisting of transmembrane bundles of α-helices have proven more difficult to solve.

It is, however, quite feasible to solve structures of fragments of membrane proteins containing 20–45 residues. We will examine how such structure determinations on membrane protein fragments can provide insight into the secondary structure of membrane proteins consisting of helical bundles.

Peptides from Helices and Turns have Intrinsic Structures that can Provide Secondary Structure Information About the Parent Soluble Protein

A growing body of data suggests that solution structures of peptides derived from some classes of proteins retain the secondary structure of the parent protein because of the dominance in α-helices and turns of short-range interactions [4] that can be captured in peptides.

Studies on segments of soluble proteins forming α-helices show that peptides containing these sequences form α-helix in almost every case under some solution conditions [5–15]. Peptides representing segments that are turns in the native protein also show turns as peptides in solution [10–13,16–22]. In some cases, the entire sequence of a helical bundle protein has been incorporated in a series of peptides spanning that sequence and the individual peptides have reported the secondary structure of much of the native protein with fidelity [19,23–26]. The implication from these studies on peptides from soluble proteins is that peptide fragments from these proteins preserve much of the secondary structure of the intact protein.

Graham A. Webb (ed.), Modern Magnetic Resonance, 335–343.
© 2008 *Springer.*

Therefore, since structure determination of intact membrane proteins is problematic, determination of structures of peptide fragments becomes an important alternative approach to structural information on membrane proteins.

Structures of Peptide Fragments from Membrane Proteins can Provide Secondary Structure Information

More recently, analogous studies have been performed for membrane proteins. Membrane proteins containing transmembrane helical bundles can be thought of as a collection of transmembrane helices (TM) and connecting turns, both elements of secondary structure stabilized by short-range interactions. It is reasonable to hypothesize, therefore, that peptide fragments corresponding to TM or to connecting turns would display local stable structure characteristic of helix or turn, respectively. This hypothesis has now been tested many times on a number of membrane proteins and found to be correct. In what follows, NMR studies on peptide fragments of a variety of membrane proteins will be reviewed, in each case demonstrating the preservation of native secondary structure in the peptide fragments.

Human Erythrocyte Glycophorin

Perhaps the earliest indication of this property of fragments from helical membrane proteins was work on glycophorin. The isolated protein was fragmented by trypsin hydrolysis. Each of the fragments was examined by circular dichroism (CD). When the CD of these individual fragments was summed, the CD of the whole protein was obtained, indicating that the secondary structure of the whole protein was largely preserved in the fragments [27]. Subsequent ^{1}H NMR studies revealed the α-helical nature of the transmembrane domain separate from the remainder of the protein [28], consistent with the CD studies.

Bacteriorhodopsin

Whether useful information of membrane protein secondary structure could therefore be obtained from peptide fragments spanning the entire sequence of a membrane protein was tested on bacteriorhodopsin. Bacteriorhodopsin is a light-activated protein from *Halobacterium salinarium* (part of the purple membrane, a specialized patch in the membrane of this bacterium) that uses light energy to pump protons against a concentration gradient. The molecular weight of this protein is 24.5 kDa [29].

Bacteriorhodopsin is the prototypical transmembrane protein consisting of a bundle of seven hydrophobic helices that constitutes the transmembrane portion of the protein with loops connecting each of the helices in the bundle. Therefore the dominant secondary structures of this protein are α-helices and turns. Both α-helices and turns are stabilized by short-range interactions (i to $i+4$ or shorter), the internal hydrogen bonds. Therefore peptides with the sequence of one of the transmembrane helices or one of the turns could be expected to contain the hydrogen bonds characteristic of the corresponding secondary structure and thus stabilize the relevant secondary structure in the peptide.

A number of three-dimensional structure determinations have been published for bacteriorhodopsin [30–34], one of the very few membrane proteins for which complete structures are available. Furthermore, experiments have shown that bacteriorhodopsin can be expressed in two separate pieces and the pieces will assemble properly in a membrane to re-form the protein [35–36], suggesting a subdomain character for the helices in the transmembrane region.

The collection of this evidence encouraged investigation into the structural stability of fragments of bacteriorhodopsin. Several fragments of bacteriorhodopsin were synthesized by solid phase peptide synthesis and their three-dimensional structures determined [37–40]. Two dimensional, homonuclear NMR experiments were used on these unlabeled, hydrophobic peptides in organic solvent. The local stability of the helices was clearly observed. Peptide fragments from some of the helical regions of bacteriorhodopsin formed helices separate from the remainder of the protein.

This question of localized stability of secondary structure was then explored in depth for the entire bacteriorhodopsin molecule. A series of overlapping peptides that spanned the sequence of the protein were synthesized. Each peptide encompassed either a (transmembrane) helical region or a turn flanked by two short helical regions (connecting two transmembrane helices). Structures of the peptides were determined by NMR in DMSO, a solvent with no propensity to stabilize any particular secondary structure and with a dielectric similar to the membrane interface at which initial folding of secondary structure of helical membrane proteins is proposed to occur [41]. All the peptides that encompassed a sequence corresponding to a transmembrane helix formed a helix in solution, except for the peptide for helix G in bacteriorhodopsin (which proved to be unstable in solution). All the peptides that corresponded to turns formed turns in solution, separate from the remainder of the protein [42,43]. Overlays of these fragments on the crystal structure showed good agreement between the structures of the peptide fragments and the X-ray crystal structure of the intact protein (see Figure 1).

These results were interpreted in terms of local stability of secondary structure, such that crucial interactions

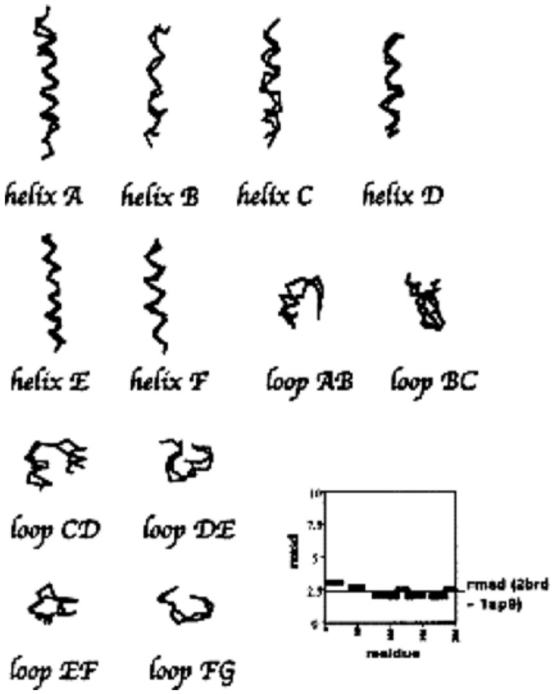

Fig. 1. Alpha carbon maps of the superposition of the backbone atoms of the peptide structures on the corresponding sequences in one crystal structure (2BRD) of bacteriorhodopsin. In each case, one member of the family of peptide structures, randomly chosen, was superimposed on the crystal structure. Similar results were obtained from superposition of these peptide structures on 1AP9. The superpositions were calculated using only the well-ordered portions of the peptide structures, as listed in Table 1. Inset: The rmsd (Å) of the superposition is plotted for each peptide as a function of the sequence of bacteriorhodopsin. The horizontal line represents the average rmsd of superposition of 2BRD on 1AP9. (Reproduced from ref. [43] with permission.)

(hydrogen bonds) could form within the peptide, just as in the X-ray crystal structure of the intact protein. The agreement between the peptide structures and the structure of the intact protein suggested that structural studies of a series of overlapping peptides spanning the sequence of an α-helical membrane protein should provide valid information on the secondary structure of the protein (α-helices and turns).

Bovine Rhodopsin

This information provided the basis for a study of the secondary structure of bovine rhodopsin, another protein built around a transmembrane bundle of 7 α-helices like bacteriorhodopsin. The initial events of low-level visual transduction take place in the retinal rod cell on the retinal rod outer segment (ROS) disk membrane. The G-protein coupled receptor (GPCR), rhodopsin, is the major protein of the disk membrane, comprising 80–90% of the total disk membrane protein [44,45]. When light strikes the ROS and is absorbed by the photopigment, rhodopsin goes through a series of spectrally defined intermediates. The transition to the Metarhodopsin II (R^*) intermediate permits the activation of the G protein, transducin and initiates the cGMP cascade [46] that culminates in the hydrolysis of cGMP and closure of the plasma membrane Na^+ channels. This results in a hyperpolarization of the plasma membrane and generates a signal at the synapse.

$$\text{Rhodopsin} + \text{light} \rightarrow \text{Meta II } (R^*) \rightarrow \text{Opsin} + \text{retinal}$$

Expression studies suggested that rhodopsin was built of subdomains. Rhodopsin can be expressed as two independent bundles of TM, such as a set of 3 TM and a set of 4 TM, and these separately expressed helical bundles will spontaneously assemble in the membrane [47]. These studies led to the hypothesis stated above that a protein built around a transmembrane helical bundle can be dissected into peptide fragments that retain the secondary structure of the native protein.

When studies based on that hypothesis were begun [48], no X-ray crystal structure of rhodopsin was available. Therefore an intense effort was dedicated to determine the secondary structure of this protein through fragments of rhodopsin corresponding to transmembrane helices or turns.

Initially, just the cytoplasmic loops were studied in depth. These loops had been shown to be biologically active, inhibiting the interaction between this GPCR and its G protein [49,50]. These loops were soluble in water and showed CD characteristic of structure under conditions similar to those in which biological activity had been demonstrated. They were therefore ideal candidates to determine whether structure of a loop could exist separate from the rest of the protein. NMR studies were undertaken and the structures determined of these peptide fragments of rhodopsin [48,51–53]. All three cytoplasmic loops formed stable structures in solution as suggested by the CD and consistent with the observed biological activity.

These studies encouraged an in-depth study of the whole protein. A complete set of overlapping peptides spanning the sequence of the protein was synthesized. The structures of the remaining fragments were determined by solution NMR techniques [15,54,56]. These peptide fragments in each case showed structure. Fragments from putative helices showed helical structures and fragments from turns showed turn structures. It became clear that most of the secondary structure of this helical membrane protein could be captured in these peptide fragments.

When a crystal structure became available [57], it was possible to verify that the secondary structure in the peptide fragments mimicked the secondary structure in the intact protein [58]. It subsequently became possible to utilize these structures of peptide fragments to assemble a structure for the whole protein. This will be discussed at the end of this review.

Lactose Permease

The lac permease is a β-galactoside transport system of *E. coli* encoded in the lac operon (lacY). The first report of this activity was in 1955 [59]. Subsequently it was shown that this transport activity was driven by a proton gradient [60], in accord with the Mitchell hypothesis [61]. This protein was cloned [62] and sequenced [63] early in the study of such membrane proteins. It was purified and reconstituted in defined lipid bilayers and found to exhibit the same transport activity that had been measured in the native membrane [64]. The protein functions as a monomer in the membrane [65,66]. Cysteine scanning has shown that six amino acid residues are essential for the transport process: E126, R144, E269, R302, H322, and E325 [67].

The structure of this protein consists of a bundle of 12 TM. The X-ray crystal structure shows a pseudo symmetry of two bundles of 6 TM connected by loops [68]. Therefore the lactose permease is a good candidate for the same analysis of secondary structure described above for bacteriorhodopsin and rhodopsin. Such a project was begun before the crystal structure was reported. A series of peptides spanning the sequence of the protein were synthesized, each peptide encompassing a putative transmembrane helix or a turn connecting two TM. As in the case of the other membrane proteins, a set of structures were obtained from solution NMR studies demonstrating the short-range stability of elements of secondary structure, including turns [69] and helices [123].

Protein Fragments of Other Membrane Proteins

Bacteriorhodopsin, rhodopsin, and lactose permease are the current examples of complete analysis of secondary structure using a series of peptides spanning the entire sequence of the membrane protein. However, a number of other examples have been reported of fragments from other integral membrane proteins that also show preservation of secondary structure in peptide fragments.

Saccharomyces Cerevisiae α-factor Receptor

The *Saccharomyces cerevisiae* α-factor receptor is a GPCR of yeast involved in mating. Peptides corresponding to all the TM of this 7TM transmembrane protein were synthesized and some of the loops. Structures were determined in organic solvent by NMR. All TM showed helical structures and one of the loop peptides was also structured [70–73]·

Parathyroid Hormone Receptor

Fragments of the parathyroid hormone receptor, a GPCR, have been studied by solution NMR techniques in detergent micelles. A peptide containing the amino acid sequence of the first extracellular loop was synthesized. The NMR structure revealed a short helix on each end of the peptide corresponding to portions of the TM on either side of the loop. The interior of the loop also contained an additional helix [74]. A peptide corresponding to the third cytoplasmic loop of this same receptor was synthesized and the NMR solution structure revealed a loop structure in the presence of detergent micelles [75,76].

The Human Cholecystokinin-2 Receptor

The third extracellular loop of the cholecystokinin-2 receptor (residues 352–379), a GPCR, was synthesized and its structure determined in detergent (DPC) micelles by solution NMR. The ends of the two attached helices, 6 and 7, are seen as is the turn [77]. Interactions between this third extracellular loop and ligands have been probed by NMR and other techniques [77–80].

The Human Cannabinoid Receptor

The human cannabinoid 1 receptor functions as a receptor for Δ^9 tetrahydrocannabinol and is coupled to $G_{i/o}$. A peptide has been expressed of 44 residues containing the third cytoplasmic loop of this GPCR. The peptide is biologically active. There is evidence for helix at both ends of the peptide, corresponding to portions of the two connected transmembrane helices, and the peptide forms a turn in detergent micelles [81]· The putative helix 8 of the cannabinoid 2 receptor has been synthesized and the structure determined in DPC micelles and in DMSO. In both environments an α-helix was observed [82].

Bradykinin B2 Receptor

The bradykinin B2 receptor is a GPCR. A peptide corresponding to the second intracellular loop of the bradykinin B2 receptor and containing 34 residues was synthesized and the structure determined by solution NMR. A helix-turn-helix motif was observed, with portions of both attached transmembrane helices visible. In addition, the structure of a portion of the C-terminus was examined in an expressed, labeled peptide containing residues 309–366 of the receptor. Evidence for helix 8 was observed as well as other structured regions [83,84].

Rat Angiotensin II AT1A Receptor

The rat angiotensin II AT1A receptor is a GPCR. The third cytoplasmic loop, the first extracellular loop and a portion of the carboxyl terminus of this receptor have been studied as peptides in solution with NMR. Two peptides spanning the third cytoplasmic loop show some of the attached transmembrane helices [85]. The peptide corresponding to the first extracellular loop forms a type 2 β turn [86], as do two of the turns in bovine rhodopsin [53]. The C-terminal peptide, corresponding to residues 300–320, form in part an amphipathic helix, perhaps corresponding to helix 8 observed in other GPCRs [87].

Tachykinin NK-1 Receptor

A peptide corresponding to the 7th transmembrane domain of the tachykinin NK-1 receptor was synthesized and the structure determined in organic solvent by solution NMR. Evidence for the helical nature of this domain was found in DMSO [88].

β-adrenergic Receptor

The β-adrenergic receptor is a GPCR. Peptides corresponding to the third intracellular loop of the turkey receptor (residues 284–295) were synthesized and studied in micelles by solution NMR. The C-terminal region of the peptide showed helical structure, likely corresponding to the beginning of TM 6. The putative helix 8 region of the human β-adrenergic receptor was examined with a peptide in detergent and in DMSO and found to be helical while in water the peptide was disordered [89].

EmrE, a Multidrug Resistance Protein

EmrE, a multidrug resistance protein is a membrane protein from *E. coli* of 110 residues. A set of peptides partially spanning the sequence of the protein was synthesized and structures determined by NMR in SDS micelles. Two of the peptides, corresponding to predicted transmembrane segments, formed helices as expected and another formed a turn [90].

Potassium ion Channel

The potassium ion channel is an oligomeric transmembrane structure. Peptides were synthesized corresponding to the transmembrane domain of three forms of this ion channel, Shaker, ROMK1, and minK. The structures of these peptides were studied in solution by NMR and CD and found to be predominantly helical [91].

Human Red Cell Anion Transporter, Band 3

The human red cell anion transporter, band 3, is one of two most abundant membrane proteins of the human erythrocyte membrane, involved in chloride transport. Two of the putative transmembrane segments of this protein, containing residues 405–424 and residues 436–456, were synthesized and their structure determined in trifluoroethanol. Predominantly α-helical structures were reported [92]. In addition, a peptide fragment corresponding to a loop on the cytoplasmic face of the protein connecting TM12 and TM13 was synthesized with 46 residues. The NMR solution structure showed a helix-turn-helix motif [93].

Phosphatidylglycerophosphate Synthase

Phosphatidylglycerophosphate synthase from *E. coli* is an integral membrane protein. Peptides corresponding to two putative TM of this protein were synthesized and their structure determined (residues 6–25 and residues 149–176). Two-dimensional ^{1}H NMR studies and CD studies revealed that these sequences were stable as helices in solution and in SDS micelles [94].

IsK

Isk is a voltage-gated potassium channel with a single TM per monomer. A peptide was synthesized containing the putative transmembrane domain (residues 42–68). This peptide exhibited biological activity and solution NMR studies in organic solvent showed an α-helical structure [95].

General Features of the Studies on Membrane Protein Fragments

This survey of structure reports on fragments of membrane proteins reveals several common features. (1) The peptides are 20–40 residues in length (if the peptides are too short, then the secondary structure can be destabilized). (2) The peptides encompass either a TM or a turn in the sequence of the fragment. (3) For studies in organic solvents, solvents of intermediate dielectric, such as DMSO, are common and stable secondary structure is often found in such solvents. (4) High-resolution multidimensional NMR experiments are effective in determining structure of such peptides in both organic solvent and in detergent micelles.

In the most favorable circumstances, these kinds of studies can provide a nearly complete picture of the secondary structure of the membrane protein if the protein is built around a transmembrane helical bundle. Of course, not every fragment of a membrane protein selected as described above forms stable secondary structure. And in the case of β-barrels, such as the bacterial porins, these kinds of studies to determine secondary structure would not be useful. However, this survey does not reveal a case where the structure of the fragment reported incorrectly on the secondary structure of the protein. Rather the only cases that did not report the correct secondary structure were cases in which the fragment was disordered and thus provided no information on secondary structure. Therefore studies on the structures of nearly 100 of these fragments of membrane proteins have not yet misled the investigator as to the true structure in the protein from which they were derived.

How Sparse Long-Distance Experimental Constraints can be Combined with Fragment Structures to Build a Structure of the Intact Membrane Protein

An interesting recent analysis demonstrated the ability to organize elements of secondary structure (α-helices) in three dimensions to mimic the structure of a native membrane protein, using a limited number of long-distance constraints [96]. The concept starts with helices as locally stable structures. In a protein like rhodopsin, the transmembrane domain consists of 7 TM in a bundle. If one assumes the structure of the helices (from, say, hydrophobicity plots), then one needs to define the density of long-distance constraints necessary to the proper organization of the helical bundle. In this study, employing just 27 experimental long-distance constraints was sufficient to define the three-dimensional organization of the 7 helices to mimic the structure of the transmembrane bundle. A conceptually similar (but different in approach) method was used previously with 7 ideal helices to build the bundle constituting the transmembrane domain of rhodopsin [97]. Again a limited number of long-distance constraints were used to organize the bundle.

These more theoretical studies provide a basis for assembling a structure of a transmembrane protein from experimental structures of protein fragments, defined as above, and additional experimental long-distance constraints from the intact protein. Structures of two membrane proteins have been successfully built using such an approach.

Bacteriorhodopsin

Bacteriorhodopsin was used as a test case to develop this approach to membrane protein structure. Bacteriorhodopsin is a seven transmembrane helical protein and several crystal structures are available. The structures of each in a series of overlapping peptides spanning the sequence of bacteriorhodopsin were determined using NMR. The solution structures of these peptides were found to have the same secondary structure as the corresponding regions of the X-ray crystal structure. These individual peptide structures, and the distance constraints obtained for them, were then used, with additional experimental long-distance constraints, to build the three-dimensional structure for the whole protein. The resulting structure agreed with structures determined from electron and X-ray diffraction data. The B factors from X-ray and electron diffraction studies are high in most of the loops of all the bacteriorhodopsin structures. Therefore quantitative comparisons were made with the transmembrane domain, which has substantially lower B factors. Accordingly, the rmsd of superposition of the NMR based structure on the crystal structure 2brd is 2.9. The structure obtained by our method is in as close agreement with the X-ray structure as the X-ray structures are with each other. [43] (see Figure 2). This work demonstrated that a three-dimensional structure could be obtained for a membrane protein using the secondary structural information

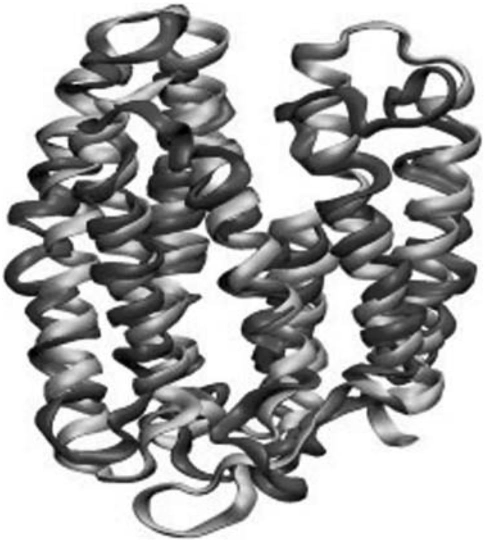

Fig. 2. Structure of bacteriorhodopsin (blue), determined from experimental data as described in the text, superimposed on a crystal structure (cyan) of bacteriorhodopsin (1FBB). (See also Plate 41 on page XXXIV in the Color Plate Section.)

obtained from peptides representing protein sub-domains (helices and turns), coupled with experimental long-range distance constraints.

Bovine Rhodopsin

The same technique was used to determine a structure of rhodopsin. Structures of all the extramembraneous domains of rhodopsin and the structures of all the transmembrane helical domains were determined by two-dimensional homonuclear ^{1}H NMR [15,43–48,51–56,98–102]. The peptides typically exhibit well-defined structures in solution. Comparison of the peptide structures to the corresponding region in the crystal structure indicates good agreement. This work formed the basis of a three-dimensional structure of rhodopsin that is in agreement with the crystal structure of rhodopsin in the dark-adapted state [57]. Furthermore, we were able to use the same approach to determine a structure for Meta II, the activated form of rhodopsin (and the only structure to date of an activated GPCR) [103]. The technique is described below.

The solution structures of a series of overlapping peptides, which spanned the rhodopsin primary sequence, were determined by two-dimensional homonuclear ^{1}H NMR and linked into a construct corresponding to the entire sequence of rhodopsin [56]. The construct was originally built by superimposing the overlapping regions of the fragments to link one fragment to the next in the sequence. 11-cis retinal was added to K296 to make a specially defined amino acid. Experimental distance constraints were written into the mol2 file for this construct in SYBYL (Tripos). 3030 short-range NOE-derived experimental distance constraints were available from the NMR structure determinations on the individual peptides. Long-range constraints from independent experiments on intact dark-adapted rhodopsin were added. For example, site directed spin labeling put pairs of spin labels at specific sites and the dipolar interactions between the spin labels provided distance measurements [104–115]. Other experimental distance constraints were obtained from engineered disulfide crosslinking [47], engineered metal binding sites [116] and other experimental measures of site-to-site distances in the intact rhodopsin. The 11-cis retinal was constrained by the solid state NMR data of Watts, *et al.* [117]. The construct with the distance constraints was subjected to several cycles of simulated annealing (1000 fs at 1000 °K followed by 1500 fs cooling to 200 °K). The resulting compact structure determined strictly from experimental data (no modeling), showed a bundle of seven helices connected by six turns.

This work demonstrates that a valid structure for membrane proteins built on helical bundles can be obtained from the secondary structures of the protein fragments and selected long-range constraints. This three-dimensional structure of rhodopsin can be quantitatively superimposing this structure on the X-ray crystal structure. Good agreement with the crystal structure [57] is observed in the transmembrane region with an rmsd of 1.85. (It is only valid to compare this structure with the crystal structure in the transmembrane region because the crystal structure is poorly resolved in the cytoplasmic face. This poor resolution is typical of crystal structures of membrane proteins and is manifest in very high B values.

New High-Resolution NMR Studies on Intact Membrane Proteins

The story of high-resolution NMR and membrane protein structure does not end here. Recent studies have exploited new TROSY [118] techniques and deuteration to obtain spectra and structures from several β-barrel porins from the outer membrane of *E. coli* [2,3,119]. While no complete structure of a membrane protein built on a helical bundle has been published at this writing, important progress is currently being made on helical bundles including bacteriorhodopsin [120] and diacylglycerol kinase [121]. Very helpful to this effort is the discovery of new detergents that produce improved NMR spectra of integral membrane proteins [122]. It is to be hoped that these early efforts presage a strong presence in the future of high-resolution NMR in the field of membrane protein structural biology.

Part I

New Developments

Fast Multidimensional NMR: New Ways to Explore Evolution Space

Ray Freeman[1] and Eriks Kupče[2]
[1]Jesus College, Cambridge, UK
[2]Varian Ltd, Eynsham, Oxford, UK

Multidimensional NMR spectroscopy [1–3] has proved extremely productive, particularly for the elucidation of the structure of biomolecules such as proteins. The essence of the technique is to allow the nuclear spins to evolve in one or more consecutive time intervals before passing on phase or intensity information to the detection stage where the spectrometer receiver is active. In the traditional implementation, the motion of the nuclear spins is monitored systematically and independently in all n evolution dimensions (t_1, t_2, $\ldots t_n$) at sampling rates that satisfy the Nyquist condition, and for durations that guarantee adequate resolution. This generates a well-digitized $n+1$-dimensional time-domain data array, and repeated Fourier transformation converts this into an $n+1$-dimensional spectrum in frequency space (F_1, F_2, $\ldots F_{n+1}$).

For years this methodology was accepted as a perfectly acceptable *modus operandi.* Although the duration of the measurement is long, particularly for high-dimensional spectra, the signal-to-noise ratio increases as the square root of the measurement time in the same manner as in multiscan averaging. But as NMR spectrometers become intrinsically more sensitive with the advent of higher magnetic fields and cryogenic receiver coils, often it is *time* that is the limiting factor rather than *sensitivity*. Long experimental durations impose an upper practical limit on the dimensionality, a slow throughput of spectra, and an inability to study time-dependent phenomena or unstable materials. The question naturally arises—are there more economical ways to sample n-dimensional evolution space? The answer of course is yes.

Standard multidimensional NMR methodology commonly sets operating conditions that are less than ideal, simply to keep the experimental duration within reasonable bounds. Although sampling rates should normally satisfy the Nyquist condition to ensure that NMR frequencies are not aliased, sometimes a controlled "folding" of high-frequency signals may have to be tolerated in the quest for speed. The maximum length of the evolution time, t_1(max), determines the achievable resolution in the corresponding frequency dimension. A common expedient is to use a shorter value of t_1(max), thereby accepting less-than-optimum resolution. Often this data set is artificially extended by linear prediction, thus avoiding truncation artifacts. But these are stop-gap measures that merely mitigate a fundamental problem crying out for more drastic solutions.

This chapter examines alternative schemes for sampling evolution space. The main focus is on three-dimensional spectroscopy ($n = 2$) although the principles apply equally well to multidimensional experiments. The aim is to discover sampling modes that are comprehensive enough to derive the full spectrum, but sufficiently economical to permit fast acquisition. Since typical three-dimensional NMR spectra are relatively sparsely populated with correlation peaks, the prognosis is optimistic. Note that any fast-acquisition mode must inevitably sacrifice signal-to-noise ratio, since signals are accumulated over a short experimental duration. Almost all fast-acquisition modes are doomed to fail in circumstances of poor sensitivity. In what follows it is implicitly assumed that the intrinsic sensitivity is adequate.

Four approaches to the speed problem are described. The first ("filter diagonalization") uses a fitting procedure in the time domain. Its key feature is the ability to compensate for sparse sampling in the evolution dimensions by fine sampling during acquisition. The second ("spatially encoded single-scan NMR") is able to monitor all the evolution steps simultaneously by storing this information as NMR responses in different slices of the sample. The third ("Hadamard encoding") avoids time-domain evolution entirely, using direct excitation of selected responses in the frequency domain. The fourth ("projection–reconstruction") shortens the experimental duration by coupling evolution dimensions together. Fourier transformation generates plane projections that can be used to reconstruct the three-dimensional spectrum.

The Filter Diagonalization Method

This novel technique [4–6] boasts a significant speed advantage for three-dimensional spectroscopy by monitoring the two evolution dimensions (t_1 and t_2) with very

Graham A. Webb (ed.), Modern Magnetic Resonance, 347–352.
© 2008 *Springer.*

few data points, but with comprehensive sampling of the acquisition dimension (t_3), since this incurs no significant time penalty. The crux of the concept is that in the resulting computed spectrum, the resolution in all three frequency dimensions depends only on the *volume* of the experimental three-dimensional time-domain array, rather than on the number of samples in any particular dimension. Fine digitization in the t_3 dimension compensates for incomplete sampling in t_1 and t_2.

The method abandons Fourier transformation in favor of fitting the time-domain data as a set of exponentially decaying sinusoids, in a manner similar to the better-known linear prediction method [7]. Repeated application of a time auto-correlation operator U is used to compute successive time-domain data points, thus creating a model for the NMR response that can be fitted to the experimental response. The aim is to diagonalize the operator U, giving eigenvalues that represent the line frequencies and widths, and eigenvectors that yield the amplitudes and phases. If this diagonalization were to be applied to the entire data set, the computation would be enormous, but the trick is to break it down into a set of much smaller bites of a rather large cherry. The key is to choose a set of basis functions that correspond to a set of localized (but overlapping) segments in frequency space. Because resonances that are far apart in frequency show negligible interference effects, far off-diagonal matrix elements of the operator U can be safely neglected. A limited set of "local" or "filtered" diagonalizations are performed, neglecting basis functions beyond the boundaries of the segment under consideration. The problem then becomes tractable and the frequency segments can be assembled into a complete spectrum. Since linear algebra is involved, the fitting process is not hindered by the usual problems of false minima. However, in the presence of appreciable noise, or in very crowded regions, the procedure can become unpredictable.

An illustration of the filter diagonalization technique is provided by the two-dimensional constant-time heteronuclear single-quantum correlation (HSQC) spectrum of a 1 mM aqueous solution of ubiquitin [6]. The conventional Fourier transform spectrum (Figure 1a) is compared with that derived by the filter diagonalization method (Figure 1b) where the number of samples in the evolution dimension has been reduced approximately sixfold. This was achieved by reduction of the constant-time parameter from 26.4 to 4.25 ms. Despite this reduction, the resolution in the conventional and fitted spectra is comparable, and only in the very crowded region are there any significant discrepancies.

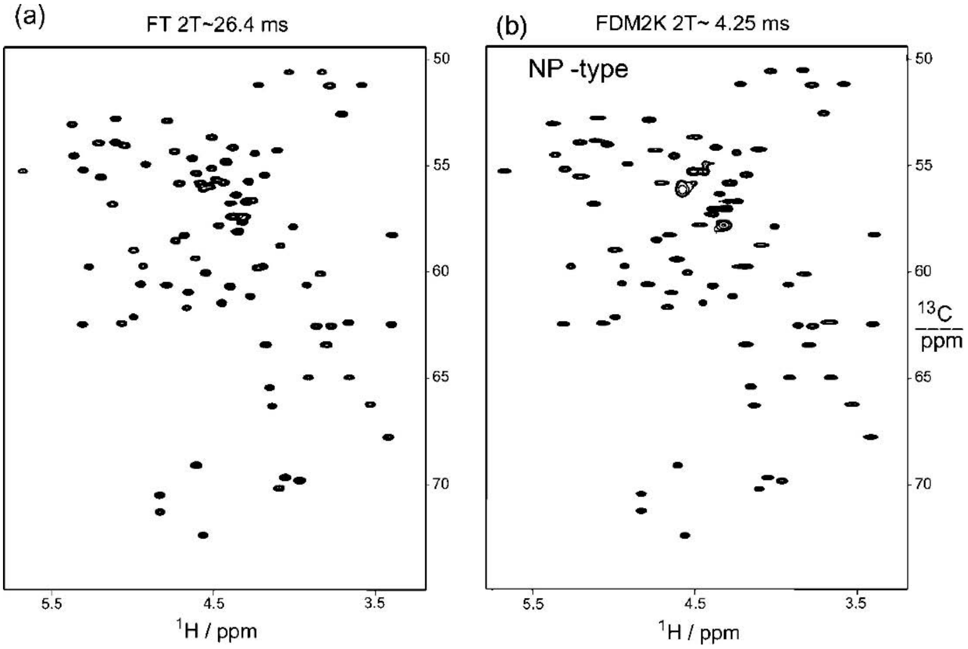

Fig. 1. Part of the 500 MHz two-dimensional HSQC spectrum of ubiquitin. (a) The conventional Fourier transform mode with the constant-time parameter (CT) set to 26.4 ms. (b) The spectrum fitted by means of the filter diagonalization method with CT shortened to 4.25 ms, requiring only 4 min of data collection. Spectra courtesy of A.J. Shaka.

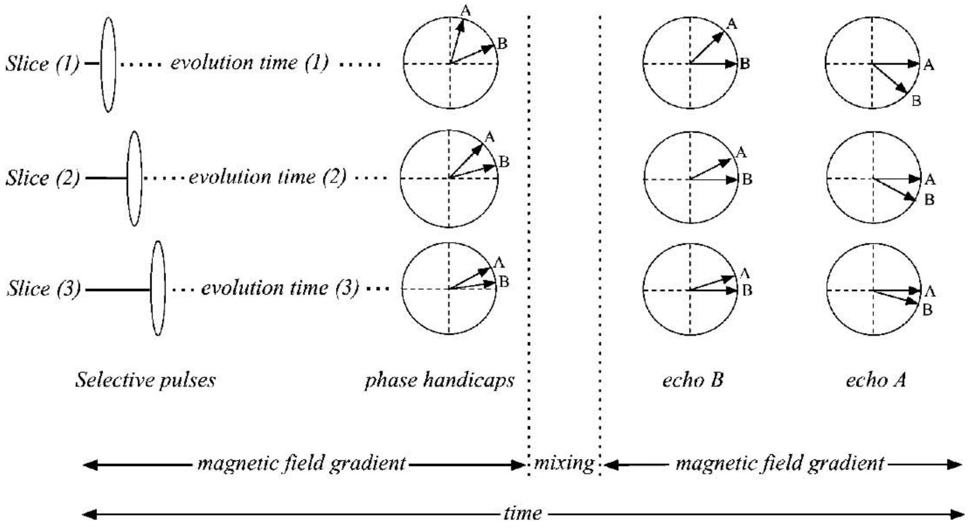

Fig. 2. Schematic representation of the spatially encoded single-scan experiment. The active sample volume is divided into slices by selective excitation in an intense field gradient. Three representative slices are considered here. Two chemical sites A and B build up different phase handicaps during evolution. After a non-selective mixing pulse, these phase handicaps are unwound in a refocusing gradient, site B forming a spin echo earlier than site A. This "spin echo spectrum" has essentially the form of the true NMR spectrum, but is obtained in a very short time, allowing the cycle to be repeated many times during a scan of less than a second.

Spatially Encoded Single-Scan NMR

One may think of this as the creation of a set of "pigeon holes" to store the evolution information, achieved in practice by selective excitation in an intense applied magnetic field gradient, thus dividing the sample into a set of thin parallel slices, excited sequentially [8–10]. The NMR signal evolves for a different interval in each slice (Figure 2). After the usual non-selective mixing pulse, the responses are detected by the application of a refocusing field gradient. (In practice both gradients are bipolar pairs.) Responses from different chemical sites, having evolved for different periods, come to a focus at different times, creating a sequence of gradient-recalled echoes (Figure 2). This "spin echo spectrum" broadly resembles the form of the true NMR spectrum in the F_1 frequency domain, but it is acquired in a very short time, typically 500 μs. This is the key to the speed factor—many acquisitions of the F_1 spectrum can be nested within the conventional acquisition scan of less than a second.

A typical application might be a two-dimensional proton COSY or TOCSY spectrum. The F_1 spectra are repeatedly recorded as a function of the acquisition parameter t_2 as correlation effects gradually build up. Only a single stage of Fourier transformation is required to generate the two-dimensional spectrum. The main drawback of the technique is its relatively poor sensitivity—engendered partly by the short accumulation time and by additional noise contributions caused by the wide frequency bandwidth employed during the spatial-encoding stage. The division of the sample into slices during evolution does not itself diminish the signal strength since NMR responses from the entire sample are brought to a focus at the same instant. Such ultrafast sampling opens up new possibilities for studying unstable materials, time-dependent phenomena, rapid screening of spectral "libraries", and flow techniques such as hyphenated liquid chromatography–NMR [11].

Hadamard Encoding

This approach abandons the conventional step-by-step exploration of evolution space, exciting the chemical sites with selective radio frequency pulses directly in the frequency domain [12–16]. Because NMR spectra are sparse, considerable time can be saved in this manner. The required NMR frequencies are obtained in a prior one-dimensional measurement that uses little spectrometer time. If the selective excitations are performed one at a time [17–20], the rate of data collection is slow, and the sensitivity is consequently poor—the famous "multiplex advantage" is lost. However by encoding the excitations (plus or minus) according to a Hadamard matrix, all the sites can be excited simultaneously, thereby restoring the multiplex advantage. The individual responses are separated by a decoding scheme based on the same matrix. Hadamard matrices [21] are higher-order versions of the simple add–subtract matrix

$$\begin{array}{cc} + & + \\ + & - \end{array}$$

that is widely used in physical science. As an example, the Hadamard matrix of order eight may be written:

$$\begin{array}{cccccccc} + & + & + & + & + & + & + & + \\ + & + & + & + & - & - & - & - \\ + & + & - & - & + & + & - & - \\ + & + & - & - & - & - & + & + \\ + & - & + & - & + & - & + & - \\ + & - & + & - & - & + & - & + \\ + & - & - & + & + & - & - & + \\ + & - & - & + & - & + & + & - \end{array}$$

Eight scans are performed with the senses of the eight selective radio frequency pulses encoded according to the rows of this matrix. Combining the eight resulting composite free induction decays according to the columns of this matrix allows the individual responses to be extracted one at a time.

The speed advantage of the multiple excitation method is given by N/Q, where Q is the order of the Hadamard matrix and N is the number of increments in the evolution dimension of the corresponding conventional experiment. The number of irradiated chemical sites S must be less than or equal to Q. Note that the operator may choose to set S less than the *actual* number of chemical sites, selecting only sites of particular interest, thereby generating a partial spectrum. This feature can be extremely useful for converting *global* isotopic enrichment (in ^{15}N or ^{13}C) to essentially *specific* enrichment, something that is very expensive to achieve chemically. The main drawback of this method is the requirement that Q scans be completed. For three- or four-dimensional spectroscopy, the intermediate radio frequency pulses are also made selective, and encoded according to the appropriate Hadamard matrices. The speed advantages in each evolution dimension are then multiplicative.

An illustration of the speed of the Hadamard method is shown in Figure 3. The sample was a 0.3 mM aqueous solution of agitoxin, a 4 kDa protein uniformly enriched in ^{13}C and ^{15}N. The 700 MHz conventional three-dimensional HNCO spectrum required 20 h and 43 min of data collection. A projection of this spectrum onto the C–H plane is shown in Figure 3A. Figure 3B demonstrates how the Hadamard technique can record a subspectrum from only seven selected sites, as if the sample had been selectively (rather than globally) enriched in ^{13}C. The Hadamard matrix of order eight was used, requiring eight scans, thus speeding up acquisition by a factor of more than 200. The smaller the number of sites selected for excitation, the smaller the required Hadamard matrix, and the faster the measurement.

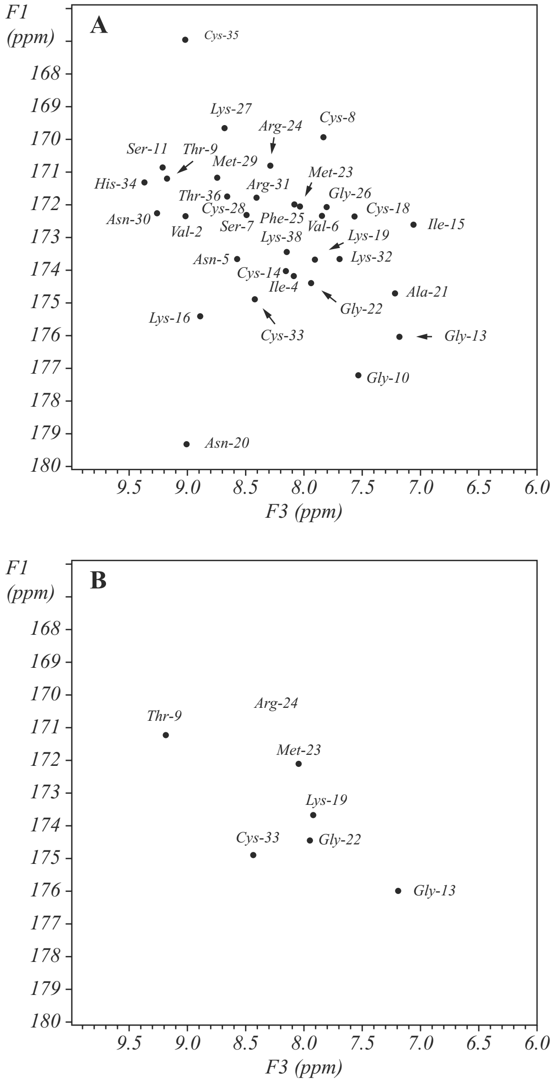

Fig. 3. Projection of the 700 MHz three-dimensional HNCO spectrum of agitoxin onto the C–H plane. (A) The conventional Fourier transform spectrum. Seven residues were selected at random, indicated by arrows. (B) The corresponding Hadamard spectrum of these seven residues, obtained more than 200 times faster.

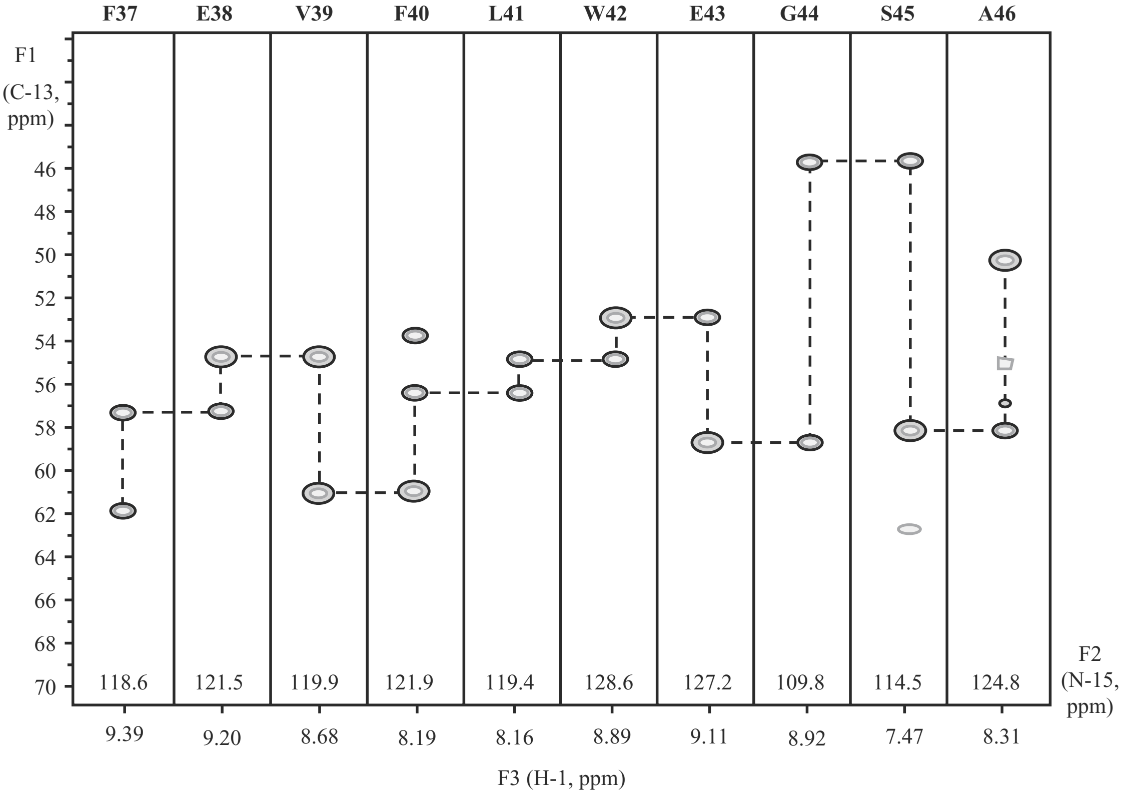

Fig. 4. Strip plots from the three-dimensional HNCA spectrum of nuclease A inhibitor mapping a chain of nine residues correlated through their ^{15}N and ^{13}C resonances. The projection–reconstruction technique shortens the experimental duration by an order of magnitude.

Projection–Reconstruction

The "accordion" experiment [22,23] and subsequent extensions [24–27] save time by coupling the incrementation of two evolution parameters t_1 and t_2, rather than scanning them separately. The evolving signal is recorded along a skew section through the time-domain data at an angle α given by $\tan\alpha = \Delta t_2/\Delta t_1$. Compared with systematic sampling of all N^2 elements of evolution space, this saves a factor of approximately N in spectrometer time (although slightly faster sampling is required along the skew axis). Fourier transformation of these signals generates a projection of the three-dimensional spectrum onto a plane inclined at the same angle α. With the standard quadrature detection in each evolution dimension, the technique gives two projections inclined at $\pm\alpha$. Thus by choosing the relative rates of incrementation, a projection can be obtained on a suitably tilted plane in frequency space.

It is well known from X-ray tomography [28] that an image of a three-dimensional object can be reconstructed from a set of projections taken at different angles of incidence. NMR spectra present a much more promising case, for they are made up of relatively sparse, discrete resonances, whereas the absorption in a physiological sample is continuous. As a result, an NMR spectrum can be reconstructed from a quite small number of projections recorded at different angles [29–33]. For three-dimensional spectroscopy the initial projections are those on the orthogonal F_1F_3 and F_2F_3 planes which are often used during the setting up procedure. The information content of these two projections is insufficient to reconstruct the three-dimensional spectrum, but it defines all *conceivable* positions for the cross-peaks, as if every resonance in the F_1F_3 plane were correlated with every resonance in the F_2F_3 plane. The actual cross-peaks are identified by imposing further constraints based on tilted projections, since the final three-dimensional array must be compatible with all the measured projections. If the signal-to-noise ratio is only marginal, projections are recorded at several different tilt angles and the inverse Radon transform [34] is employed for the reconstruction.

The 800 MHz three-dimensional HNCA spectrum of a 3 mM aqueous solution of the 143-residue nuclease A inhibitor [35] serves as an illustration of the projection–reconstruction technique [33]. The strip plots of Figure 4 show ^{15}N–^{13}C correlations for a chain running between residues 37 and 46. Based only on projections recorded at 0°, ±30°, ±60°, and 90°, the measurements were completed in 1 h, compared with an estimate of 11 h for the conventional mode.

Acknowledgments

The authors thank Lucio Frydman for several illuminating discussions, Gerhard Wagner for the sample of agitoxin, Robert London for the sample of nuclease A inhibitor, A.J. Shaka for permission to reproduce Figure 1, and the *Journal of Biomolecular NMR* for permission to reproduce Figure 3.

High-Sensitivity NMR Probe Systems

P.J.M. van Bentum and A.P.M. Kentgens
Institute for Molecules and Materials, Radboud University Nijmegen, 6525ED Nijmegen, The Netherlands

Abstract

Nuclear magnetic resonance (NMR) has become the method of choice for many types of applications. Still, sensitivity is a limiting factor in the applicability of NMR, leading to long measurement times in advanced multidimensional experiments, and becoming prohibitive when very limited sample quantities are available. This low sensitivity is mostly an intrinsic consequence of the low energy scale of the nuclear moment in a static field, when compared to other thermodynamic energies like $k_B T$. The commercial developments are mostly aimed at an increase in the static field and simultaneously a reduction of the noise using cryocooled detection coils. Current research shows a number of interesting developments toward the enhancement of the nuclear polarization by optical pumping or by transfer from the electronic bath in dynamic nuclear polarization (DNP) experiments. A more technological approach is based on the miniaturization of the RF coils. In the next decade, one may expect the advent of the "lab on a chip" with *in situ* chemical processing and NMR analysis capabilities. A brave new method to improve detection sensitivity is based on very sensitive micromechanical force detectors. Recently, it was demonstrated that the low-temperature force detection sensitivity is sufficient to detect the magnetic moment of a single (electron) spin. These developments show that the NMR detection limits in terms of absolute sensitivity or imaging resolution are still open to significant improvements.

Sensitivity Issues in NMR Spectroscopy

NMR and magnetic resonance imaging (MRI) have had a tremendous impact on research in physics, chemistry, biology, and medicine. This success is rather surprising, given the fact that even at the highest possible fields the nuclear Zeeman splitting, and thus the electromagnetic radiation to pump the transitions, remains much smaller than the thermal energy $k_B T$ at room temperature. Hence, the equilibrium magnetization that can be manipulated and detected in an NMR experiment is many orders of magnitude smaller compared to e.g. electron spin resonance (ESR). In optical, infrared or mass spectroscopy one is used to work with near quantum efficiency detectors, and a single photon or mass fragment can be detected with a reasonable signal-to-noise ratio. In radio-frequency detectors, this is not the case. In spectroscopy, typical sample sizes are of the order of 10–100 mm^3 and one typically requires more than 10^{16} nuclei in the sample. It is clear that there are many research topics that would benefit from even a modest improvement in sensitivity or resolution. An improvement in sensitivity by a factor of 10 would bring the data acquisition times down from days to minutes and would allow for example online quality control in chemical or pharmaceutical production. In chemical synthesis, one would be able to reduce the volume of the reactants to microliters and be able to map out the full phase diagram in an *in-situ* "lab on a chip" procedure. Apart from the gain in time there is also an environmental advantage because the flow of waste chemicals is substantially reduced.

Gradual improvements of equipment and measurement procedures have pushed up the sensitivity of NMR by nearly a factor of 10 in the last decade. Current research shows a number of interesting new or renewed developments toward sensitivity enhancements through polarization transfer or detector optimization.

In the following, we will first summarize the options available to increase the effective magnetization of a given sample. Mostly, these are based on thermodynamic approaches, including higher magnetic fields, lower temperatures, and transfer of magnetization. This can be for example the transfer of magnetization from protons to low-gamma nuclei in a cross-polarization (CP) experiment. Also, polarization transfer from electrons in dynamic nuclear polarization (DNP) or from optically polarized nuclei, like Xe and ^{3}He, is feasible. In some cases, one can pump the molecules directly, and combined with an optical detection full spin polarization can be reached, at least for electron spins. In half-integer quadrupolar spins systems generally only the central transition of the multiplet is observed as the other transitions are much more strongly affected by the quadrupolar interaction. In this case, one can transfer polarization from the satellite transitions to this central peak using adiabatic passages.

In the second part, we will review the basic physical laws that determine the inductive response of a traditional RF coil. We will discuss the options available to optimize the inductive detection for mass limited samples such as

Graham A. Webb (ed.), Modern Magnetic Resonance, 353–361.
© 2008 *Springer.*

small crystals or thin surface layers. In the last part of this contribution, we will discuss approaches that move away from the traditional inductive detections, like for example the detection of the magnetic force in a magnetic resonance force microscopy (MRFM) scanning probe setup.

Thermodynamics

For a nuclear spin system, the magnetization (or total magnetic moment per unit volume) is given by Curie's law in the limit for high temperatures:

$$M = N\gamma^2\hbar^2 I(I+1)\frac{B_0}{3k_B T}$$

where N is the number of spins per unit volume, γ the gyromagnetic ratio, I the spin quantum number, B_0 the static field, T the temperature, and $\hbar$ and k_B are Planck's and Boltzmann's constant, respectively. For a give nucleus studied at room temperature, one can only manipulate the concentration N or the static field B_0. Technological progress in high-homogeneity magnets has pushed the field limit to 22.3 T (950 MHz). This is near the limit that can be produced with conventional niobium-based superconductors. With high T_c superconductor insert coils, 1 GHz can be reached, but the technological problems in reliability and reproducibility are still substantial. On the other hand, if the samples allow measurements at low temperatures, a substantial gain can be achieved. The equilibrium magnetization at very low temperatures is given by:

$$M = N\gamma\hbar I,$$

since now only the lowest level is occupied. For protons in a field of 14 T at 300 K, the equilibrium magnetization is thus of the order of 5×10^{-5} of the low temperature fully polarized limit. For very small nano-crystals, it therefore pays off to go to special facilities that employ installations with a very high B/T ratio. In various high magnetic field facilities, one typically can reach a base temperature of 40 mK at a static field of 40 T, in which case the low temperature limit is well satisfied. An early example of this approach is given by Gonen *et al.* in 1989 [1]. They showed that it is possible to detect the ^{13}C signal of a chemisorbed CO layer on SnO_2 oxidizing catalyst. Despite the low number of spins in their sample, the low-temperature population enhancement allowed a fully resolved spectrum in a single scan. Note that the spin–lattice relaxation time T_1 may become very long at low temperatures, so this approach is mostly relevant for one-dimensional experiments where no signal averaging or phase cycling is necessary. Also, one often needs to study the material at ambient temperatures, for example in liquid solution, and cryogenic cooling of the sample is not an option.

Polarization Transfer

There are various options to increase the magnetic polarization of the nuclei under study. In typical NMR sequences, one can transfer the polarization from abundant protons with a much larger Zeeman splitting to the low-gamma nuclei such as ^{13}C in a CP experiment. The enhancement factor is typically of the order of the gyromagnetic ratios, and is thus substantial for very low-gamma nuclei. In liquid NMR, many variations of the nuclear overhauser effect (NOE) [2] are used to transfer polarization to for example the ^{13}C nuclei. In general, all these methods rely on the fact that the total (coupled) spin system tries to keep overall thermal equilibrium when one of the transitions is saturated by RF radiation. For example in distortionless enhancement by polarization transfer (DEPT) type experiments, one ^{1}H transition is saturated, leading to a strong enhancement of the ^{13}C resonance (Figure 1).

Another option to beat the thermodynamic equilibrium is to use the hyperfine coupling between electrons and nuclei to transfer effective magnetization from the electrons to the nuclei. Since the electron magnetic moment is much larger than all nuclear moments, one can achieve an appreciable electronic polarization even at ambient conditions. With the method of DNP, one basically saturates the electron spin system with high-power microwaves at the ESR.

In the so-called solid effect DNP [3], one selectively excites the four-level system of the coupled two-spin state (see fig. 2). Effective polarization between the electron and nuclear bath is exchanged in the zero and double quantum transitions, which may have quite different probabilities. In theory, this might give a magnetization enhancement by as much as the gyromagnetic ratio between the electron and the nuclei ($\gamma_e/\gamma_p = 658$). In the solid effect scheme, it is required that the ESR line width is much smaller than the nuclear Larmor frequency. This is not easy to realize in practice and generally the homogeneous and inhomogeneous line broadening is considerable. However, by off-resonance excitation of the ESR transition one can still lower the nuclear spin temperature in a so-called thermal mixing scheme [4]. In practice, an enhancement by a factor of 400 has been demonstrated. The main problem is to find a suitable paramagnetic species that couples to the nucleus but does not disturb the local environment that is studied in the NMR experiment. Also, there is a substantial problem in moving to higher fields, where suitable sub-millimeter sources (above 500 GHz) are lacking. It should be noted, however, that good progress is made by the group of Griffin who have demonstrated the feasibility of DNP-enhanced

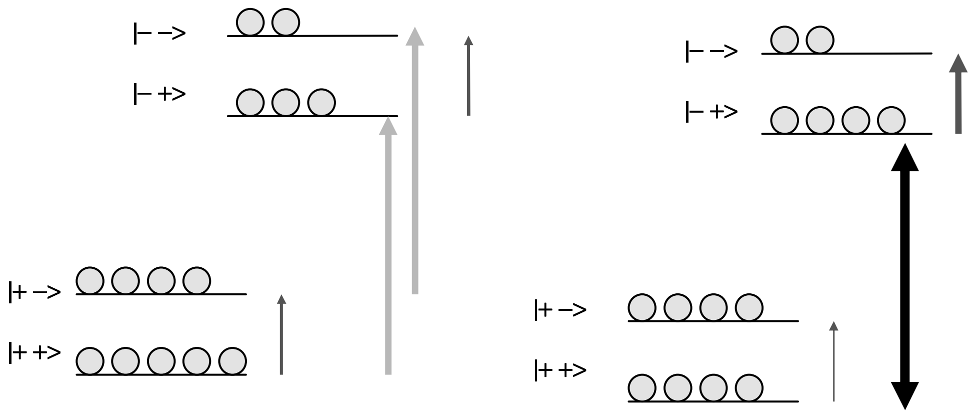

Fig. 1. Illustration of the polarization transfer in distortionless enhancement by polarization transfer (DEPT) type experiments for a system of two coupled spins (^{1}H and ^{13}C). The corresponding NMR resonance signals are indicated by red (^{13}C) and blue (^{1}H), where the linewidth symbolizes the relative intensity. The left side represents the system in thermal equilibrium. If the proton resonance is saturated by the external RF field, indicated by the black arrow, then the spin temperature of the carbon subsystem is cooled, leading to a stronger resonance signal.

magic-angle spinning (MAS) NMR spectroscopy for biologically relevant materials at fields up to 9 T [5]. In high energy physics, fully polarized solid proton or deuterium targets are used to study the spin structure of the nucleon with muon scattering. In this case, a combination of cryogenic cooling (to 40 mK) and DNP is used to create a nearly 100% polarization. Such an approach was also used by Golman and coworkers [6] in order to polarize liquids, which can subsequently be used for metabolic studies in MRI.

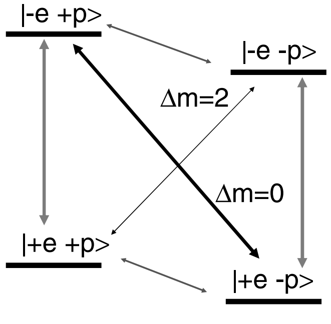

Fig. 2. Illustration of the solid effect dynamic nuclear polarization (DNP). The blue arrows represent the electron spin resonance (ESR) transitions, while the red arrows refer to the nuclear resonance. The cross transitions represented by black arrows are the double quantum (flip–flip) and the zero quantum (flip–flop) transitions that transfer effective polarization from the electron to the nuclear system. Under proper conditions, this can give a nearly 100% polarization of the nuclei.

Half-integer quadrupolar spin systems have multiple spin levels without coupling to other nuclear or electron spins. In spectra of powdered samples, commonly, only the central $-1/2 \leftrightarrow +1/2$ transition is observed, while all other transitions are broadened over a MHz-wide frequency range. It is possible to use either pulses or adiabatic sweeps to invert the population of two adjacent levels [7,8,9]. If this is done simultaneously for both satellite transitions, for example in a so-called double frequency sweep [10] or fast amplitude-modulated pulse train [11], one can increase the population difference between the central levels to that of the outer levels in the multiplet. The procedure is schematically illustrated in Figure 3. For nuclei with spin $I = 3/2$, this can give a threefold increase in intensity for the central transition, and thus a factor 9 reduction in measurement time to obtain the same signal-to-noise ratio [11,12]. For higher spin nuclei like ^{27}Al with spin 5/2, one can get an enhancement up to 5 depending on the details of the adiabatic sweep method. With repetitive sweeps one can transfer basically all the polarization and enhancements near the theoretical maximum are observed in practice [13].

A final trick to induce a nuclear magnetization above the thermodynamic equilibrium is based on the selection rules in optical transitions. In an alkali metal vapor one spin selectively pumps an atomic transition and by spin-exchange collision this magnetization in transferred to a noble gas of ^{3}He or ^{129}Xe atoms [14,15]. This optical pumping can lead to a nearly 100% polarization of the nuclear moment, and because of the very long relaxation times the gas can be transported to the experiment. In medical (lung inhalation) or catalysis (zeolites), the effective

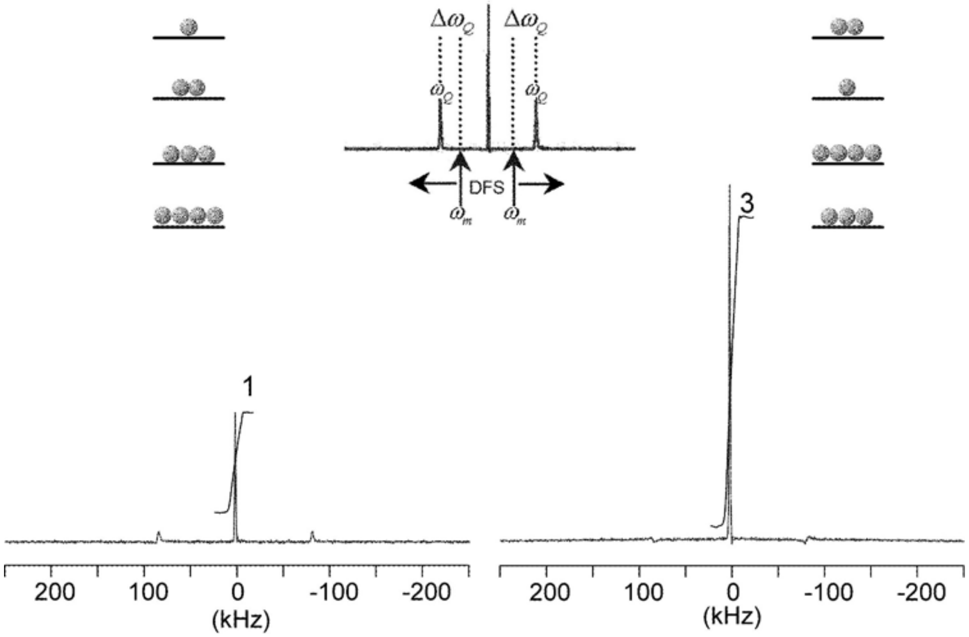

Fig. 3. Illustration of the signal enhancement in a quadrupolar nucleus with spin 3/2. On the left, we have the situation in thermal equilibrium with the experimental spectrum below showing three resonances as expected. The resonances corresponding to the lower and upper transition are considerably broadened. As shown on the right, the population levels can be inverted using adiabatic sweeps. Under proper conditions, this may give a factor 3 enhancement of the intensity in the central transition, and thus nearly a factor of 10 gain in measurement time.

surface area is big enough to allow a reasonable enhancement of the magnetization of the relevant nuclei in the sample. For example it was recently demonstrated by Jansch *et al*. [16] that a single monolayer of hyperpolarized Xe adsorbed on an Ir(111) single crystal surface could be measured successfully by NMR spectroscopy. In this case, the large Knight shift that was observed indicates a large overlap of the conduction electron wave function at the Fermi level of the metal with the Xe atomic states at the surface.

Very interesting from a chemical point of view is the proposition of Bowers and Weitekamp [17–19] to use parahydrogen (p-H_2) in hydrogenation reactions, allowing the detection of reaction products and intermediates with high sensitivity. p-H_2 exhibits a pure nuclear singlet state and is stable even in liquid solutions. Due to the symmetry breakdown of the parahydrogen during hydrogenation reaction typical polarization patterns are observed in the NMR spectra of the hydrogenation products. In a simple AX-spin system, the $|\alpha\beta\rangle$ and $|\beta\alpha\rangle$ spin functions are overpopulated relative to a normal Boltzmann distribution. This gives signal enhancements of some orders of magnitude but typically ranges around a factor of a few thousand. The method is extremely sensitive for the detection of short-lived intermediates and reaction products in small concentrations [20].

Note that one is not restricted to the noble gasses for efficient optical nuclear polarization (ONP). As was first suggested by Kastler in 1952, any two-level spin system can be used for optical pumping [21]. The procedure is illustrated in Figure 4.

Because the optical photon in the beam of circularly polarized light carries an angular momentum of one, the selection rules dictate that only transitions from the ground state with $J = -1/2$ to the excited state with $J = +1/2$ are allowed. Relaxation paths generally leave the angular momentum untouched and the electrons in the excited state relax to the ground state and populate the upper spin level. If there is a spin flip during the relaxation, the electron ends up in the original level, and the pumping scheme can start all over again until virtually all electrons end up in the inverted spin ground state. Since the optical pumping depends on light intensity, one uses powerful laser systems or UV light sources, and a nearly 100% polarization of the electron spins can be achieved in rather short times (typically in the microsecond range) [22,23].

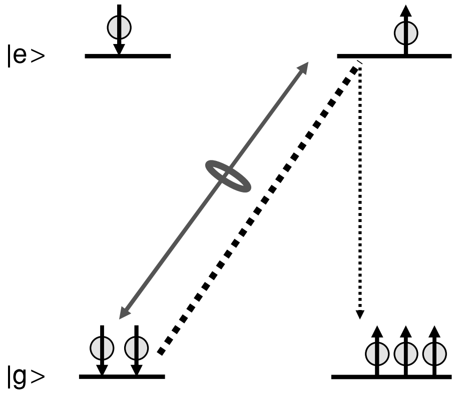

Fig. 4. Illustration of the optical nuclear polarization (ONP) process. With circular polarized light, one can spin selectively pump the transition from the electronic ground state to an excited level. After relaxation, this gives a fast polarization of the ground state electron population. As in the case of NOE, this polarization is then transferred to the nuclear system.

As in the case of DNP, the electron polarization is transferred to the nuclei by the hyperfine coupling and by spin diffusion, polarization is transferred to the molecule under study. Theoretically this could achieve a polarization enhancement of about 4 orders of magnitude. In practice, however, one is limited by the choice of suitable doping molecules, the efficiency of the spin diffusion on the T_1 timescale etc. Also, the optical pumping is most efficient in the low field range and the sensitivity is offset by the effect of the lower B_0 field. In some cases, one can shuttle the sample between low and high field positions, but this does not appear to be a practical solution for all experiments. In special topics, however, this method can be quite useful and for example the NMR spectrum of individual layers in semiconductor quantum wells can be resolved [24]. Note that in ONP, one typically uses optical methods to measure the magnetization as well (ODMR). Since optical photons can be detected with near quantum efficiency, this can be very sensitive and in fact already in 1993 two groups demonstrated that (electron) magnetic resonance of a single molecule can be detected [25,26].

None of the above methods is sufficiently versatile to be employed as a standard enhancement tool. However, in specific cases, these techniques can be very useful and more research is needed to widen the application area into mainstream NMR spectroscopy.

Optimized Detection Coil Design

For solid-state NMR, the most common approach to detect the NMR signals is the inductive detection in a helical coil wound around the sample cylinder. After a 90° pulse, the magnetization rotates in the laboratory frame at the Larmor frequency and the oscillating flux induces an EMF that can be measured in high-sensitivity digital quadrature detection. The noise of high-frequency components like oscillators, mixers, and IF amplifiers is nowadays at such a level that the effective noise in the signal is dominated by the resistive noise in the pickup coil. The signal-to-noise ratio in a typical NMR experiment can be written as: [27]

$$\frac{S}{N} = \frac{k_0(B_1/i)V_s\omega_0\left(1/\sqrt{2}\right)M}{F\sqrt{4k_B T R_{\text{noise}}\Delta f}} \propto \frac{k_0 B_1 V_s}{i\sqrt{R}},$$

where k_0 is a scaling factor accounting for the RF-inhomogeneity of the coil, B_1/i is the magnetic field induced in the RF coil per unit current, and V_S is the sample volume. M is the magnetization as described before. The denominator describes the noise using the noise factor of the spectrometer (F), conductive losses of the coil, circuit, and sample (R_{noise}) for the spectral bandwidth Δf. The main factor that saves the day for inductive detection is the Larmor frequency in the nominator because the time derivative of the magnetic flux through the coil scales with ω_0. As is clear from the right hand side of this equation, the rule of thumb is to make a detector coil with a homogeneous field ($k_0 = 1$), a high field factor B_1/i, and a low resistance R.

As usual there is no single solution to a multitude of problems. In high-resolution liquid NMR, the optimal configuration is that of a saddle coil. This geometry allows the best static field homogeneity and gives sample access along the bore axis of the magnet. However, it comes at a price, since the field factor is generally lower when compared with a helix. (If we consider a cylindrical volume with the length of the cylinder equal to the diameter, then the B_1/i field factor for a saddle coil is only 60% of the helix version). In addition, the length of wire is larger for the saddle coil, making the total sensitivity a factor of three less than the helix version. A similar argument is true for imaging experiments. To have a wide access bore, one cannot use helical coils oriented perpendicular to the field axis. On the other hand, a combination of orthogonal saddle coils can detect the full circular polarized magnetization of the processing spins gaining a factor equal to the square root of two. In MRI, one typically uses birdcage coils that are basically just a series of phase-shifted saddle coils. Also, because the B_1 field gradient is mostly close to the wires or strips that form the saddle coil, one can move to cryogenically-cooled RF coils without losing too much effective space for the sample. In this case, a decrease in temperature (from 300 to 25 K) leads to a factor of 3–4 reduction in noise. Although the helical coil is theoretically more sensitive, this geometry is much more prone to susceptibility effects and unless special matching fluids are used to embed the coil, one sees deterioration in resolution, and for narrow lines therefore also a reduction in sensitivity. In solid-state NMR, this is less of a concern and in this field the helix largely dominates. Note, however, that in experiments where the B_1 homogeneity is essential, one can use only part of the available volume. If we allow a 10% variation in B_1 field, the effective volume is about half the space inside the coil. Given the fact that roughly one half of the magnetic field energy is anyway outside the coil, it is clear that none on the conventional geometries are ideally matched to the NMR problem.

In order to have the best detection sensitivity, one needs to place the detection coil as close as possible to the sample. Put in another way, if we increase the sample volume V, we do not gain a linear increase in signal but as a result of the $1/R$ term in the inductive voltage, we see only a $V^{2/3}$ increase. If we have only a small amount of sample, we have no other option than to scale the detection coil in a proper way. This is the rationale behind various development efforts to produce very small microcoil probes using lithographic or micromachining methods [28–30]. The smallest helical coil that was reported for NMR spectroscopy had a diameter of about 20 μm. When compared with a traditional probe of a few millimeters diameter, this microcoil would give a better sensitivity by about 2 orders of magnitude. It was indeed demonstrated by Seeber *et al.* [31] that with this type of solenoidal microcoils one can attain a sensitivity sufficient to measure the NMR proton signal in a water sample of only 10 femtoliter, or 7×10^{11} spins with a signal-to-noise ratio of 1 in a single scan.

Solid-state NMR probeheads using solenoid microcoils with an inner diameter of 300–400 μm have been implemented for the study of mass-limited solid samples [30]. The performance, in terms of sensitivity and RF-characteristics, of these probeheads was demonstrated for ^{1}H, ^{31}P, and ^{27}Al in different model compounds. The sensitivity is approximately 10^{14} spins/$\sqrt{}$Hz to get a signal-to-noise ratio of 1 in a single scan. A specific advantage of microcoils for solid-state NMR applications is that they can generate extremely high RF-fields if implemented in appropriate circuits. Using RF powers in the hundreds of Watts range, RF fields up to 5 MHz were realized. This allows the excitation of spectra of nuclei whose resonance lines are dispersed over several MHz. This is particularly useful for quadrupolar nuclei experiencing large quadrupolar interactions. This type of microcoil circuitry also proved compatible with double tuning allowing the implementation of double resonance experiments as is shown for ^{13}C CP spectroscopy of glycine in Figure 5 [32].

One of the appealing aspects of lithographically produced RF coils is that it may fulfill the promise of a “lab on a chip” in which the material synthesis and analysis are integrated on a single chip [33,34]. It is even possible to integrate the NMR RF source and data acquisition electronics on the same chip. An additional advantage of the high sensitivity and small volume of the microcoil approach is that one can multiplex the excitation and data acquisition over many different samples in an efficient way. This allows a very high throughput of the instrument (Figure 6) [35].

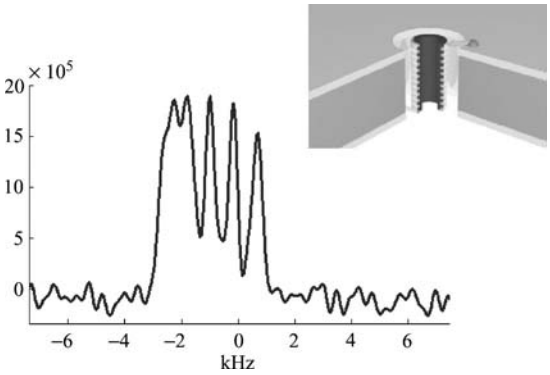

Fig. 5. Static ^{13}C cross-polarization spectrum of a 25% ^{13}C$_2$-enriched glycine sample, containing 6 microcrystals (100 μm)^3 measured in a dual-channel microcoil probe, averaged in 5000 scans. The inset shows the microcoil configuration with the helix embedded in the center of a low loss capacitor to form the resonant LC circuit [32]. (See also Plate 42 on page XXXIV in the Color Plate Section.)

Magnetic Resonance Force Microscopy

A relatively recent method for improving the detection sensitivity of NMR is based on mechanical detection. Although the ideas with respect to the mechanical detection of the magnetic resonance phenomenon were proposed as early as 1964 and its concepts proven in 1967 for electron spins [36], mechanical detection of the nuclear magnetic moment was only achieved much later. The first method that was successfully applied to this end is called magnetic resonance force microscopy as proposed by Sidles in 1991 [37]. It was demonstrated for magnetic resonance detection of electrons by Rugar and coworkers in 1992 [38] and for protons in 1994 [39]. It uses a mechanical cantilever as is known from atomic force microscopy (AFM) to detect forces exerted on a spin system in a very inhomogeneous magnetic field. The deflection of the cantilever can be measured very accurately with sub-angstrom resolution by optical methods. In the most common situation where both the field gradient and the modulated component of the magnetic moment are pointed along the z-axis, we can write the time dependent force $F(t)$ on the sample as:

$$F_z(t) = \int_V M_z(t) \frac{\partial B_0}{\partial z} \mathrm{d}V.$$

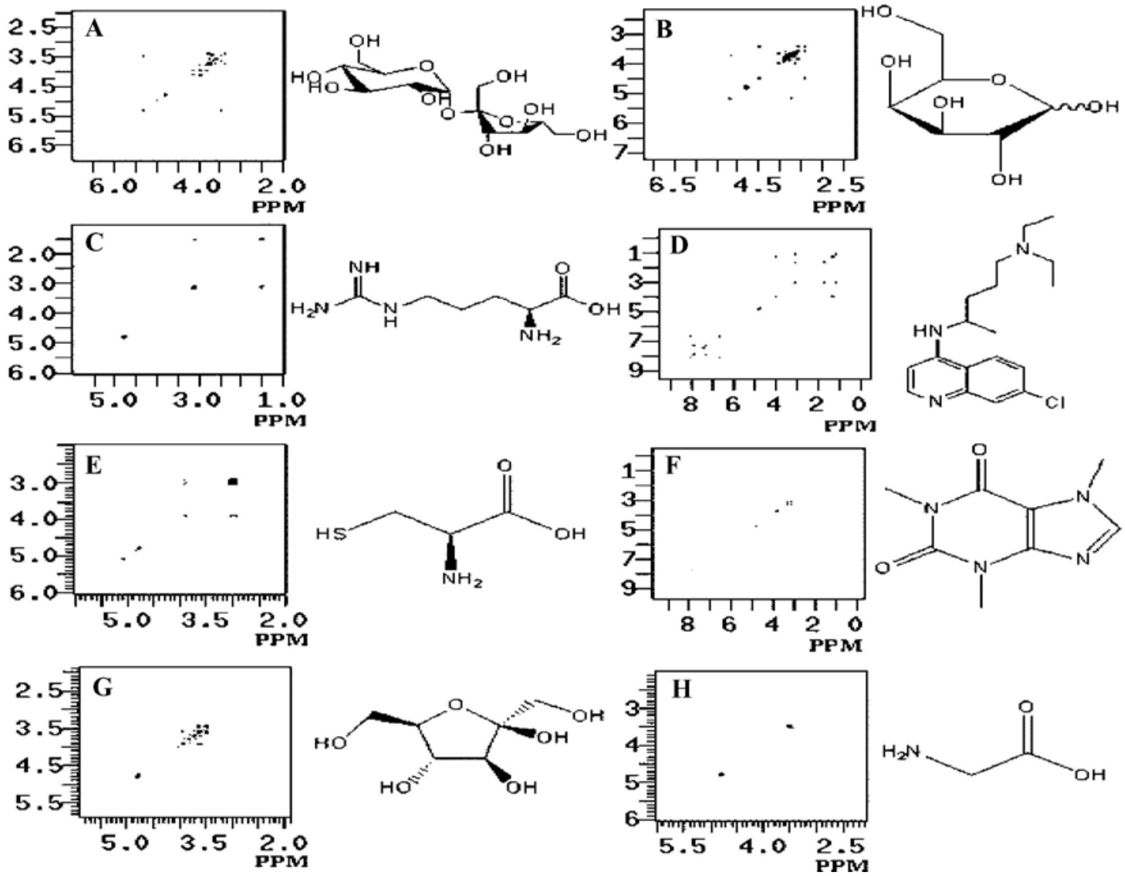

Fig. 6. COSY spectra acquired in a probe with eight microcoils of about 300 μm diameter, resulting in a typical sample volume of 35 nl. The small space required for these capillary sample tubes allows one to measure multiple compounds quasi simultaneously. Each sample (10 mM solution in D_2O) was loaded into the coil via the attached teflon tubes. (A) sucrose, (B) galactose, (C) arginine, (D) chloroquine, (E) cysteine, (F) caffeine, (G) fructose, and (H) glycine. Results are shown corresponding to an averaging of eight scans (reproduced from ref. [35]).

Furthermore, as a result of the presence of the magnetic field gradient, the Larmor resonance condition, $\omega_0 = \gamma B_0$, varies over the sample, i.e. becomes spatially dependent. Thus, we have the option to selectively excite slices from the sample through variation of the irradiation frequency or by altering the position of the magnetic field gradient source. In nuclear MRFM, the gradient field is usually brought about by introducing a small magnetic particle in an otherwise homogeneous magnetic field (B_0). Since this external B_0 magnetic field is very strong, the magnetic particle will be completely saturated.

The main reason for the high sensitivity in the MRFM experiment is the fact that the gradient is introduced by a microscopic particle that is well matched to the small size of the sample. Also, the current densities that mimic the magnetization of a saturated Ferro magnet are much higher than what is common in electrical circuits. Finally, the friction losses in a mechanical resonator are generally much smaller than the resistive losses in a coil, leading to higher Q values of the resonator. For protons, a break-even point is typically reached for samples of a few hundred micrometers in size. In smaller samples, the MRFM method will be more sensitive. For a 10 μm sample in a hypothetical RF coil of 50 μm diameter, the inductive detection limit will be typically of the order of 10^{12} spins in a bandwidth of 1 Hz, corresponding to a concentration of about 1 mol/l. For the same sample size, a mechanical detection at room temperature may give an order of magnitude better sensitivity. The ultimate goal of MRFM is to improve detection sensitivity to the single nuclear

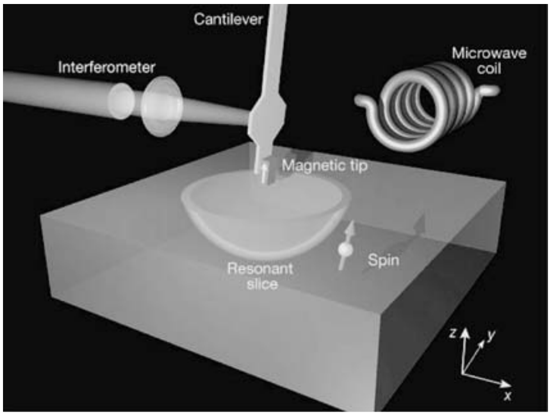

Fig. 7. Configuration of the single-spin MRFM experiment. The magnetic tip at the end of an ultrasensitive silicon cantilever is positioned approximately 125 nm above a polished SiO_2 sample containing a low density of unpaired electron spins. The resonant slice represents those points in the sample where the field from the magnetic tip (plus an external field) matches the condition for magnetic resonance. As the cantilever vibrates, the resonant slice swings back and forth through the sample causing cyclic adiabatic inversion of the spin. The cyclic spin inversion causes a slight shift of the cantilever frequency owing to the magnetic force exerted by the spin on the tip. Spins as deep as 100 nm below the sample surface can be probed (reproduced from ref. [40]). (See also Plate 43 on page XXXIV in the Color Plate Section.)

spin level, and thus enable three-dimensional imaging of macromolecules (for example, proteins) with atomic resolution. MRFM has also been proposed as a qubit readout device for spin-based quantum computers. A breakthrough was established recently when Rugar *et al.* reported the first successful detection of an individual electron spin by MRFM [40]. The spatial resolution that can be achieved in this setup is of the order of 25 nm as demonstrated for an unpaired spin in silicon dioxide (Figure 7).

Despite the impressive detection sensitivity, a few words of caution are in order. First, the experiment is done at very low temperatures where the mechanical noise of the cantilever is very small. At ambient temperatures the noise increases substantially. Combined with the thermodynamic population and the much lower moment of the nucleus as compared to the electron spin, one cannot hope to achieve such ultimate sensitivity in a routine NMR experiment. Moreover, since the very strong local gradient is essential in the detection mechanism, it is not straightforward to do spectroscopy with any significant resolution. On the other hand, it should be able to improve the sensitivity and thus the spatial resolution in a magnetic resonance microscopy experiment by several orders of magnitude. The main challenge in the field is to find suitable methods to combine the superior detection sensitivity of mechanical detection with the high frequency of operation, preferably at the Larmor frequency and without the loss in spectral resolution caused by the static field gradient. A possible solution in this direction was proposed by Weitekamp [41]. In this so-called BOOMERANG configuration, a compensating gradient ring is positioned around the magnetic particle on the cantilever, in such a way that the sample sees a nearly homogenous field (allowing spectroscopy) while the force between cantilever and sample remains.

In conclusion, there are no strict physical laws that prohibit further improvement of sensitivity and there are several paths that lead toward sensitivity optimization in NMR. In fact, there are at least two proven methods to detect a single electron spin and it is conceivable that with further improvements we will see single nucleus detection. Even for the traditional inductive detection, there is no fixed limit and for specific cases we can expect an increase in sensitivity by several orders of magnitude. The bigger challenge is to find ways to improve the sensitivity without compromises to the wealth of information that can be obtained with modern pulsed NMR techniques. The quest for ultimate sensitivity without this in mind may become rather academic. For the near future, the detection method of choice depends very much on the sample shape and characteristics. For small solid-state samples with broad resonance lines, the optimum configuration is probably that of a suitably matched microcoil. In this case, one profits both from the high-sensitivity and the high excitation fields. This configuration can also be used for micrometer scale imaging where one combines the high sensitivity with the ability to produce the large pulsed field gradients that are needed to obtain the required spatial resolution. In the quest for the ultimate imaging resolution, the MRFM technique is clearly at the forefront and true chemical (quadrupolar) contrast may be possible down to the 10–100 nm scale.

This method is particularly suitable for low field applications and low-gamma nuclei. For the ultimate-resolution liquid state NMR, the present method of choice is the cryocooled saddle coil inductive detection. The relatively low concentrations in for example protein solutions do not allow a downscaling to very small coil sizes. In addition, the susceptibility issues connected with (micro)coils very close to the sample are not easily solved and parts per billion resolutions are still to be demonstrated. There are options to restore the full resolution even in inhomogeneous static fields, but these generally lead to lower sensitivities. Sensitivity enhancement methods based on DNP are still in the research stage, with as the main bottleneck the absence of suitable mm-wave sources.

Another niche in NMR spectroscopy is the study of thin surface layers. Methods to achieve a reasonable sensitivity for this configuration are still very much in its infancy, although impressive results have been reported from ONP experiments. There have been some efforts to use *ex situ* methods where the sample is in the projected field outside the actual magnet enclosure. Although the sensitivity can be quite reasonable, the inhomogeneity of the field precludes spectroscopy with any sensible resolution.

Indeed, the main challenge in the field is not so much the search for new physical methods for sensitivity enhancement but to find a practical way to incorporate these methods without compromises to the versatility of modern NMR pulse sequences and with the full spectral resolution that is possible in the modern high field magnets. At present, the low-noise cryoprobe systems have become widely available in many labs. Despite their considerable costs, it is considered to be essential for an improved throughput in liquid NMR research. For online screening or combinatorial chemistry applications, it will become relevant to implement high-sensitivity microcoil probes. Although the susceptibility broadening of the present designs still puts some restraints on the applicability, this does not seem to be an intrinsic problem and the technology for a "lab on a chip" NMR implementation is not far away.

Introduction

Combined rotation and multiple pulse spectroscopy (CRAMPS) [1] is one of a number of techniques for narrowing NMR spectra in solids, the broadening of which in this case is predominantly associated with:

(a) homogeneous homonuclear dipolar interactions in ensembles of spin 1/2 nuclei (e.g. ^{1}H in poly(ethylene) or ^{19}F in Teflon, but not ^{23}Na in NaCl) and
(b) shielding anisotropies.

Rotations in both co-ordinate space [via magic angle spinning (MAS)] and spin space [via radio frequency (rf) pulses] are combined to achieve narrowed spectra. The CRAMPS technique utilizes single quantum coherence and is not used for narrowing broadened spectra of quadrupolar nuclei in solids.

The basic ideas are that:

(a) Coherent averaging [2] is used to attenuate dipolar interactions via resonant cyclic, and periodic multiple pulse excitations over cycle times short compared to the inverse of the homogeneous dipolar coupling, $f_{\mathrm{D}} \equiv \omega^{\mathrm{D}}/2\pi$ and
(b) MAS, with spinning frequency, f_{MAS}, small compared to the cycle times of the multiple pulse sequences (but see the comments under section "Magic angle spinning"), is used to average shielding anisotropies to their isotropic values.

The details of the basic theory and techniques for achieving narrowed lines of spin 1/2 nuclei in one-dimensional experiments utilizing: (a) multiple pulse decoupling and (b) in the limit where spinning frequencies are small compared to multiple pulse cycle times have been presented [3] and reviewed [4].

Theory

Coherent Averaging; Average Hamiltonians in Spin Space

The time-dependent Schrödinger equation is

$$H|\Psi\rangle = i\frac{\mathrm{d}}{\mathrm{d}t}|\Psi\rangle \tag{1}$$

With the density operator defined as $\rho = \overline{|\Psi\rangle\langle\Psi|}$, the bar implying an ensemble average, Equation (1) becomes

$$i\frac{\mathrm{d}\rho}{\mathrm{d}t} = [H, r] \tag{2}$$

The expectation value of any observable, $\hat{O}$ is

$$\langle\hat{O}(t)\rangle = \mathrm{tr}\rho(t)\hat{O}(t) \tag{3}$$

The observable in a pulse NMR experiment is a signal proportional to the decay of magnetization with time, $M(t)$, associated with an oscillating magnetic moment, proportional to the transverse component of angular momentum, $I^{\pm}$ which in turn is proportional to the component of nuclear magnetization perpendicular to the applied static field;

$$M^{\pm}(t) \sim \langle I^{\pm}(t)\rangle = \mathrm{tr}\rho(t)I^{\pm} \tag{4}$$

Such a signal, $M(t)$, observed after some type of excitation which removes the magnetization of the ensemble of spins from its equilibrium state polarized along the static field, is shown at the top of Figure 1. Here the ensemble of protons are in liquid water. The oscillating decays, designated as $M_{x,y}(t)$ are a series of single points taken by a digital recorder at intervals, or "dwell" times, set by the

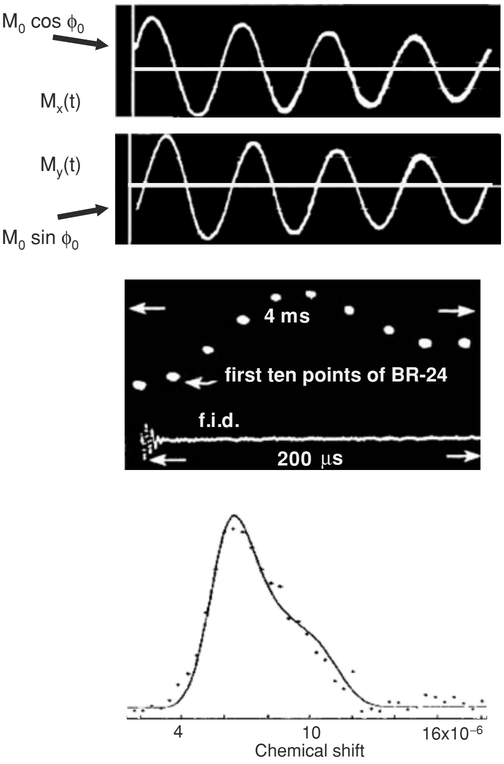

Fig. 1. Examples of the experimental observation of the decay of magnetization, $M(t)$, with time, after various excitations. *Top:* decay of the magnetization of protons in H_2O after a single pulse excitation; absorption and dispersion both shown. While seemingly continuous, these are in fact a series of single points taken by a digital recorder at "dwell" times, set by the experimenter. Here, the dwell was 20 μs, and on the timescale of the photo shown in Figure 1, the plot appears to be continuous. *Center:* First 10 points of the decay of magnetization of protons in linear high density poly(ethylene) (with thanks to Dr. D.L. VanderHart for supplying the sample) observed under homonuclear decoupling by the BR-24 sequence. Below those points, again in the center portion is shown the signal obtained on the same sample, and on the same timescale, after a single pulse excitation. *Bottom:* The shielding tensor of this sample obtained from the Fourier transform of the points under the BR-24.

experimenter. In the case of the top scans in Figure 1, the dwell was 20 μs, and on the timescale of the photo shown there, the plot appears to be continuous.

In the case of the 1-D CRAMPS experiment utilizing multiple pulse decoupling, the signal is observed in the windows between pulses in the cyclic and periodic (*vide* infra) excitations which are used to attenuate homogeneous dipolar interactions among the spin 1/2 nuclei in the ensemble under observation. Such observed points are shown in the center portion of Figure 1. The oscillating decay labeled "first 10 points of BR-24" is that obtained on linear, high density poly(ethylene) under the BR-24 homonuclear decoupling sequence [5] on a static sample. Shown at the top of the center portion of Figure 1 is the digitized decay of the voltage induced by the magnetization of protons in this sample under homonuclear decoupling. Below that decay, again in the center portion of Figure 1, and on the same timescale, is shown the signal obtained on the same sample after a single pulse excitation using a dwell of 0.5 μs. Note that this signal decays in about 10 μs due to dephasing of the magnetization associated with homogeneous dipolar interactions. The bottom plot in Figure 1 exhibits the shielding tensor of ^{1}H in this sample obtained from the Fourier transform of the points obtained under the BR-24.

A physical picture which may be useful in understanding how rf pulses may be used to decouple two-body dipolar interactions from each other results from the fact that the dipolar Hamiltonian between spins i and j is of the form

$$H^{\mathrm{D}}_{i,j} = \omega^{\mathrm{D}}(r_{i,j}, \theta_{i,j})(\hat{I}_i \cdot \hat{I}_j - 3I_{zi}I_{zj}) \qquad (5)$$

Note that the form of $H^{\mathrm{D}}_{i,j}$ is a product of spin, $(\hat{I}_i \cdot \hat{I}_j - 3I_{zi}I_{zj})$, and co-ordinate $(\omega^{\mathrm{D}}(r_{i,j}, \theta_{i,j}))$ space variables. The co-ordinate space portion of $H^{\mathrm{D}}_{i,j}$, designated as the frequency $\omega^{\mathrm{D}}(r_{i,j},\theta_{i,j})$, scales as the product of the magnetogyric ratios of the two nuclei involved, the inverse cube of the internuclear distances, $r_{i,j}$, and the spherical harmonic $(1 - 3\cos^2\theta_{i,j})$. Here, $\theta_{i,j}$ is the angle between the internuclear two-body dipolar vector, $\mathbf{r}_{ij}$, and the axis of quantization, which is set by the dominant static field, $\mathbf{B}_0$. One easily sees two facts from Equation (5):

First is that if the spins are forced to lie along the x, y, and z axes of the spin co-ordinate system for equal times, τ, then since the scalar product is invariant to rotation, the average over time of the term $(\hat{I}_i \cdot \hat{I}_j - 3I_{zi}I_{zj})$ becomes $3\tau(\hat{I}_i \cdot \hat{I}_j - \hat{I}_i \cdot \hat{I}_j)$, or zero. Another way of visualizing this picture is that the spins, on time average, are aligned along the (1, 1, 1) axis of the spin co-ordinate system. In the former case, one uses finite pulses to align the spins along x, y, and z, the basic pulse sequence the "solid echo," or "dipolar echo" sequence [6–8], one form of which may be expressed as $(\tau, 90_x, \tau, 90_y, \tau)$. In the latter case, the spins are first aligned along the (1, 1, 1) axis of the spin co-ordinate system, and then spin-locked there, which is the Lee–Goldburg [9] technique recently resurrected and improved by Vega and co-workers [10].

The solid echo sequence is neither cyclic nor periodic, but has the charm that at time 3τ, the homonuclear dipolar interaction becomes severely attenuated as a perturbation on the Zeeman interaction.

Second is the term $(1 - 3\cos^2\theta_{i,j})$ may also be averaged in time by motion of the sample. In particular, MAS may average this term to zero. The result is that under MAS with spinning speeds appropriately large compared to the magnitude of the interaction being averaged, the shielding tensor is averaged to its isotropic value, σ_{iso}, and the dipolar tensor is averaged to its isotropic value of zero. But since the magnitude of the dipolar interaction, $|H^{\text{D}}_{i,j}|$ can be of the order of 100 kHz and for protons, at least, the magnitude of the shielding anisotropy is generally less than 6 kHz at a proton frequency of 600 MHz, MAS at currently achievable frequencies of $\leq$50kHz rather easily averages shielding anisotropies of protons to their isotropic value, but does not completely average dipolar interactions in sufficiently rigid systems such as linear, high density poly(ethylene). CRAMPS, therefore, utilizing either pulse decoupling or Lee–Goldburg spin-locking, (it must be mentioned that the "MP" portion of the CRAMPS acronym means "Multiple Pulse, so perhaps it is not appropriate to place Lee–Goldberg decoupling under the term CRAMPS, but we are not going to invent new acronyms at this point) both homogeneous dipolar coupling and homogeneous shielding anisotropies are averaged to their isotropic values.

As a variation on the theme of pulse decoupling, the Emsley group has recently developed the technique of random phase decoupling [11]. The technique uses an optimal search scheme on the phases of windowless sequences to maximize resolution and minimize the effects of rf field inhomogeneity, and offers what is perhaps the best resolution to date on strongly coupled solids such as alanine.

Here we consider pulse decoupling with phases, which are not random. Attacking the spin space portion of $H^{\text{D}}_{i,j}$, the dipolar echo sequence, symmetrized to become cyclic, meaning that under this sequence the system is returned to its initial state (in the absence of relaxation) may be expressed as [12] (τ, 90_x, τ, 90_y,τ, τ, 90_{-y},τ, 90_{-x}, τ). A general discussion of constructing symmetrized pulse sequences has been presented by Mansfield [13].

Then in the 2τ windows between the pulse decoupling sequence, the time decay, $M(t)$, at times $t = Nt_{\text{c}}$, with t_{c} being the cycle time for the periodic and cyclic pulse sequences used to average internal interactions, and $N = 1, 2, \ldots$, may be expressed in terms of the density operator at multiple pulse cycle times Nt_{c} . The density operator, $\rho(Nt_{\text{c}})$, is proportional to the expectation value of a transverse component of nuclear angular momentum, $\langle I_{\pm}(Nt_{\text{c}})\rangle$.

$$M(t = Nt_{\text{c}}) \sim \langle I_{\pm}(Nt_{\text{c}})\rangle \sim \text{tr}\rho(Nt_{\text{c}})I_{\pm} \tag{6}$$

and may be expressed via the use of the Magnus Expansion for the propagator associated with internal interactions, $U_{\text{int}}(Nt_{\text{c}}, 0)$. With the definitions

$$i\text{d}U_{\text{int}}/\text{d}t = H_{\text{int}} \cdot U_{\text{int}} \tag{7}$$

and

$$\tilde{H}_{\text{int}}(t) = U_{\text{rf}}(t, 0)H_{\text{int}}U^{+}_{\text{rf}}(t, 0) \tag{8}$$

$$i\text{d}U_{\text{rf}}(t)/\text{d}t = H_{\text{rf}}(t)U_{\text{rf}}(t) \tag{9}$$

we arrive at the result (see Chapter 4 in Ref. [3])

$$\rho(Nt_{\text{c}}) = [\exp\{-i\bar{H}^0_{\text{int}}t_{\text{c}} + \cdots\}]^N \tilde{\tilde{\rho}}[\exp\{i\bar{H}^0_{\text{int}}t_{\text{c}} + \cdots\}]^N. \tag{10}$$

$\tilde{\tilde{\rho}}$ is the density operator as manipulated by the internal, and rf propagators as stated in Equations (7)–(9);

$$\tilde{\tilde{\rho}} = U^{+}_{\text{rf}}(Nt_{\text{c}}, 0)U^{+}_{\text{int}}(Nt_{\text{c}}, 0)\rho(t)U_{\text{int}}(Nt_{\text{c}}, 0)U_{\text{rf}}(Nt_{\text{c}}, 0). \tag{11}$$

Since for cyclic and periodic pulse sequences the system is returned to its initial state at then end of each sequence, $\tilde{\tilde{\rho}}$ may be identified as $\rho(t = 0)$. $\bar{H}^0_{\text{int}}$ is the average Hamiltonian, including in this case, the homonuclear dipolar interaction and the scaled shielding interaction.

$$\bar{H}^0_{\text{int}} = 1/t_{\text{c}} \int_0^{t_{\text{c}}} \text{d}t\,\bar{H}_{\text{int}}(t) \tag{12}$$

and $\bar{H}_{\text{int}}(t)$ is the internal Hamiltonian, in this case dipolar plus shielding, as manipulated by the rf pulses [see Equation (8)].

In the quasi-static limit, $f_{\text{s}} \ll (1/t_{\text{c}})$, under, e.g. the cyclic and periodic MREV-8 homonuclear decoupling sequence, at cycle times $Nt_{\text{c}} = 12\tau$ for appropriately short rf pulses, the time average of the magnitude of the dipolar Hamiltonian, $1/t_{\text{c}} \int_0^{t_{\text{c}}} \text{d}t\,\bar{H}_{\text{D}}(t)$, becomes severely attenuated compared to $|\text{H}^{\text{D}}|$. The condition that the rf pulses, with field strength $|\mathbf{B}_1| \equiv \omega_1/\gamma$, are able to "manipulate" H_{D}, the magnitude of which scales as ω_{D}, is that $|\omega_1| \gg |\omega_{\text{D}}|$. This means that the cycle times t_{c} must be short compared to $(|\omega_{\text{D}}|)^{-1}$. For $t_{\text{c}} \ll (2\pi/|\omega_{\text{D}}|)$, there is effective homonuclear decoupling.

As we will see in section "Applications," for cycle times greater than the inverse of the dipolar frequency, i.e. for $t_{\text{c}} \gg (2\pi/|\omega_{\text{D}}|)$, coherent averaging of H_{D} is destroyed. This means that with appropriate adjustments of t_{c}, experimental conditions such as receiver gain and cycle time, a minor, mobile species can be detected independently of the major, solid component, with negligible signal from the probe background, to an accuracy of $\leq$0.01

mol.% in the cases of some organic solids crystallized from solution (*vide infra*).

Scaling Under Pulse Sequences

A phenomenon important to understanding how the data taken under a multiple pulse experiment may be compared with data from a single pulse excitation is that of scaling. In the presence of a magnetic field of $\mathbf{B}_0$ magnetic moment with magnetogyric ratio γ will precess at a frequency $\omega_0 = \gamma|\mathbf{B}_0|$. Under series of resonant pulses in the rotating frame, the magnetic moments precess under the effective field. For example, under the cyclic and periodic flip-flop sequence, $(\tau, 90_x, \tau, 90_{-x})$, the response of protons in water is shown in Figure 2. With an average Hamiltonian for an offset $\Delta\omega$, under the flip-flop cycle being

$$\bar{H}^0_{\text{flip-flop}} = (\Delta\omega/2)(\mathbf{k} - \mathbf{j}), \qquad (13)$$

with $\mathbf{k}$ and $\mathbf{j}$ being unit vectors along the z and y axes in the Zeeman frame of the spins, the effective field in the rotating frame is $|\Omega| = \Delta\omega/\sqrt{2}\gamma$, so the scaling factor in this case is $1/\sqrt{2}$. This means that in the frame of observation, the magnetization under the flip-flop cycle will precess more slowly by roughly a factor of 0.7 than the response under single pulse excitation as seen in Figure 2.

Under the MREV-8, the scaling factor is $\sqrt{2}/3$ for perfectly short pulses with no phase errors. The details of the treatment for non-ideal pulses are given in Chapter 5 of Ref. [3].

The manner in which the scaling factor is experimentally determined is discussed here in section "Experimental".

Magic Angle Spinning

As shown by Lowe [14] and Andrew *et al*. [15], under physical rotation of a sample at an angle to the static field of 54.74°, the chemical shielding anisotropy and homonuclear dipolar interactions between spins 1/2 are averaged to their isotropic values at spinning frequencies, f_{rot} sufficiently greater than the line-widths of these two interactions. This is to say that an interaction the coordinate space portion of which scales as $(1 - 3\cos^2\theta)$ can be averaged to its isotropic value by sufficiently fast spinning at the magic angle. Since the isotropic value of the dipolar Hamiltonian between spins 1/2 has zero value, in principle, CRAMPS is not needed to remove this interaction. In fact recent studies [16] on protons in mesoprous silicas with spinning frequencies ≥40 kHz have shown that pulse decoupling is unnecessary for high resolution NMR of ^{1}H in such samples. The development of relatively high spinning speeds [17] up to 70 kHz has therefore to a certain extent made the use of CRAMPS

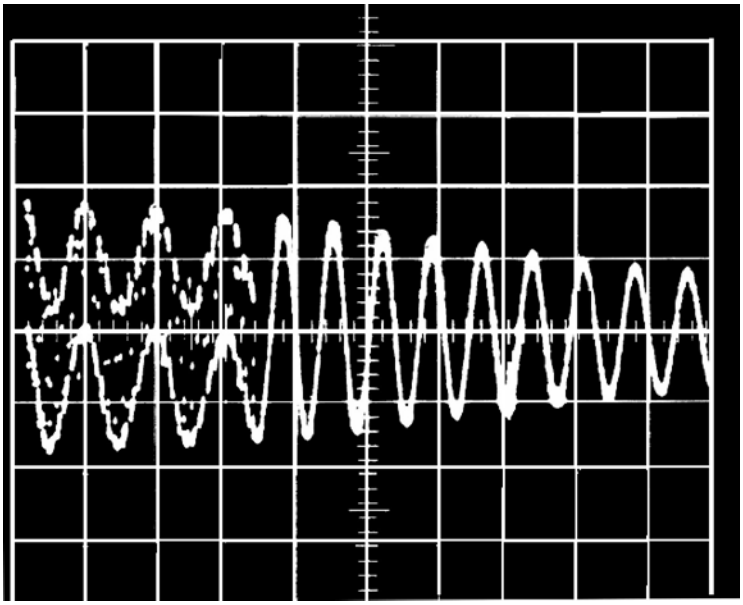

Fig. 2. Time decay of protons in water under the flip-flop cycle $(\tau, 90_x, \tau, 90_{-x})$, and a resonance offset $\Delta\omega$, (left side of figure), and under the same offset in the absence of the pulse sequences (right side of the figure). With an average Hamiltonian for an offset $\Delta\omega$, under the flip-flop cycle being $\bar{H}^0_{\text{flip-flop}} = (\Delta\omega/2)(\mathbf{k} - \mathbf{j})$, the effective field in the rotating frame is $|\Omega| = \sqrt{2}\Delta\omega/2$, so the scaling factor in this case is $1/\sqrt{2}$. This means that in the frame of observation, the rotating frame, the magnetization will precess more slowly by roughly a factor of 0.7 as seen in the figure.

for simply narrowing proton spectra in many solids unnecessary. At the time of writing, probes achieving such spinning speeds are not generally available. But there still exist systems, e.g. high-density linear poly(ethylene), in which the dipolar frequency can be as high as 100 kHz, so fast MAS to achieve high-resolution proton spectra would not work in that case.

We now become more explicit about the physics implied in the term "quasi-static" limit. In the case of CRAMPS, the movement of the sample can destroy the experiment if the dipolar interaction becomes time-dependent on a scale similar to the cycle time of the multiple pulse sequence attacking H^{D}. For example, a multiple pulse cycle time of 30 μs would imply that the spinning frequency $f_{\mathrm{rot}} \ll (10^{-6}/30)\mathrm{s} = 30\,\mathrm{kHz}$. Practically, rotation speeds of 4–6 kHz are easily achieved and at static fields in which the shielding anisotropies of the protons studied are ≤ 10 ppm (which is 3 kHz at a resonant frequency of 300 MHz), the CRAMPS experiment works well.

However, the development of commercial probes in which spinning speeds can routinely be in the neighborhood of 45 kHz has led to considerations of how to combine pulse decoupling with MAS outside of the quasi-static regime. The implications of this development are discussed in the next section.

Two-dimensional Experiments

If one wishes to achieve a higher resolution for NMR of strongly coupled spin 1/2 nuclei than is available from one-dimensional CRAMPS, e.g. in relatively rigid solids containing carbon bound to hydrogen, and is willing to give up the time needed for gathering of data in two dimensions, one ties the resolution of the proton lines to that of the carbon lines via 2-D HETCOR. Here, because the resolution of the proton signal is tied to that of the carbon, the proton signal being obtained from the t_2 domain in the 2-D experiment, there is no reason to be concerned with ring-down and windows in which to observe the proton signal. In fact, with appropriately high sample spinning speeds, on relatively mobile samples, e.g. protons in some mesoporus silicas, there is no need to use pulse, random phase, or spin-lock decoupling at all.

As stated above, adding a second dimension to any NMR experiment adds time to the acquisition of data. It is therefore to great advantage to achieve as high a sensitivity as possible with a maximum magnetic field. The sensitivity of detection is roughly proportional to the three-halves power of the static field. Along with higher fields comes, however, a relative problem. This is that to avoid the problem of sidebands without using some scheme such as rotor synchronization, which limits the dwell to the inverse of the rotor period, the spinning speed must be maximized.

The fact that the dipolar interaction re-focuses every 180° of the sample's physical rotation has been used by Hafner and Spiess [18] to combine the timing of pulse sequences in such a manner that the dipolar interaction is attenuated to a certain extent by the spinning, and pulse sequences then used remove the residual broadening, and the results utilizing relatively slow spinning are recovered.

Experimental

General

We limit our discussion here to the CRAMPS experiment under the quasi-static limit, which is easily achieved, even with spinners capable of 70 kHz spinning speeds, if they are capable of stable spinning at 3–6 kHz.

When the CRAMPS technique was initially performed, the stability of transmitters, of the pulse widths controlled by the pulse programmers, and of the phases in the rf unit, were such that quite careful tuning was required for a successful experiment. These factors seem to have led to the mythology that the CRAMPS technique was for the initiated only, and not worth taking the time.

Fortunately, with the advent of modern spectrometers with relatively stable amplifiers, digital control of phases, and nanosecond control of pulse widths, obtaining CRAMPS spectra of protons even in the most rigid of strongly coupled systems (e.g. high-density linear poly(ethylene) and adipic acid; see the bottom of Figures 1 and 3) is now relatively easy if one has a reasonable grip on the experimental and theoretical foundations of the experiment, and quite reasonably possible even if one has not.

Spectrometer Requirements; the Probe and Receiver

Modern spectrometers suitable for NMR of solids, e.g. those supplied by Bruker, JOEL, and Varian, have the capabilities for power, timing, phase control, pulse programming, and sample rotation suitable for the CRAMPS experiment. The place where care must be exercised is in the receiver and probe ring-down.

To illustrate what is needed, consider an ensemble of protons in a solid in which the internuclear distance is similar to that in high-density poly(ethylene), leading to a homogeneous line-width of $\delta\omega/2\pi \approx 100$ kHz (see the time decay in the central portion of Figure 1 taken under a single-shot excitation). Those data were taken with an MREV-8 cycle time of 21 μs, meaning that $12\,\tau = 21$ μs, $\tau = 1.75$ μs, and the data were accumulated in the

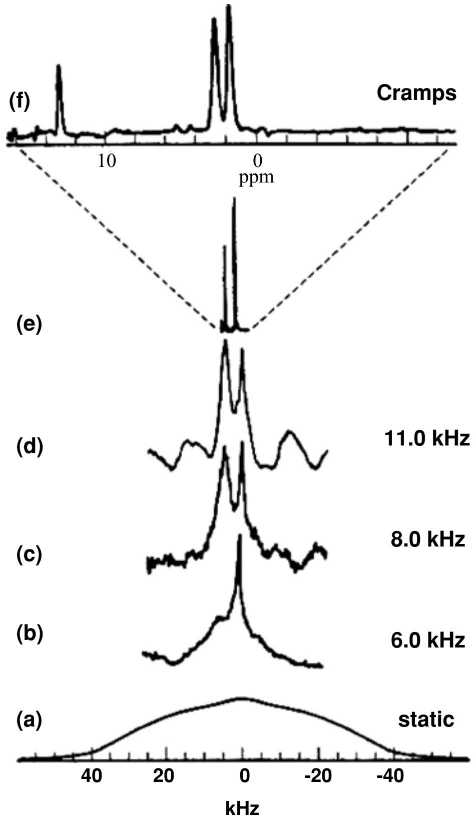

Fig. 3. Comparison of narrowing of proton spectra in the strongly coupled protons in adipic acid (HOOC–$(CH_2)_4$–COOH) under:

With thanks to Gary Maciel for the figure.

$2\tau = 3.5$ μs windows of the sequence. With pulses of 500 W, and pulse widths of 1 μs, into a probe with impedance 50 Ohms, implying a p–p voltage of about 160 V, the time needed to ring-down this voltage to 10^{-7} V is 3.3 μs. The value of 10^{-7} V is what one wishes to have to keep the receiver happy. This ring-down time is approximately 21 $Q/3f$, where f is the resonant frequency in Hz and Q the quality factor of the probe. $Q \cong (f/2\Delta f_{\text{res}})$ where Δf_{res} is the width of the tuning curve of the probe at resonant frequency, f_{res}. For example, at a resonant frequency of 300 MHz, a tuning curve with a half-width of 1 MHz would have $Q \cong 150$. We wish for the receiver to be able to take data for at least 0.2 μs at the end of the window of 2τ. This means a total ring-down of $3.5 - 0.2 = 3.3$ μs. So for a spectrometer operating at 300 MHz, a requisite probe Q is calculated as follows:

$$\begin{aligned} 3.3\times10^{-6} &= 7Q/f = 7\times3.3\times10^{-9}Q \\ &\Rightarrow Q = 140. \end{aligned} \tag{14}$$

This is a reasonable Q for a solid-state probe, but unusual for a probe set to receive signals from liquids where the dwell is allowed to be of the order of ≥ 20 μs.

In addition, the receiver must be protected during the high power pulses, and in such a manner that the voltage between each stage of the receiver must be arranged to ring-down so that there is ample time in the 2τ windows for each stage to receive signal. One such scheme is presented on page 222 of Ref. [3]. To the author's knowledge all of the instrument producers of solid-state NMR spectrometers are able to meet the above requirements in receivers and probes.

Tuning to Maximize Resolution; Pulse Impurities

One further point about probe tuning deals with what might be described the "art" (but is well understood analytically, as discussed in pp. 177–82 of Ref. [3]) deals with pulse impurities.

A pulse of rf may be thought of as a continuous wave of rf multiplied by a window function. For pedagogy, we consider only a rectangular window, as illustrated in Figure 4. The frequency domain fingerprint of such a window function is a sine function, $\sin x/x$, which contains many frequencies. The envelope also oscillates. Therefore, at the

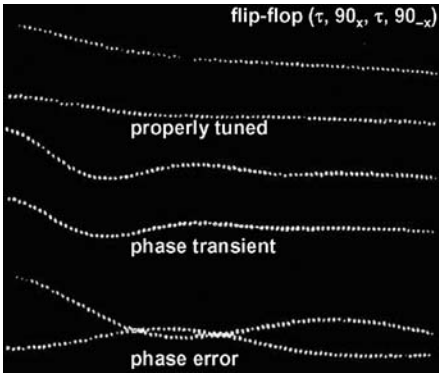

Fig. 4. Response of protons in water under the flip-flop tuning cycle. *Top:* Properly tuned. *Middle:* Phase transient present. *Bottom:* Phase error present.

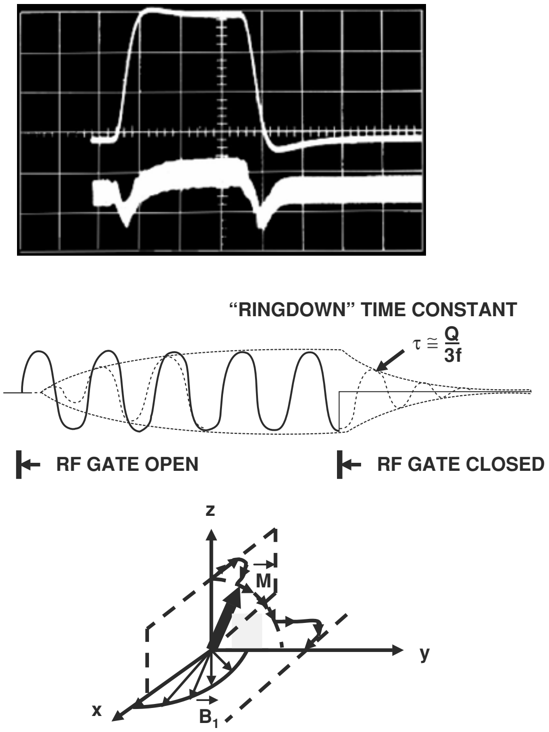

Fig. 5. The phase-detected envelope of an rf pulse. *Top:* upper trace, the in-phase component. Lower trace, the out of phase component, with increased gain of the oscilloscope channel used for detection. *Middle:* Comparison of the response the signal under a "square-wave" envelope with that associated with ring-up and ring-down. Note that both frequency and phase impurities are present during the transient periods after turn-on, and turn-off. *Bottom:* vector picture of the magnetization associated with the phase transients.

turn-on and turn-off periods of the pulses, there are both phase and frequency transients. The phase transients may be viewed as being orthogonal to the broadcast phase, i.e., an "*x*" pulse, will have "*y*" components during the ring-up and ring-down times. This idea and the experimental evidence are illustrated in Figure 5. It is necessary to minimize the cumulative effects of these "impurities" for maximum resolution under the CRAMPS experiment. One method is to slightly de-tune the probe to achieve maximum decay time for the sample under investigation. Because a slight de-tuning also affects the pulse widths, it is necessary to iterate the de-tuning with a check on pulse widths. Another, perhaps preferable method (personal communication Drs. Charles Bronnimann and Jim Frye, Varian, Inc., 12-29-04) is to place variable—length transmission lines in the nominally quarter-wave length portions of the transmission and receiving part of the circuitry (see Figures 5–24 in Ref. [13]) in order to maximally damp frequencies other than the carrier and vary the length to achieve maximum resolution. The procedure is described in "Commonly Run Solids NMR Experiments" which can be downloaded as a .pdf file from Varian's web site, under User Pages "list of manuals title (alphabetical)" or "list of manuals by part number," manual #0199907600A.

Determination of the Scaling Factors

As may be inferred from Figure 2, the Fourier transform of the decay shown there will yield peaks at two different frequencies. The difference between these immediately supplied the scaling factor under the flip-flop cycle. In the CRAMPS experiment, the difference in the frequencies of protons in water under a number of different offsets, generally 1 kHz apart, summed to produce a spectrum of peaks 1 kHz apart under an offset using a given homonuclear decoupling pulse sequence, compared to the experimental offset used to produce that signal immediately yields the scaling factor. It is an interesting fact that the scaling factor depends upon the offset [19], and this fact must be taken into account for each resonance detected under the CRAMPS experiment when applying a scaling factor to a given sample.

Applications

CRAMPS in One Dimension

After it became clear that pulse NMR could be a powerful tool for probing identities of protons in coals, the first applications of CRAMPS were the determinations of high-resolution proton NMR of coals [20–25], and in polymers [26]. The CRAMPS spectra of ^{1}H in coals, which accompanied by high resolution of carbon in these systems, were used to infer aromaticity, and the average sizes of aromatic rings in the systems studied. The spectra of polymers, with varying cycle times, were used to infer amorphous fractions of polymers. Later applications were to determinations of structures of biological solids [27–32], and of environments of protons in silicas [33].

Finally, most recently at the time of writing [34], 1-D CRAMPS, with varying cycle times to selectively detect rigid and mobile portions of the sample, has been used to provide quantitative and qualitative determinations of solvents occluded during the process of crystallization in organic solids, to an accuracy of ≤ 0.01 mol.%. The fascinating part of this experiment is the lovely match between experiment and theory, in that if $t_c \ll (|\omega^D{}_{\text{solid}}|)^{-1}$, the solid portion of the sample is detected. With the mobile impurity being of the order of 0.01 mol.%, this portion contributes negligibly to the observed signal under CRAMPS. If $(|\omega^{\mathrm{D}}_{\mathrm{solid}}|)^{-1} \ll t_{\mathrm{c}} \ll (|\omega^{\mathrm{D}}_{\mathrm{mobile}}|)^{-1}$, and the gain increased appropriately relative to the gain used to detect the major, rigid component, only the relatively mobile portion of the sample is detected. Since only signal of the sample inside the inductor contributes to the signal under CRAMPS, the observed signal of the mobile portion contains essentially no signal from the protons in the probe. Figure 6 illustrates how the observed signal under CRAMPS detects the rigid component for $t_{\mathrm{c}} \ll (|\omega^{\mathrm{D}}_{\mathrm{solid}}|)^{-1}$, changes gradually as t_{c} is increased, and finally detects only the mobile portion when the inequality $(|\omega^{\mathrm{D}}_{\mathrm{solid}}|)^{-1} \ll t_{\mathrm{c}} \ll (|\omega^{\mathrm{D}}_{\mathrm{mobile}}|)^{-1}$ is satisfied.

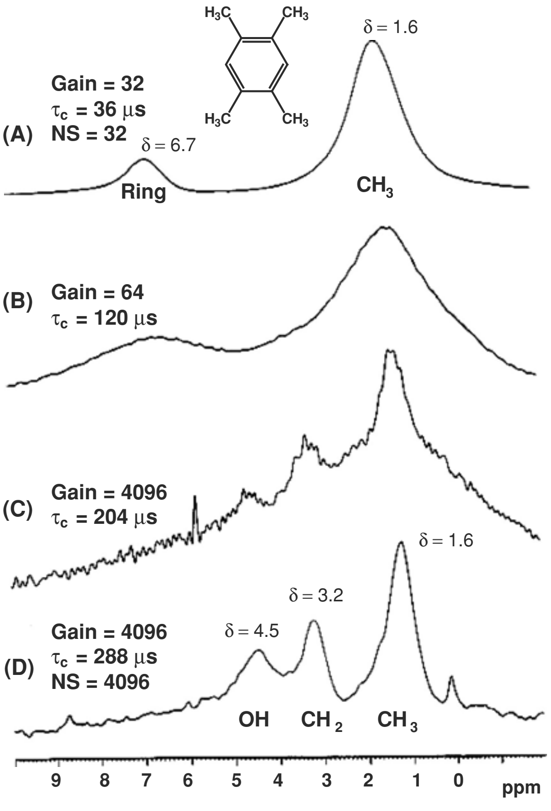

Fig. 6. NMR Spectrum of durene crystallized from ethanol under CRAMPS using the MREV-8 sequence, with varying cycle time t_{c}, and varying receiver gain. Spinning frequency is 5 kHz. At a cycle time of 288 μs, only the mobile portion, representing durene dissolved in ethanol, is seen. At a cycle time of 36 μs, only solid durene is observed. As the cycle time is increased from 36 to 288 μs, the line broadens, averaging of the dipolar interaction for the rigid portion is destroyed, and finally, only the mobile portion is detected.

CRAMPS in Two Dimensions

The addition of a second dimension to experiments involving homonuclear decoupling of protons, along with excitation of a second nucleus (excepting protons in the case of proton–proton HETCOR) has the usual disadvantage of added time for accumulation of signal. But the advantage is that, at least in heteronuclear HETCOR, the signal from protons (or fluorine) is observed in the t_2 domain of the 2-D experiment. Therefore, there is no need to have the exacting conditions for ring-down and probe tuning optimizing the 1-D experiment. In addition, windowless sequences [11,35] may be used such that the limitations involved in the requirements of the quasi-static condition for pulse decoupling, when used with rotor-synchronized pulse sequences, allow for 2-D ^{13}C–^{1}H HETCOR with spinning speeds much higher than that used in the 1-D CRAMPS discussed above.

As a final remark, we note that all techniques of detection described above utilize single quantum coherence for the narrowing and detection of spin 1/2 nuclei in solids. For narrowing and detection of half-spin quadrupolar nuclei, e.g. ^{23}Na and ^{27}Al, combinations of multiple pulse excitation and MAS utilizing multiple quantum coherence have been used [36].

Acknowledgments

The authors appreciate the invitation from Professors Ando, Saito, and Asakura to submit this article. We acknowledge the use of the facilities of the Chemistry Department at Iowa State University. Careful readings of the manuscript by Drs. Marek Pruski, Jim Frye, and Charles Bronniman were greatly appreciated. We are especially grateful to Drs. Bronnimann and Frye regarding information on minimizing the effects of phase transients on the CRAMPS experiment. The authors have attempted to fairly represent the work of all major contributors to this area of technology, but nevertheless make the apology regarding the excess of references to our own work which mirrors that which Thoreau made about his own writing. *If I knew other's lives as well as I do mine, I should write about them as well.*

Mobile NMR

B. Blümich and F. Casanova
Institute of Technical Chemistry and Macromolecular Chemistry, RWTH Aachen University, Germany

Introduction

The widespread use of NMR in materials testing is hampered by the fact that the object needs to be carried to the NMR equipment and needs to fit inside the magnet [1]. Both limitations are removed by mobile unilateral NMR at the expense of a lower and inhomogeneous magnetic polarization field [2]. Originally, open sensors were developed by the well-logging industries [3]. There, transverse relaxation decays are measured from the fluids in the porous formation with a spectrometer positioned inside the borehole. For well-logging sensors, the field gradient is minimized in a sweet spot or adjusted to a small value so as to eliminate signal attenuation from translational diffusion for short echo times [4–6]. Parallel to the development of the first well-logging tools, the first unilateral sensors were developed mostly for measuring moisture in soil, bridge decks, building materials, and food [7–12]. Some of these instruments employed electromagnets weighing several hundred kilograms. As long as solid materials including rubber are investigated even large field gradients can be tolerated as diffusion is absent. This is the idea behind the NMR-MOUSE, which operates with permanent magnets at frequencies between 10 and 20 MHz with magnetic field gradients up to 20 T/m (Figure 1) [13–16]. The NMR-MOUSE weights less than 1 kg, but is limited to depths typically less than 15 mm.

With the commercialization of well-logging instruments and the availability of the NMR-MOUSE about 10 years ago, the NMR methods for use in inhomogeneous magnetic fields were systematically developed [17–24]. A variety of open magnet geometries are currently being explored for portable use [25–32]. For investigation of large objects, open magnets are fitted with surface coils that provide a magnetic radiofrequency (rf) field $\boldsymbol{B}_1$ [15,16,33]. The volume outside the magnet, where $\boldsymbol{B}_1$ exhibits perpendicular components to the polarization field $\boldsymbol{B}_0$, is the sensitive volume of the sensor. A unilateral NMR sensor essentially selects the signal of a pixel from the object, the size of which is defined by the sensitive volume. A recent development complementary to unilateral NMR devices is lightweight and comparably inexpensive, cylindrical magnets in the Halbach geometry constructed from many small blocks of permanent magnets [34,35]. Such magnets are suitable for studying pipe flow, geophysical drill cores [36], and plants at the site of the object.

Measurement Methods

The open magnets used for unilateral NMR exhibit inhomogeneous magnetic polarization fields $\boldsymbol{B}_0$. When positioned on a large object the response bandwidth is always much larger than the excitation bandwidth, and any excitation is selective [24], a situation encountered also in stray-field NMR imaging [18]. In addition, the surface coil provides an inhomogeneous rf field $\boldsymbol{B}_1$, so that the flip angle of an rf excitation pulse varies across the sensitive volume. Most methods known from NMR in homogeneous fields can be adapted for use in inhomogeneous fields, but need to be reevaluated to account for selective excitation and the flip-angle distribution.

Transverse relaxation decays are readily measured by Hahn echoes and CPMG echo trains (Figure 2a) [37–39]. Due to the flip angle distribution, Hahn and stimulated echoes are generated in a CPMG train, and different coherence pathways need to be discriminated [23]. One striking manifestation of this is, that the first echo in a CPMG train is always lower than the second [18–21]. But also, the echo envelope decays slower than in homogeneous fields, so that effective relaxation times $T_{2\text{eff}}$ are measured in inhomogeneous fields.

Similar to the different variables that define the pixel amplitude in an NMR image [1], parameters and parameter-weighted spin densities can be extracted from the signal measured by the NMR-MOUSE (Figure 2b). Parameters are obtained by fitting the relaxation decay with a model function such as the stretched exponential function [40], or a parameter-weighted signal is obtained, for example, by forming the ratio of the signal at a given decay time with the signal amplitude at decay time zero. To improve the signal-to-noise ratio, several echo amplitudes are added in a defined time interval instead of just taking one amplitude value, for example, $w(0,\ t_1,\ t_2,\ t_3) = I(t_2,\ t_3)/I(0,\ t_1)$. Furthermore, relaxation decays with sufficiently good signal quality can be inverted to distributions of relaxation times by a regularized inverse Laplace transformation (Figure 2c), a procedure which is routinely applied in NMR well logging

to facilitate data interpretation [3]. Parameters other than those referring to transverse relaxation can be measured as well but not directly in inhomogeneous fields. To this end the initial magnetization probed by a CPMG train is prepared for example, by a saturation or inversion recovery T_1 filter [41–43], a multi-quantum filter [44,45], chemical shift [46,47], space encoding [48–51], flow encoding [52,53], or a diffusion filter (Figure 2d) [54–59], and the filter parameter is varied systematically in successive scans [55]. To improve the signal-to-noise ratio, successive echoes of the CPMG train employed for detection can be added. Single-shot encoding of diffusion and flow can be achieved by selection of suitable coherence pathways in multi-echo experiments [60,61].

Using such two-dimensional (2D) methods, a unilateral sensor can be employed for imaging (Figure 3) similar to a magnifying glass to measure, for example, an image of a defect in a textile-reinforced rubber hose (Figure 3c) and the axial velocity image of laminar water flow through a pipe (Figure 3e and f). In this case, the image and flow information is encoded in the detected magnetization by preparing the initial magnetization with pulsed linear gradient fields, which are generated with additional coils fitted to the unilateral sensor [48–53]. Images and profiles involving the depth direction are constructed from several data sets acquired for subsequent slices through the object.

For a long time it has been accepted that chemical shift cannot be measured in inhomogeneous $\boldsymbol{B}_0$ fields. However, this is not so, as has been demonstrated recently in high field with experimental 1D and 2D spectra [46,47]. The currently most successful approach to acquire chemical-shift-resolved spectra in inhomogeneous fields employs mixed echoes with dephasing and rephrasing evolutions in $\boldsymbol{B}_1$ and $\boldsymbol{B}_0$ fields with matched inhomogeneities (Figure 4a) [62]. The evolution in $\boldsymbol{B}_0$ depends on the chemical shift and the one in $\boldsymbol{B}_1$ does not. As a result, the amplitude of the mixed echo is modulated by the chemical shift. For example, a low-field ^{19}F NMR spectrum (Figure 4b) of a mixture of two perfluorinated solvents can already be measured with a unilateral sensor with a resolution better than 10 ppm in just 3 min [63]. However, the sample needs to be small and accurately positioned in the small region where the fields are matched. Unilateral NMR spectroscopy will be of most use for materials analysis, where high-resolution solid-state spectra of ^{1}H or even heteronuclei are needed, and it is a current challenge to develop adequate methods that include line narrowing [64,65].

Fig. 3. Unilateral imaging and flow NMR. The object to be investigated, a rubber pipe (a) or a tube with flowing water (d) is placed on the sensor, here a 36 kg magnet with a field of view of $40 \times 40 \times 20\ \text{mm}^3$. With pulsed gradient fields and phase encoding techniques, the image (c) of the defect in the tube (b) was obtained in 2 h with a spatial resolution of 0.7 mm in each dimension. Similarly, flow images (e, f) can be obtained, here for laminar water flow through a circular pipe (d). Images across depth are constructed from data acquired with multi-slice techniques.

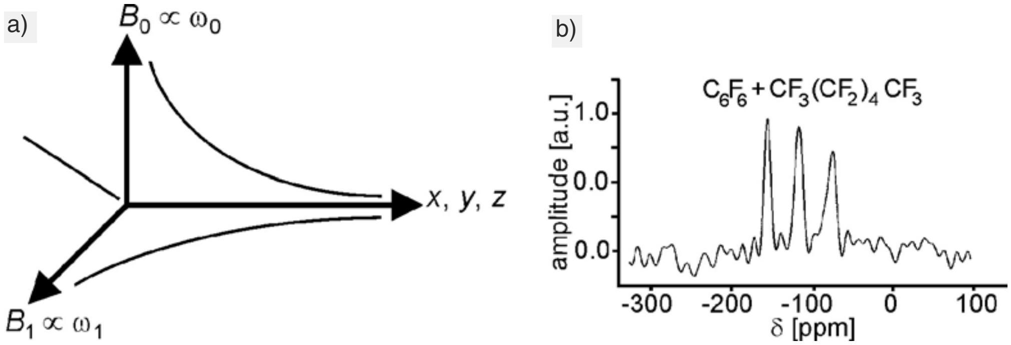

Fig. 4. Chemical-shift resolved spectroscopy in inhomogeneous fields. By matching the precession of magnetization in the inhomogeneous polarization field $\boldsymbol{B}_0$ to the precession in an inhomogeneous rf field $\boldsymbol{B}_1$, chemical-shift resolved spectra can be obtained by unilateral NMR. (A) Principle of matching $\boldsymbol{B}_0$ and $\boldsymbol{B}_1$ profiles in space. (B) NMR spectra of fluorinated solvents acquired *ex situ* of the magnet.

Applications

The most attractive applications of portable NMR are with unilateral NMR in materials science. But portable NMR is also being used with earth field instruments to study sea ice in Antarctica [66–68], and a Halbach magnet has recently been used to study naturally wet rock core samples at a geological drilling site (see below) [36]. A few illustrative examples of portable NMR are given in the following.

Soft matter can readily be studied by NMR as is demonstrated by the great success of medical imaging which maps biological soft matter. Rubber is synthetic soft matter from cross-linked macromolecules with a number of additives and fillers like carbon black. $T_{2\text{eff}}$ is sensitive to the technically important chemical cross-link density [69,70] but also to the homogeneity and state of the material [40]. The cross-link density correlates with the glass transition temperature T_{g}, which is determined in the physical testing laboratory on samples taken out of the production process. $T_{2\text{eff}}$ correlates well with T_{g} (Figure 5b), but needs to be measured at constant temperature [71] or extrapolated to a reference temperature and calibrated. As measurements by unilateral NMR are fast and non-destructive, $T_{2\text{eff}}$ and its spread can be followed at all steps during the production of rubber parts (Figure 5a). This has been demonstrated for the production of tires [72]. The spread of $T_{2\text{eff}}$ for five different tires and their intermediate products at different equivalent measurement positions were quantified in terms of the coefficient of variation and compared to the same quantity for the initial torque measured with a rheometer (RPA: rubber process analyzer) on samples drawn from

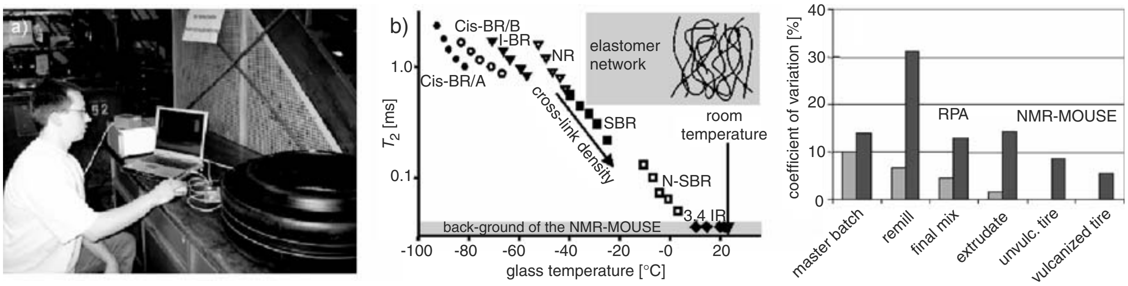

Fig. 5. Mobile NMR of rubber. (a) Large objects like tires can be investigated locally and non-destructively. (b) Transverse relaxation times measured near room temperature with the NMR-MOUSE and extrapolated to a reference temperature scale with the glass transition temperature and consequently with the cross-link density. (c) The spread of NMR parameters within a product and between products provides information about homogeneity and quality. It can be measured at all intermediate steps of the production process and at the final product, as demonstrated for the transverse relaxation times $T_{2\text{eff}}$ in the tire production.

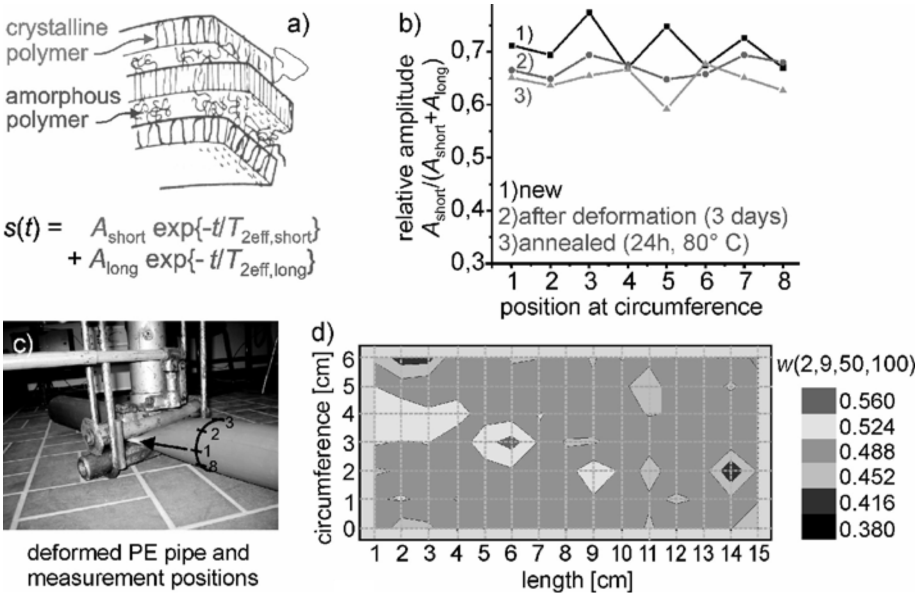

Fig. 6. Semi-crystalline polymers. (a) Morphology of semi-crystalline polymers with chain-folded crystalline regions and disordered amorphous regions, and biexponential model fit function for separation of signal contributions. (b) Crystallinity of a PE pipe at different points around the circumference before deformation, after deformation, and after annealing. (c) Deformation of a PE water pipe. (d) 2D crystallinity map acquired on a 1 cm^2 raster inside a PE pipe at 0 to 1 mm depth. The weighted spin density $w(2, 9, 50, \text{and } 100)$ was computed from the echo maxima a_n according to $\sum_2^9 a_n \Big/ \left(\sum_2^9 a_n + \sum_{50}^{100} a_n\right)$.

the same compounds (Figure 5c). The coefficient of variation decreases from one processing step to the next for the torque, but not for $T_{2\text{eff}}$, demonstrating that rheometer and NMR measurements provide somewhat complementary information. Also the coefficients of variation of $T_{2\text{eff}}$ are larger showing a higher sensitivity of $T_{2\text{eff}}$ to material properties than the torque. Finally, torque measurements are destructive and cannot be done on the final product, whereas the NMR-MOUSE can be used for quality control there [40,73,74]. When testing tires with the NMR-MOUSE, the presence of a steel belt is no obstacle. In fact even thin polymer coatings have been measured on steel sheets with the NMR-MOUSE [75].

Strained elastomers exhibit macroscopic molecular order, which can be probed with the u-shaped NMR-MOUSE by the orientation dependence of the relaxation rate [76], an effect which is also observed for tendon [77]. Aging and fatigue also lead to changes in $T_{2\text{eff}}$, and can consequently be studied non-invasively by unilateral NMR [71,78].

Leathery, semi-crystalline polymers like poly (ethylene) and poly(propylene) are less soft than rubber but still give excellent signal when short echo times like 25 μs are used. The transverse relaxation time $T_{2\text{eff,short}}$ of the chain-folded macromolecules in the crystalline domains is considerably shorter than the $T_{2\text{eff,long}}$ of the coiled chains in the amorphous domains (Figure 6a). Consequently, both components can be discriminated in a biexponential fit of the transverse relaxation decay, and the relative amplitude of the short component defines the NMR crystallinity. This quantity has been determined at well-defined positions on the circumference of a PE water pipe (Figure 6b and c) [79]. Even in the new state, it varies from point to point due to shrinkage while cooling during fabrication (Figure 6b). When laying or repairing pipes, the water flow is stopped by squeezing the pipes. When applied for an extended time, such a deformation reduces the crystallinity due to strained amorphous chains creeping out of the crystalline domains. At the same time the order in the amorphous domains has initially been increased as the chains are strained. Upon annealing well below the glass temperature these, chains relax by the melting of small crystallites, so that the overall crystallinity decreases further. By measuring a 2D array of NMR crystallinity data, the inhomogeneities of a PE pipe can be depicted in a 2D map (Figure 6d).

Another semi-crystalline polymer is cellulose. It is contained in wood and is the main component of paper. The state of wood and paper is inherently associated with the amount of bound water. The NMR-MOUSE has been applied to characterize the degradation state of historic paper [80–82] and to map the moisture distribution in wood panels [83].

The original u-shaped NMR-MOUSE (Figure 1a) has the $\boldsymbol{B}_0$ field approximately parallel to the scanner surface. With decreasing rf frequency the sensitive volume is shifted away from the surface, and its shape flattens. To obtain an extremely flat shape, the magnet geometry needs to be somewhat modified. While the original NMR-MOUSE collects signal from a slice about 1 mm thick near the surface, the optimized profile NMR-MOUSE collects signal from planar slices 30 μm thin and less (Figure 7a) [84]. To acquire high-resolution depth profiles, the sensitive slice can be shifted through the object by adjusting the distance between the NMR-MOUSE and the object with a precision lift of the NMR-MOUSE (Figure 7b). Even higher resolution can be obtained by Fourier transforming the echo acquired from the sensitive slice. Despite the thin sensitive volume, the sensitivity is good enough to acquire depth profiles of moisture in polymer sheets within a few minutes (Figure 7c and d). In this way the water uptake can be followed with a precision better than 0.2%. Even the water uptake from air can be studied (Figure 7d). Here the profile NMR-MOUSE provides information similar to that of the GARFIELD magnet [85,86], which has been designed with specially shaped pole shoes that ensure a linear gradient field with a strong gradient in the magnet gap. But contrary to the Garfield design, the NMR-MOUSE provides completely open access, for example, for *in vivo* skin studies and profiling of composites and adhesive layers [87–89]. Instead of shifting the sensitive volume mechanically through the object, it can also be shifted electrically by changing the field strength of the NMR-MOUSE [90] and by varying the rf excitation frequency on the expense of a changing shape of the sensitive volume.

The characterization of moisture in soil and building materials are one of the earliest applications of unilateral NMR [8–12,40,57,91,92]. Absolute values of moisture per volume can readily be obtained, as the size of the sensitive volume is fixed and defined [93]. Pore-size distributions cannot as easily be obtained. There are two reasons: (1) The $\boldsymbol{B}_0$ field of the NMR-MOUSE is strongly inhomogeneous and the acquired transverse relaxation decay is attenuated from diffusive motion in the larger pores. As a consequence, the distribution of $T_{2\text{eff}}$ obtained by Laplace inversion of the CPMG decay appears compressed for larger $T_{2\text{eff}}$, and $T_{2\text{eff}}$ is no longer proportional to the pore size in the fast diffusion limit. (2) The material to be investigated needs to be completely fluid saturated. This cannot be achieved for rock once it has been dried. For complete saturation, the CPMG signal amplitude or the integral of

(d) Relaxation time distributions for two frames, one not treated and the other one treated with a stone conservation agent.

the relaxation time distribution should be proportional to the porosity. But for rocks soaked after drying it depends on the fluid conductivity (Figure 8a). So originally wet cores need to be measured to obtain reliable porosity values by NMR. This is one further area of application of portable NMR in geophysics.

For porosities lower than 5% the sensitivity of the NMR-MOUSE is not good enough and a Halbach magnet with a more homogeneous $\boldsymbol{B}_0$ field and a larger sensitive volume need to be employed (Figure 1d). Its more homogeneous field permits the measurement of reliable relaxation time distributions, which, for example, in a drying study, reveal the preferential water loss from large pores with long relaxation times (Figure 8b) [36]. Nevertheless, the NMR-MOUSE has produced interesting results in a pilot study of the effect of stone conservation treatment conducted at the sandstone window frames of Paffendorf Castle near Cologne, Germany. The areas to be measured were partially wetted (Figure 8c) and differences in the relaxation time distributions of the untreated and treated frames reveal a more frequent occurrence of faster relaxation for the treated material. This promises, that unilateral NMR can be developed into a method to assess the success of stone conservation efforts non-invasively. A related study concerns the characterization of water and oil emulsions as model systems for food, where it has been demonstrated that the concentration of oil and water can be determined from the NMR-MOUSE signals [94].

Summary

Portable unilateral NMR concerns methods and NMR devices, which are carried to the object under study. It is an offspring of well-logging NMR. For materials analysis strongly inhomogeneous magnetic fields can be employed. NMR in inhomogeneous fields is an active area of research, and in addition to NMR relaxation, it has recently been demonstrated that NMR images, flow profiles, and even spectra can be measured by unilateral NMR. Mobile unilateral sensors like the NMR-MOUSE are lightweight and inexpensive. The measurement is non-destructive, and arbitrarily large samples can be investigated *in situ* up to depths of some 10 mm. The NMR-MOUSE can be employed for product development and quality control in a manufacturing environment. Other portable magnet geometries with better field homogeneity, such as the Halbach magnet, are also being explored for portable NMR. They can be used to study pipe flow, geophysical drill cores, and the like, where the completely open access provided by unilateral sensors is not required.

Rheo-NMR

Paul T Callaghan
MacDiarmid Institute for Advanced Materials and Nanotechnology,
Victoria University of Wellington, New Zealand

One recent application of NMR concerns rheology [1,2], the study of the mechanical properties of fluids. This application has come to be known as “Rheo-NMR” [3–7].

Many interesting materials in their condensed phase possess both solid and liquid-like properties. These include high molecular mass polymers and elastomers, lyotropic and thermotropic liquid crystals, micellar surfactant phases, colloidal suspensions, foams, emulsions, micro-emulsions and bicontinuous phases. Such materials, strongly represented in the biological world, comprise what is often called “soft matter” or “complex fluids”. Complex fluids manifest both an elastic and a viscous response, and they generally possess “memory”, which means that the stress which they exhibit at any moment will depend on the history of prior deformation. They often exhibit non-linear flow behavior, which means that properties may change as the deformation increases, an effect which is generally attributed to molecular reorganisation. And they invariably possess a wide range of characteristic time scales, from the rapid (ps to ns) local Brownian motion of small molecules or molecular segments, to the very slow (ms to s) motions associated with the reorganisation or reorientation of large molecular assemblies or macromolecules.

While rheology involves mechanical measurement of flow properties, the really interesting questions concern the molecular basis of these properties. Under flow, competition arises between the molecular organisational dynamics and the externally imposed deformation, with outcomes including conformational distortion [8], re-organisation of mesophase structure [9], double-valuedness in the constitutive properties [10] banded flow [11], the driving of the material through nearby phase transitions [12], and soft glassy dynamics, the slow aging of a system as the structure reorganizes [13].

The interest in the molecular-mechanical link has led to the amalgamation of a number of spectroscopic and rheological techniques in which a flow or deformation cell is incorporated within the spectrometer detection system. Examples include the use of neutron scattering, light scattering, birefringence, and dichroism techniques [2]. The most recent addition, NMR, allows one to study materials which are optically opaque. The imaging capability of NMR means that it can be used to directly measure local velocity profiles and molecular densities. And the wide-ranging spectroscopic tools available to Rheo-NMR make it possible to measure molecular order and dynamics.

Rheo-NMR based on micro-imaging approaches [14] allows the mapping of fluid velocity in small (mm to cm scale) deformation cells, the small volumes allowing the study of specialized materials. The velocimetry mode of micro-imaging generally employs a Pulsed Gradient Spin Echo (PGSE) sequence in which magnetic field gradientpulses define a wave vector domain, q, which imparts a phase shift to the spins depending directly on the motion of their parent molecules [14]. Inverse Fourier transformation of the signal with respect to q returns the local distribution of velocities, $P(v)$, for each pixel of the image. A typical velocity image will take between seconds and several minutes to acquire, depending on signal-to-noise trade-offs. The upper limit to velocity is determined by image distortion or inflow-outflow effects and is typically 1 ms^{-1}. The lower limit is determined by Brownian motion, enabling velocity resolution on the order of 10 micrometer per second for small molecules such as water but down to 100 nms^{-1} for macromolecules or colloidal particles, as shown in Figure 1 which depicts the velocity field for a soft glassy material formed from a close packing of 370 nm diameter latex spheres [15]. This example exhibits both slip and yield stress behavior, indicating the value of such flow visualization.

Rheo-NMR flow geometries [16,17] include cone-and-plate cells, cylindrical Couette cells, four roll mills and bi-axial extension cells, these latter devices being used to produce purely extensional flow. All these deformational flow devices are driven by a drive shaft which sits in the bore of the magnet and which is turned by a stepper-motor gearbox assembly mounted above the magnet bore. By contrast flow-though geometries include simple pipe as well as opposed jet systems. A typical Rheo-NMR kit is shown in Figure 2.

In most materials there exists a monotonic relationship (“flow curve”) between the applied stress σ and the rate of strain, $\dot{\gamma}$ [1]. In a rheological cell for which the stress is nearly uniform, such as the small angle cone-and-plate device, one would therefore expect a unique strain rate to occur at any applied stress. One of the first significant contributions of Rheo-NMR has been to show that

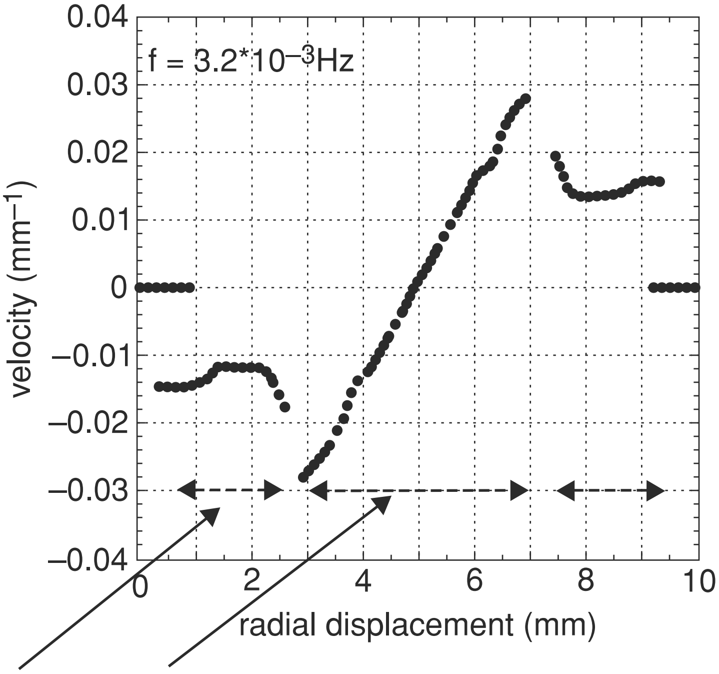

Fig. 1. Velocity profile across a cylindrical Couette cell of inner cylinder ID 5 mm and outer cylinder ID 9.4 mm, for 0.48 volume fraction 370 nm diameter core-shell latex spheres suspension in water. The left hand arrow indicates the region of the annular gap where a yield stress point is apparent, dividing fluidized material from the glassy state. The right-hand arrow point to fluid within the center cylinder undergoing rigid body motion. Note the slip at the inner and outer walls (adapted from ref. [15]).

the uniform shear-rate assumption may be violated in the case of certain classes of fluids in which pathological flow properties are exhibited. Figure 3 shows velocity maps and associated shear-rate maps [18] obtained for the worm-like surfactant system, cetylpyridinium chloride/sodium salicylate in water. While the velocity gradients show no deviation from uniformity at very low shear rates, above a certain critical value $\dot{\gamma}_c$ a dramatic variation across the 6° cone gap is apparent in which a very high shear rate band exists at mid-gap.

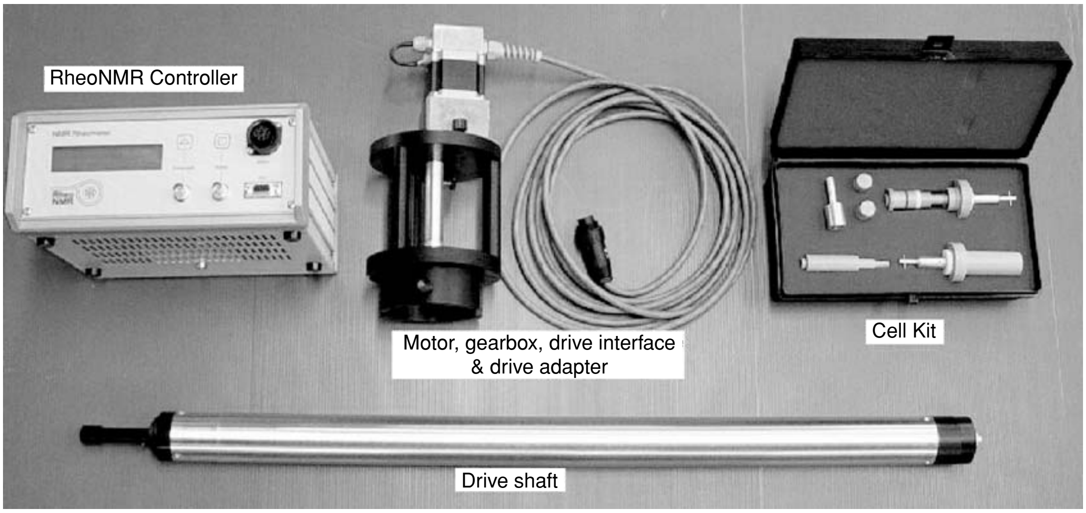

Fig. 2. Set of Rheo-NMR cells and drive attachments for a 89 mm vertical bore NMR magnet (http://www.magritek.com). (See also Plate 44 on page XXXIV in the Color Plate Section.)

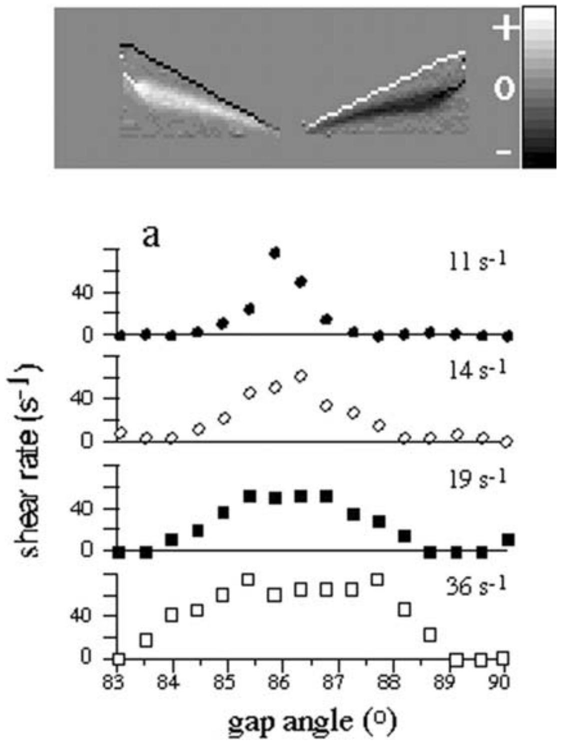

Fig. 3. Shear rate distribution for cetylpyridinium chloride/NaSal wormlike micelle solution at an apparent shear rate of 16 s^{-1}, well beyond the critical shear rate and in an unstable region of the flow curve (horizontal field of view 25 mm with vertical field of view smaller by a factor of 6) Also shown are experimental shear rate profiles along a line of approximately fixed radius (adapted from reference from reference 18).

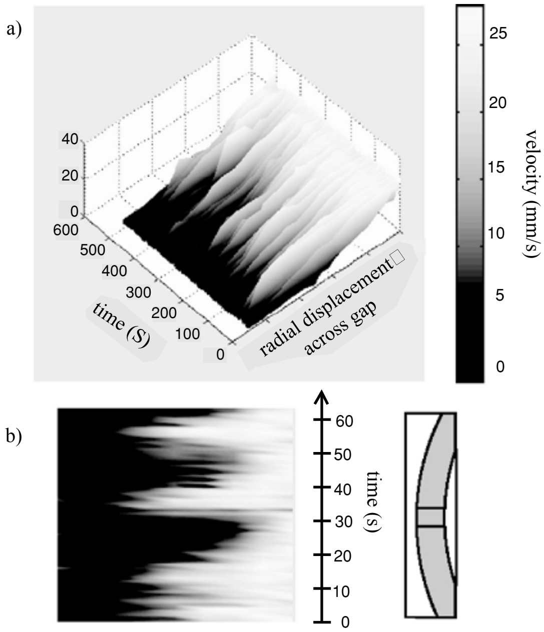

Fig. 4. (See also Plate 45 on page XXXV in the Color Plate Section.)

This shear banding phenomena is believed to arise from an inflected flow curve that includes an unstable branch in which the stress declines with increasing shear rate. The fluid thus "phase separates" onto the upper and lower rising branches of the underlying flow curve and the proportions of each band will be as required to satisfy the average shear rate, in the manner of a lever rule. That the NMR results are consistent with this picture is clear in Figure 3 where a series of profiles show that as the gap apparent shear rate, is increased the high shear rate band expands in width at approximately constant maximum shear rate. More recent work has shown that these bands fluctuate extremely rapidly, as seen in the successive profiles taken, at one second intervals, in the Couette cell geometry of Figure 4 [19]. To achieve this time resolution, a high speed imaging sequence was employed. These NMR results have stimulated new theoretical models for the coupling of flow to micro-scopic molecular order parameters.

Rheo-NMR is also capable of investigating molecular order and alignment [20] through utilising internuclear dipole interactions or nuclear quadrupole interactions. It is through the use of such spectroscopic approaches that Rheo-NMR holds the promise of further linking mechanical and molecular properties. Figure 5 shows the result of a shearing study on a wormlike micelle system (20% CTAB/D_2O at 41 °C) close to an isotropic-nematic transition [21,22]. The D_2O ^2H NMR spectrum, is plotted as a function of radial position across the gap of a cylindrical Couette cell where the magnetic field is aligned with the vorticity axis. At the inner wall, where the stress is highest, a splitting is observed [21], indicative of a finite quadrupole interaction, while at the outer wall a single peak is observed. These data suggest the formation of a nematic phase at high stress and the transition to an isotropic phase, through a mixed phase region, at the region of low stress.

Another intriguing correlation between shearing and molecular conformation concerns a random coil polymer melt being subjected to shear. Here the polymer chain suffers a biaxial deformation in which the principal axis of extension has a preferred orientation with respect to the

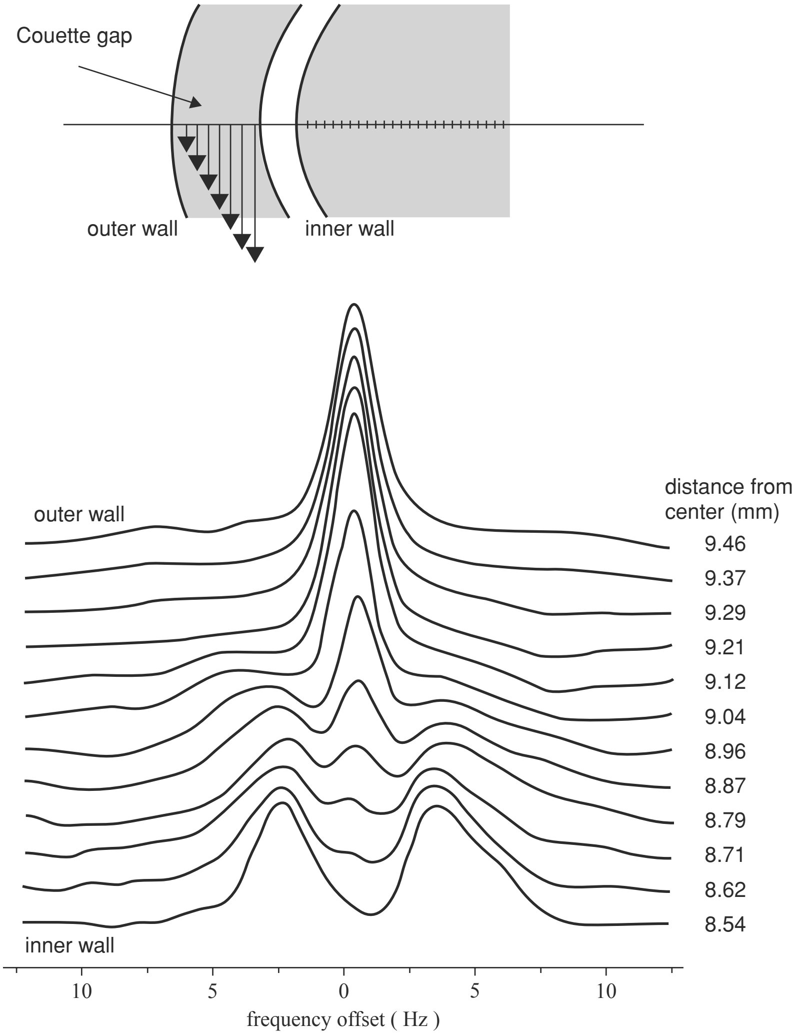

Fig. 5. ^{2}H NMR spectra obtained from 20% w/w CTAB/D_2O (41 °C) at different positions across the annular gap of a cylindrical Couette cell and at an apparent shear rate of 20 s^{-1}. Near the inner wall, where the stress is highest, a quadrupole splitting is observed, consistent with an ordered phase, while near the outer wall the single peak of an isotropic phase is seen. In between a mixed phase region exists (adapted from reference 21).

hydrodynamic velocity direction, the deformation being described by means of an averaged segmental alignment tensor that may be evaluated using the Doi–Edwards formulation of entangled polymer dynamics [8]. Rheo-NMR has been used to obtain elements of the tensor in a high molecular weight polymethylsiloxane melt confined to a Couette cell of 0.5 mm gap [23,24]. In this work a small deuterated benzene probe undergoes steric interactions with the polymer segments and experiences an anisotropic mean orientation. NMR micro-imaging is used to view the PDMS both to image the velocity distribution across the gap and to excite a desired region of the sample for spectroscopy experiments during steady-state shear. The deuteron NMR signal exhibits a scaled down quadrupole splitting proportional to the average value of the selected tensor element. Figure 6 shows the measured alignment tensor elements along with fits using the Doi–Edwards model, which is parameterized by the tube disengage-

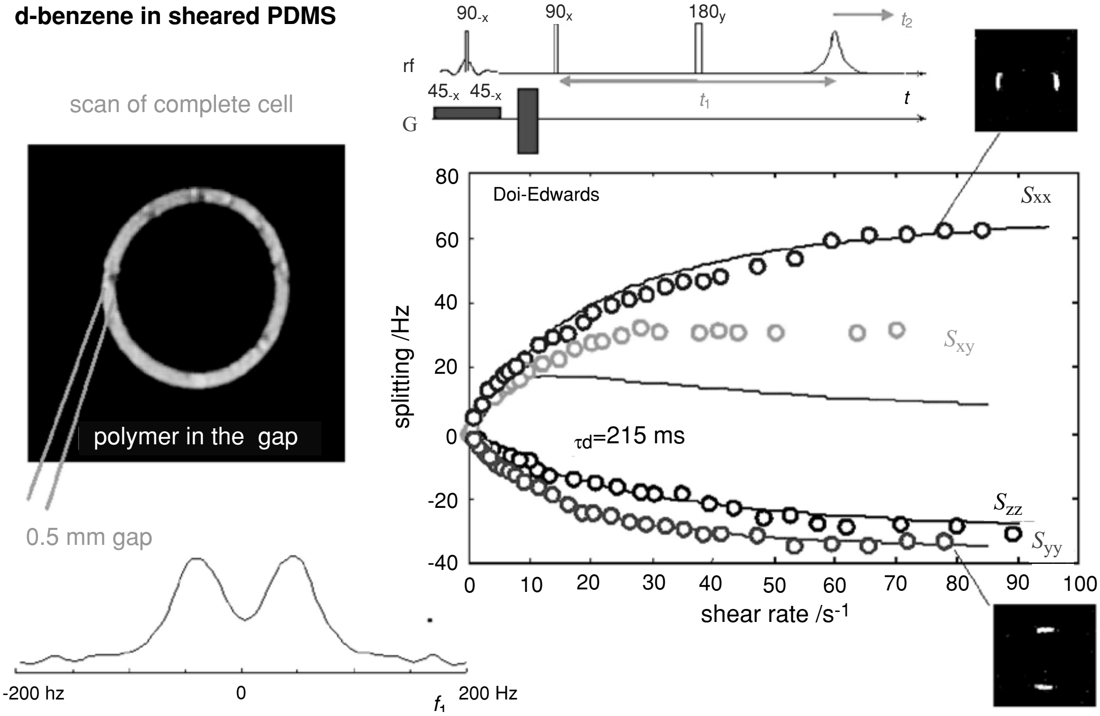

Fig. 6. Quadrupole splittings, $\Delta\nu$, vs. Deborah number, obtained from deuterated benzene in 350 kdalton PDMS, using a selected region of the horizontal Couette cell in which the velocity direction (solid circles) and gradient direction (open circles) are respectively parallel to the magnetic field. The lines are fits using the Doi–Edwards model in which the horizontal axis is scaled to yield the tube disengagement time, τ_d (adapted from ref. [24]). (See also Plate 46 on page XXXV in the Color Plate Section.)

ment time associated with reptation. Also shown are the selected regions in which either the velocity direction or the velocity gradient (shear axis) is parallel to $\mathbf{B}_0$.

These examples provide a glimpse of possible applications of Rheo-NMR. While this is a very new field of research in which only a handful of groups presently participate, the potential exists for a substantial increase in Rheo-NMR research activity. Systems studied to date include polymer melts and semi-dilute solutions, thermotropic and lyotropic liquid crystals and liquid crystalline polymers, micellar solutions, food materials, and colloidal suspensions. The ability to combine velocimetry with localised spectroscopy, and the ability to access a wide range of molecular properties relating to organisation, orientation, and dynamics has enabled Rheo-NMR to provide a direct window on a variety of behaviors, including slip, shear-thinning, shear banding, yield stress behavior, nematic director alignment, and shear-induced mesophase reorganisation. The unique information available with this method suggests that it is likely to become an important tool in elucidating the intriguing rheological behavior of a wide range of complex fluids.

Analytical Aspects of Solid-State NMR Spectroscopy

Cecil Dybowski
Department of Chemistry and Biochemistry, University of Delaware, Newark, Delaware 19716-2522 USA

Introduction

In one sense of the word, every use of nuclear magnetic resonance is analysis, so to discuss analytical aspects of solid-state NMR spectroscopy is to discuss its myriad uses. Clearly, such a general approach is neither feasible nor appropriate in a short article, so one needs to focus the discussion. Roughly speaking, experiments involving NMR spectroscopy belong to one of two classes: (1) those that primarily focus on nuclear magnetic resonance as a process, with the goal of learning about or expanding its utility; and (2) experiments that involve NMR as a tool to address some question about the nature of a chemical or physical system and in which development of NMR technology is of secondary importance. While experiments in the first class may provide new information on samples (usually model materials), it is the latter sort of experiment that I make the theme of this chapter. It is important to emphasize that this dichotomy is not clear, and one must often include experiments on models to understand the nature of analysis with NMR spectroscopy.

Uses of Isotropic Shielding to Identify Materials

A discussion of the analytical aspects of solid-state NMR spectroscopy involves an understanding of what is meant by “analytical.” To many NMR spectroscopists, the word connotes determination of molecular structure by a careful correlation of spectroscopic absorptions with expected functional groups. NMR spectroscopy is an excellent means to determine the details of molecular structure of a pure material by such experiments, whether the material is a solid or is in the liquid state. The long, successful history of organic structural analysis with liquid-state NMR spectroscopy exemplifies this analytical aspect of NMR spectroscopy.

Analyses that specify the nature of functional groups in the solid state demonstrate a similar analytical methodology for addressing questions of molecular structure in the solid state. Of course, the information on molecular structure in the liquid state and the solid state may differ because of physical differences between the solid-state structure and the average structure detected with solution-state NMR spectroscopy. The classical example of this kind of analysis of a solid is found in the application of ^{29}Si MAS NMR spectroscopy to the examination of zeolite structure, exemplified by the work of the Exxon NMR group [1]. The isotropic position of NMR spectroscopic absorption depends strongly on the local environment of the nucleus, which allows one to assign the resonances in the NMR spectrum to specific silicon sites [2]. By examination of a wide variety of materials, it has been shown that the variable that most significantly affects the resonance position is the number of aluminum atoms in the nearby environment. In experiments that account for the effects of relaxation rates on line intensities, it is possible to use the intensities of lines from silicon in various environments to estimate the distribution of silicon in various sites. Such an NMR-derived distribution can then be compared with theoretical predictions of the distribution of silicon in the zeolite framework [3]. The concurrent examination of a zeolite by X-ray diffraction, where possible, and magic-angle spinning (MAS) NMR of a zeolite provides a synergy that often allows one to unambiguously assign structures. These techniques have been used repeatedly over many years to analyze zeolite structure and are a foundation of modern zeolite analysis.

MAS NMR spectroscopy of spin-$\frac{1}{2}$ nuclei in solids is particularly relevant to organic materials. For example, an early application of MAS NMR to poly(phenylene oxide) revealed that in the solid state, the protonated aromatic in the carbon spectrum appears as a doublet, whereas in solution the carbon resonance is a singlet [4]. The explanation of this observation is that, in the solid state, the structure is locked on the NMR timescale, with the result that carbons that are nominally equivalent in solution become inequivalent in the solid state. Observation of such differences between solution- and solid-state spectroscopy points up the fundamental fact that chemical shielding depends on the details of structure, but it also provides an interesting use of solid-state NMR spectroscopy to investigate the existence of structural differences between the solution state and the solid state.

An interesting use of MAS NMR spectroscopy is the application to archaeology. For example, the study of residues on pottery has given information on the nature of materials present on pots [5]. Similarly, the qualities

Graham A. Webb (ed.), Modern Magnetic Resonance, 389–394.
© 2008 *Springer.*

of woods in certain archeological materials may be examined with solid-state NMR spectroscopy [6]. A wide variety of applications in this area can be envisioned in which a determination of the nature of substances resolves some question.

An analytical application of the solid-state NMR technology derived from the sensitivity of the chemical shielding to local structure is the study of polymorphism in solids. Although two solid samples may be chemically identical, i.e. have the same atoms bonded in the same pattern, the constraints of packing in the solid state may produce structures that are different. If these structures result in different physical properties such as dissolution or accessibility, the differences may influence uses of the solid material. The ability to distinguish different polymorphic structures simply is an aid in formulation chemistry that has wide applicability. An example of this effect is seen in the differences in the spectra of solid 2,6-di-tert-butylnaphthalene prepared by recrystallization from ethanol or acetone [7]. The carbon NMR spectra of the aromatic region of these materials clearly show that the two solids are distinct from each other. One area where the identification of polymorphic and pseudopolymorphic structures with NMR spectroscopy is tremendously effective is the analysis of pharmaceuticals [8]. For example, carbon NMR spectroscopy has been used effectively to identify several polymorphic structures of neotame and to specify the conditions under which each may be made.

The fundamental principle behind interpretation of NMR spectra, be they of solids or solutions, is that there is an intimate connection between the local electronic structure and the resonance frequency. Early on, chemists correlated a wide variety of solution-state NMR isotropic chemical shift measurements in empirical rules, such as those given by Grant and Paul [9]. The effects of perturbation of the electronic structure (and thus the chemical shift) by appending groups to a center was given by a rationalized set of effect parameters. With these rules, one could predict with reasonable accuracy the isotropic positions of carbons in different chemical environments. Such rules work reasonably well for analysis of isotropic carbon chemical shifts in solid materials, but there can be discrepancies between solution and solid isotropic values due to differences in local environment, when comparing the solid to a solution of the same material [10]. Thus, using empirical rules based on solution-state NMR data to interpret solid-state data must be done with great care.

A major consideration in determining isotropic chemical shifts in solid-state NMR spectroscopy is referencing. In the solution state, introduction of the reference material into the same solution as the material being analyzed allows a compensation for susceptibility shifts. In the solid state, one almost always uses external referencing to specify chemical shifts. As a result, there is an inherent limit to accuracy of measurement of chemical shifts in the solid state, even though the measurement precision may be higher. There are two means to reference externally: (1) by mixing a small amount of the reference material (as a solid) with the material to be studied and (2) by substitution of a sample of the reference to calibrate the spectrometer, with the assumption that substitution changes none of the parameters of the spectrometer system. By far the most common method is the second method, and practitioners should realize that this method, in particular, does not account for susceptibility differences between the material and the reference, a potential source of systematic error in reporting chemical shifts determined with this method. In addition, for either method, one usually uses a secondary reference standard to make chemical-shift determinations. The two most commonly used reference standards for solid-state ^{13}C NMR spectroscopy are adamantane and hexamethylbenzene. According to Duncan's compilation [11], the positions of the resonances for adamantane are 28.7 and 38.2 ppm relative to the position of an external tetramethylsilane (TMS) sample, and the aromatic resonance of hexamethylbenzene falls at 132.3 ppm relative to external TMS.

Uses of Shielding Tensors to Identify Materials

While the isotropic chemical shielding is a principal parameter for specifying the identity of an unknown material, one of the advantages of analysis of materials in the solid state is the opportunity to observe all the tensor components of chemical shielding. Such additional information may provide a means to distinguish resonances that have identical, or nearly identical, isotropic chemical shieldings. The initial report of proton-enhanced carbon NMR spectroscopy, for example, showed the systematic dependence of the carbon chemical shielding elements of a carbonyl carbon, as exhibited in the powder pattern, on the nature of groups bound to the carbonyl center [12]. A flurry of activity to evaluate chemical-shielding tensors for simple situations resulted in reports of chemical-shielding tensors for carbons, protons, and other nuclei [11].

A particularly interesting example of the use of chemical-shielding tensor analysis to address a problem in solid-state chemistry is a study of the cadmium NMR chemical-shielding tensor elements of $CdSO_4 \cdot 8H_2O$ [13]. For this material, there initially existed an apparent anomaly between the structure gleaned from NMR chemical-shielding anisotropy/Cd–O bond distance relationships and the bond distances determined earlier by more conventional scattering methods. The discrepancy was resolved by a redetermination of the structure that showed that the refined distance data were in agreement with the NMR correlations.

A problem arises with analysis of chemical-shielding tensor elements of a complex material such as a multicarbon organic material: the powder patterns (from which the tensor elements are obtained) of carbons in samples examined without MAS generally overlap. Thus, analysis of powder patterns is generally restricted to materials in which there exist a limited number of unique chemical sites [14]. It is sometimes possible to use techniques like factor analysis to extract the tensor components in overlapping spectra [15].

In samples that contain a limited number of sites, there may be problems with the analysis, if the dispersion of the line is too large. Distortions in the powder-pattern line shape resulting from inadequate or non-uniform excitation, inherent limitations of bandwidth, or the effects of apodization may limit analysis of the chemical-shielding tensor elements directly from the spectrum. There are at least three ways to overcome this problem: (1) determination of a transfer function that predicts the nature of distortions and that is used as a parameter in fitting distorted spectra [14]; (2) determination of the spectrum is a point-by-point fashion [16]; or (3) by determining sections of the resonance line in single experiments, and then assembling the entire powder pattern from the overlap of these sections. Each has advantages and disadvantages, and the method to use depends on the spectral features. For example, to obtain spectra of platinum particles the resonant absorption of which was spread over tenths of a percent of the mean resonance frequency, it was necessary in studies of catalysts to use the second method to obtain a representation of the spectrum [17]. The use of the first method has provided chemical-shielding tensor elements for a variety of simple ^{207}Pb-containing materials [18], and the third method has been used to examine chemical shielding in lead-based oxides [16].

The dispersion of each resonance in the spectrum of a powdered solid material substantially lowers the apparent resolution of the spectrum, as compared to the spectrum of the material dissolved in solution. This loss of resolution was the impetus for the use of MAS as a means to simplify the ^{13}C spectroscopy of solids, mentioned above (MAS spectroscopy represents for many the quintessential solid-state NMR technique). Because spinning of this sort is a coherent modulation of the chemical-shielding interaction, the spectroscopic band is split into a center band and a series of sidebands, separated from the center band by an integral multiple of the spinning frequency. The MAS technique improves the resolution to the point that one may resolve the positions of the center bands, provided one may identify them. To have the spectra be essentially the maps of center bands (and therefore like solution-state spectra) requires one to spin the sample at speeds such that the first sideband is well outside the bandwidth of the dispersion. Since this may be practically difficult, most solid-state spectra exhibit some sidebands. With the development of technology for ever-faster spinning, obtaining center-band maps is much easier than it has previously been, and analysis with the isotropic chemical shifts is now a nearly-routine technique for many nuclear species.

In early work, Herzfeld and Berger demonstrated that an analysis of the relative intensity distribution among the sidebands of a resonance could be used to recover information on the chemical-shielding tensor elements [19]. The techniques involve a careful evaluation of relative intensities, which are then compared to the results of calculations, often presented as maps of relative intensity vs. certain parameters related to the tensor elements. (This can be done in several ways, but a common means is to compare them directly to theoretical maps of expected intensities of several sidebands to specify the values of parameters, from which the tensor elements are determined by a simple algebraic expression.) With this knowledge, it becomes possible to analyze the spectrum of a reasonably complex material containing multiple resonances to obtain both the isotropic chemical-shifts and the components of the chemical-shielding tensors for each site. In later work, several groups have demonstrated various means to create two-dimensional NMR spectra that correlate the isotropic chemical shift with the anisotropic chemical shielding [20,21]. The result of using these kinds of experiments is the availability of chemical-shielding tensor elements for nuclei (particularly carbon) in a wide range of chemical environments.

Using Quadrupolar Coupling to Identify Materials

The presence of the quadrupolar coupling for spins with quantum numbers greater than $\frac{1}{2}$ adds an extra dimension to the analysis of solid materials that contain these nuclei. The line shape for a quadrupolar nucleus is determined by the electric-field gradient at the nuclear site. Like the chemical shielding, the quadrupole coupling constant characterizes the local electronic state. A vast majority of nuclei in the period table have at least one quadrupolar isotope, so determining the quadrupolar coupling is a generally useful analytical tool for identifying chemical type in a host of different situations. The borosilicate glasses are representative of a system in which the study of the quadrupolar coupling can give information on local structure [22,23]. In inorganic systems, such as the Keggin ions, analysis of quadrupolar couplings can be used to analyze the kinds of sites quadrupolar nuclei like vanadium occupy [24]. Zeolites have been extensively studied with quadrupolar NMR spectroscopy, especially the aluminum centers. The studies of the quadrupolar coupling give information on site symmetry and structure [25]. Changes in the quadrupole coupling of aluminum in certain zeolites used as catalysts for reactions such as the conversion of methanol to higher alkyl structures give clues to structural changes in catalyst accompanying adsorption of the substrate [26].

Structure Determination

An analytical measurement of great importance is the determination of physical structure. As seen above, the chemical connectivity can be inferred from the isotropic chemical shielding through its known correlation with chemical group identity. Physical structure is equally important in specifying the nature of materials, e.g. synthetic polymers or biological systems. The classical means to identify physical structure is through diffraction methods with X-rays or neutrons. These methods, however, require single crystals to extract maximal information. Solid-state NMR spectroscopy can be used to define physical structure to a degree, without the creation of single-crystal samples. The structural information is obtained by measurement of dipole–dipole coupling between two nuclear spins, the magnitude of which depends only on the distance between the spins. One may divide the sorts of dipolar-coupling measurements into two types: (1) homonuclear dipolar coupling experiments and (2) heteronuclear dipolar coupling experiments. Depending on how the experiment is run, these are sometimes called recoupling experiments [27]. As an example, selective enrichment of nuclei at points in amyloid fibrils allows the measurement of distances in these systems, an important piece of information in understanding the structures implicated in Alzheimer's disease [28,29]. Combining several dipolar measurements with restrictions from chemical shielding limits the possible structures that, for example, a protein can adopt [30]. The study of structures of many systems, e.g. catalysts [31], can be addressed by these kinds of measurements. One may use the dipole-measurement techniques to determine distance constraints in technologically important systems such as polymer electrolytes [32] or to determine hydrogen-bond distances with great precision [33].

There are ways to address structure in solids that do not directly involve the dipolar coupling to determine distances. For example, knowledge of the orientation of the chemical-shielding tensor in the local molecular frame may be used to determine the orientation in partially oriented samples, as was demonstrated for uniaxial deformation of poly(tetrafluoroethylene) [34]. The orientation distribution function can be discerned for partially ordered samples from other NMR parameters such as the deuterium quadrupolar line shape [35]. By correlating chemical shielding as a function of orientation in a field, one may study biaxial orientation, as has been shown for the carbon resonances of poly(ethylene terephthalate) [36]. Such experiments show the strength of multidimensional techniques in the NMR of solids, in this case to determine orientation quantitatively.

The identification of relations between parameters such as the quadrupolar coupling constant and local structure allows one to infer structural features from measurements of these parameters. An example of this sort of relationship is the connection between the oxygen quadrupolar parameters and the Si–O–Si bond angles in silicates [37]. Another example that shows the utility of measurements of quadrupolar coupling constants involves determining the state of ionic materials, for which the electric-field gradient is a strong indicator of structure [38].

Quantification with Solid-State NMR Spectroscopy

A principal concern of the analyst is determining the amounts of identifiable species in a sample, about which not everything is known. The resolution of a question very often involves measuring with great precision and accuracy tiny amounts of material in a sample. Anyone involved in analytical chemistry receives requests for such determinations and appreciates the difficulty of achieving accuracy and precision at very low levels. For example, the identification and quantification of species in samples of environmental importance is of crucial importance in determining the nature of contamination.

NMR spectroscopy, like other forms of spectroscopy, can—in principle—provide a means to determine the amounts of various species in a sample by careful intensity measurements. However, there are caveats that accompany that statement. It is important to remember that the NMR experiment gives the intensities of the various unique nuclear magnetizations under the conditions of preparation in the experiment. These magnetization intensities may not be proportional to the number of spins in each environment in every experiment.

A simple and obvious example of quantification with NMR spectroscopy is the measurement of relative intensities in solution-state NMR spectroscopy, a principal means of specification of chemical structure. As most NMR spectroscopists know, one must account for effects, such as incomplete relaxation or nuclear overhauser enhancements, to make such experiments relatively quantitative. Even with these precautions, the measurements provide information on the relative amounts of material not absolute amounts. Inclusion of a material of known concentration may be used to determine concentrations of unknown materials absolutely, through ratio to the known material.

The situation in solid-state NMR spectroscopy is more complex than that in solution-state NMR spectroscopy.

Many techniques used in solid-state NMR spectroscopy create magnetization by complex manipulation of spin interactions that do not necessarily affect all spins in the same manner. The quintessential example of this effect is the cross-polarization technique for creating magnetization in rare spins. Because of the different kinetics of polarization transfer, the magnetizations created for various centers may not be in the ratio of the number of nuclei at those centers. In certain cases, one may model NMR processes, from which one produces a relative quantitation of spins [39]. In other cases that are particularly important for organic materials, the magnetization development may be very complex and not fit by simple models, leading to the situation in which it is difficult to quantify rare spins directly [40]. Certain sequences that simplify or enhance spectroscopic features do so by canceling portions of the magnetization (e.g. the part in sidebands in TOSS sequence). Comparison of magnetization amplitudes in this sort of experiment can never be guaranteed to reflect the ratio of numbers of spins in various environments, without invoking some assumption about the nature of the chemical shielding at various sites [41]. Thus, it is often necessary to avoid cross-polarization and other spectroscopic-enhancement techniques to ensure that the signal intensity ratios represent ratios of numbers of spins. So, for example, in measurements to detect ^{13}C in organic solids, it is preferred to measure intensities in spectra obtained with direct excitation, rather than with cross-polarization, to avoid these complications. However, this may be difficult or impossible because of the ^{13}C long relaxation times for pure crystalline solids.

The measurement of relative numbers of spins in various environments may be hampered by certain interactions that make some spins "invisible" in NMR spectroscopy. Such is the case for materials like coal that contain paramagnetic centers [42]. In a complex, heterogeneous substance such as coal, if the paramagnetic centers are clustered in one phase, the NMR spectrum may not adequately represent that phase relative to another, resulting in incorrect quantitation.

There has been a long tradition of using NMR spectroscopy of abundant spins to quantify materials such as polymers but often at low resolution. Because of spin diffusion, differential relaxation of these abundant spins is not necessarily a problem for this spin system. Thus, relative intensities may be used to determine the relative numbers of spins in various environments. For example, it has been shown that multiple-pulse NMR experiments may be used to infer the relative numbers of spins in the amorphous regions of poly(ethylene) [43]. Even in that relatively simple case, it was found necessary to extrapolate intensity ratios on the duty factor of the experiment because that affected the relative intensities of the crystalline and amorphous phases.

Uniform excitation of transitions is a problem when observing quadrupolar nuclei with large coupling constants. In such cases, the spectroscopy often yields only one transition not the full spectrum. Comparison of this spectrum to that from a material with a smaller coupling constant may skew the determination of the amount of material. The multiple-quantum methods for studying quadrupolar nuclei have been promoted in recent years. The study on how to relate signal intensity to concentrations is ongoing [44,45].

The usual NMR determination of relative numbers of spins in a material is not an absolute measurement. To determine the absolute numbers of spins in a sample, one must compare the intensities to a known amount of a standard material. In solution-state NMR, the standard can be frequently added to the solution, which allows easy comparison. For a solid-state measurement, one may add the material as a component of a physical mixture in the sample region, in analogy to the solution-state process. Comparison of intensities, taking into account the ramification discussed above, allows an absolute measurement of number of spins. However, care must be exercised to ensure uniform excitation of all parts of the sample, including the reference.

Summary

NMR spectroscopy is the preeminent technique for determination of many material properties. This was obvious even in the early days of solution-state NMR, a fact that resulted in its relatively quick adoption by chemists. The application of NMR spectrocopy to solids has led to a similar utility for a wider range of solid materials. The analysis may involve identification of species, determination of structure or "sizes" of various interactions, and relative or absolute quantification of species. To analyze a material properly requires a careful consideration of all factors that affect the spectroscopy.

Introduction

Radiochemistry (tritium chemistry in particular) and nuclear magnetic resonance (NMR) spectroscopy are hardly ever taught within the same undergraduate degree course. This is one of the main reasons why those who become NMR spectroscopists are so reluctant to see radioactive material being used in their instruments. The main thrust for the development of ^{3}H NMR spectroscopy [1] has therefore come from the radiochemistry area and from those in the pharmaceutical and life sciences who appreciate the potential benefits of working with this radionuclide.

Radiochemical Facilities and Radiation Safety

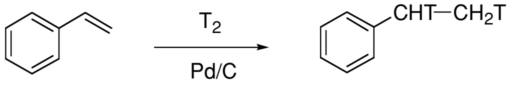
Ideally, one should have access to two laboratories, one where high levels, i.e. millicurie (mCi, 1 mCi = 37 MBq) quantities, and higher amounts of tritium, can be handled, and the other, less specialized, where the work is confined to the tracer level (mCi down to μCi). The Curie (Ci, 3.7×10^{10} disintegration per second) is the "old" unit of radioactivity and represents a very large amount of radioactivity, hence the frequent use of millicurie and microcurie quantities. On the other hand, the "new" SI unit, the Becquerel (Bq, 1 disintegration per second), is an extremely small amount of radioactivity so that e.g. megabecquerels (MBq), are frequently encountered. In addition, there should be a separate counting room where the scintillation spectrometer(s) are kept.

The synthesis and handling of tritiated compounds should all be done in fume cupboards of the necessary specification. Operations over spill trays ensure that any contamination is limited to a specific area while regular monitoring provides the necessary reassurance. Much preliminary labeling work can be performed using the stable deuterium isotope. Where compounds at very high specific activity e.g. 20 Ci/mmol or more are required, it is necessary to obtain a supply of T_2 gas but rather than use a glass vacuum line, it is better to purchase a commercially available instrument in which the tritium is stored on a uranium bed—on warming the latter sufficient T_2 gas can be released for the proposed experiment and on completion any unused tritium can be taken up by another uranium bed specially kept for this purpose. In this way, all the tritium can be easily accounted for. Purification of tritiated compounds relies heavily on one or more radiochromatographic methods of which radio-HPLC is the most widely used.

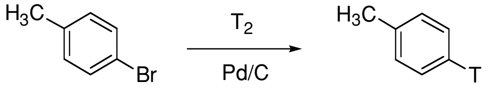
Tritiation Procedures

For most, but not all, applications, it is necessary to introduce the tritium at specific sites and for this reason the following reactions are chosen [2,3]:

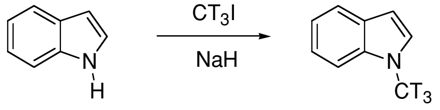
(a) Catalytic hydrogenation



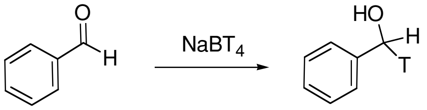
(b) Catalytic aromatic dehalogenation (usually debromination)



(c) Methylation using ^{3}H-methyl iodide



(d) Sodium [^{3}H]borohydride reduction



Graham A. Webb (ed.), Modern Magnetic Resonance, 395–398.
© 2008 *Springer.*

In this way compounds of very high specific activity can be prepared e.g. the introduction of two tritium atoms to produce ethyl benzene can give a product with a maximum specific activity of 58 Ci/mmol.

In addition to the above-mentioned reactions, there are a number of others, chief among them being hydrogen isotope exchange reactions that can lead to either specific or generally labeled compounds but at a lower specific activity. The reason for this is that tritiated water is now the source of the tritium and for health and safety reasons it is usually used at the Ci/cm^3 level.

Some of these reactions are slow, requiring many hours to come to completion. Others such as the catalytic aromatic debromination and borohydride reduction are isotopically inefficient, leading to the production of large amounts of radioactive waste (50% in the first example and 75% in the second). Consequently, there has been much interest of late in the development of new, microwave-enhanced procedures [4–6] that proceed much more rapidly (matter of minutes), more efficiently, and with the production of much reduced levels of radioactive waste. In some cases, it is no longer necessary to use a solvent while in others an ionic liquid can be used to replace the more conventional solvent. A good appreciation of how organic compounds interact with microwave irradiation is necessary in order to maximize the benefits of these new procedures [7,8].

Tritium NMR Spectroscopy

Now that a large number of tritiated compounds can be rapidly produced via microwave-enhanced procedures, there is a corresponding need for a fast and sensitive analytical method for determining the pattern of labeling. Tritium possesses ideal NMR properties (Table 1)—it has a nuclear spin of ½ and is the most sensitive of all NMR-active nuclei (21% better than ^{1}H). Unfortunately, NMR spectroscopy by comparison with other analytical methods e.g. mass spectrometry is not a very sensitive method although considerable improvements have been made in recent years through the design of higher performance magnetic fields. This is not an inexpensive exercise and it is fortunate that the most recent improvement, through the development of cryoprobes [9], is much more cost effective although the challenge of keeping the tritiated sample at or close to room temperature while the radiofrequency coils nearby are cooled to below 35 K was a formidable one.

In early studies, a 10 mCi sample of a tritiated compound gave a satisfactory ^{3}H NMR spectrum when using a spectrometer operating at 64 MHz. A more recent example—a spectrometer operating at 533.5 MHz with a cryoprobe accessory—gave a ^{3}H NMR spectrum with as little as 11 μCi (S/N ratio of 21, Figure 1A). In both cases, the accumulation time was overnight. This 1000-fold improvement in sensitivity still leaves one with much higher levels of radioactivity than are used in liquid scintillation counting. Fortunately, the natural abundance of tritium ($<10^{-16}$%) is much lower than that for the stable isotopes ^{2}H (0.0156%) and ^{13}C (1.11%) so that the potential for further improvement in sensitivity is enormous.

Until recently all signal processing relied on, and was restricted by, conventional passive analysis where a signal must be some measurable parameter greater than background in order to be discriminated from background. A new revolutionary process—quantum resonance interferometry [10]—is an example of active signal processing in which new data is derived by interference with the original data. This makes it possible to improve detection sensitivity and so far it has only been applied to gene expression microarrays although its extension to mass spectrometry and NMR spectroscopy has been anticipated.

Whatever the NMR spectrometer, it is always advisable to have a solution of the tritiated compounds in a sealed cylindrical tube which itself is placed in another tube. In this way double containment makes the chance of a breakup and the subsequent contamination most unlikely. The fact that the ^{3}H chemical shifts are virtually the same as the ^{1}H chemical shifts makes in most cases the interpretation of the spectra a straightforward exercise.

With compounds at the mCi mmol^{-1} and lower specific activity, it is customary to produce ^{1}H decoupled spectra so that each labeled site gives a very sharp singlet. It is very rare therefore that overlapping signals cause problems of signal assignment—this is not always the case with the

Table 1: Important properties of tritium and its non-radioactive isotopes

Nucleus	Natural abundance (%)	Nuclear spin	NMR sensitivity	Radioactivity
^{3}H	$<10^{-16}$	½	1.21	weak β^-, $t_{1/2} = 12.3$ years, $E_{max} = 18$ KeV, and maximum specific activity = 29 Ci mmol^{-1}
^{1}H	99.985	½	1	No
^{2}H	0.015	1	9.65×10^{-3}	No

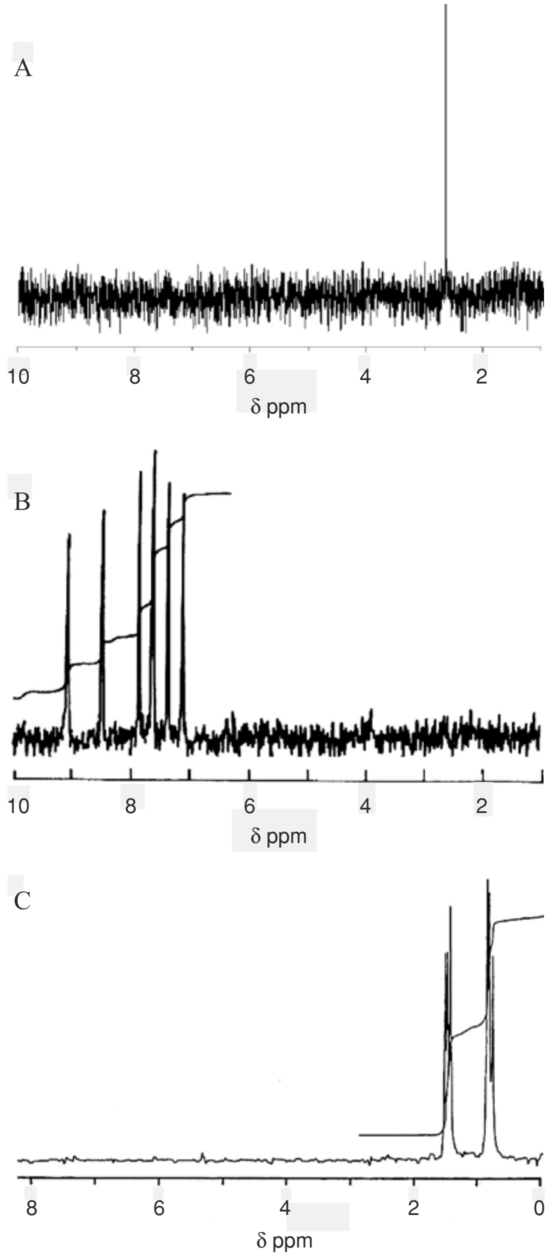


Fig. 1. (A) ^{3}H NMR spectrum (^{1}H decoupled) of tritiated *o*-methoxyacetophenone (*o*-CH_3O-$C_6H_4COCH_2T$, 11 μCi) with a proton/tritium cryoprobe at 533.5 MHz. (B) ^{3}H NMR spectrum (^{1}H decoupled) of [G-^{3}H]quinoline (~10 mCi) at 96 MHz (reproduced with permission by The Royal Society of Chemistry). (C) ^{3}H NMR (^{1}H decoupled) of [^{3}H]dihydroalprenolol showing T–T coupling and multiplicity of isotopomers (reproduced with permission by The Royal Society of Chemistry).

broader ^{2}H NMR signals. It follows therefore that one-step metal-catalyzed procedures that lead to generally labeled compounds are very useful. Figure 1B shows the ^{3}H (^{1}H decoupled) spectrum of [G-^{3}H]-quinoline prepared this way. In the absence of any differential nuclear overhauser effects (usually justified), the integrals give the relative percent tritium incorporated at each site.

Where T_2 gas has been used as, for example, in hydrogenation reactions, there will be characteristic T–T couplings and the spectra will be more complex (Figure 1C). The corollary of this is that, with careful analysis, much useful information can be extracted, e.g. the relative concentration of the various isotopomers can be ascertained. The relative proportion of CT_3, CT_2H, and CH_2T in compounds methylated with tritiated methyl iodide can similarly be calculated.

Applications

Although there are relatively few academic establishments that are set up to carry out tritium-related research, the pharmaceutical industry and the commercial companies that supply tritiated compounds have clearly recognized the importance of the technique and the benefits it bestows. Consequently, its main use has been in confirming that the tritium has been incorporated at the intended site and that if there is tritium at other sites these can be identified and the relative incorporation determined. At the same time, the technique can be used to determine the specific activity of a given compound—particularly useful when the latter has no suitable UV spectrum.

The availability of ^{3}H NMR spectroscopy as an analytical tool has encouraged researchers to look at the possibility of using a wider range of catalysts. Thus, to give but a few examples—$RhCl_3$, Crabtree's catalyst [$Ir(cod)Py(PCy_3)PF_6$], other iridium complexes, and $Ru(PPh_3)_3Cl_6$ have all met with varying degrees of success in the labeling area [11–13]. High temperature solid-state catalytic isotope exchange, as pioneered by Myasoedov and colleagues [14], would have been considerably less attractive but for the availability of ^{3}H NMR spectroscopy. Many of these reactions could benefit from further mechanism studies, as it is only through such investigations that more efficient and selective catalysts will be developed. With further improvements in sensitivity it should be possible, at least for homogeneous reactions, to see the formation of tritiated intermediates along the reaction pathway. This would represent a major advancement.

Improvements in sensitivity would also benefit other areas where so far relatively little use of ^{3}H NMR spectroscopy has been made. One of these is reaction kinetics where multisite T/H exchange and relative rates could provide useful information, e.g. on kinetic acidities [15]. Another area would be in biosynthesis, and in the study of substrate–receptor interactions where again the number of reported investigations is relatively small, despite the self-evident advantages [16,17].

Finally, ^{3}H NMR spectroscopy has been used to study aspects of radiation decomposition [18], isotope effects in chromatographic separations [19], stereochemistry [20], and isotope effects in hydrogen bonding [21].

Conclusions

^{3}H NMR spectroscopy is now a well-established technique that is invaluable for those engaged in tritium-related research. Despite tritium being the most sensitive of all NMR active nuclei the radioactivity required in order to produce ^{3}H NMR spectra of satisfactory S/N ratio is still high (by comparison with liquid scintillation counting for example). Future research directed at improving the sensitivity is likely to be richly rewarded as the range of attractive applications will be greatly expanded. The fact that microwave-enhanced labeling procedures now make it possible to rapidly tritiate so many compounds with much reduced levels of waste will contribute significantly to this process.

On-line Coupling of LC and NMR

On-line coupling of chromatographic systems to spectroscopic techniques, often called a "hyphenated technique" [1], has been proven to be an effective method for the analysis of complicated mixtures. Among such coupled systems, the hyphenation of liquid chromatography with NMR spectroscopy (LC–NMR) is a uniquely powerful and versatile combination, as NMR gives molecular-level structural information, with the advantage over other common LC detectors.

In 1978, Watanabe and Niki reported the first on-line LC–NMR experiment on three isomeric dimethylphenols with a 60 MHz spectrometer in the stop-and-flow mode in which the flow of the mobile phase was halted for the acquisition of NMR spectra [2]. The first continuous-flow LC–NMR experiments were reported by Bayer *et al.* in 1979 [3].

In the mid-1990s a substantial progress has occurred in both the hardware and the software relating to LC–NMR. The following four technical improvements particularly have contributed to the innovation of this method:

1. disadvantage of low sensitivity of NMR as compared with other common LC detectors has been considerably overcome by the advent of ultrahigh-field NMR spectrometers up to 800 MHz for the ^{1}H observing frequency [4];
2. effective techniques of solvent signal suppression using the pulsed field gradient (PFG) and frequency-selective pulses have made non-deuterated solvents accessible for the mobile phase of LC–NMR [5,6];
3. dedicated LC–NMR probes with optimized flow cells have become commercially available;
4. advanced computer technologies have enabled the real-time handling of large LC–NMR data matrices by sophisticated software and operating systems.

A schematic diagram of a typical LC–NMR system is shown in Figure 1. The eluate is directly introduced into the LC–NMR probe via capillary tubing from the outlet of the LC column. The cell has an optimized symmetry and volume (e.g. 60 μl) so as to avoid dispersion effects and to maintain the quality of chromatographic separation. The PFG coils attached to the probe are useful for solvent signal suppression.

On-line SEC–NMR

The applications of LC–NMR cover such fields as pharmaceutical and clinical chemistry, combinatorial chemistry, natural products, and foodstuffs [7–11]. From the viewpoint of polymer characterization [12,13], on-line coupling of NMR spectroscopy with the LC in the size exclusion mode [size exclusion chromatography (SEC) or gel permeation chromatography (GPC)] would be the most straightforward approach. Synthetic polymers are mostly mixtures of macromolecules with dispersion in molecular weight, composition of monomer units, stereoregularity, and so on. Among these structural non-uniformity, molecular weight distribution (MWD) is the most important characteristic of polymers, for which SEC is a facile and widely applicable chromatography [14,15].

The on-line SEC–NMR experiment was first reported by Hatada *et al.* in 1988 [16], in which a flow cell with detection volume of 60 μl (2 mm i.d.) or 140 μl (3 mm i.d.) was equipped on a 500 MHz NMR spectrometer. The experiment demonstrated the direct determination of the number-average molecular weight ($\bar{M}_n$) of isotactic (*it-*) poly(methyl methacrylate) (PMMA, see Equation 1) without a calibration curve [16,17]. A decade later, they reported 750 MHz SEC–NMR experiments on the same objectives [18].

Instrumentation of SEC–NMR

For most organic polymer samples, chloroform-d can be used as an eluent. Ethanol-d_6 is often added as a stabilizer in the amount of ca. 0.5%. The background signals due to the small amounts of impurities in the eluent, except for the water signal, can be eliminated by subtracting the NMR data for the eluent. Non-deuterated solvents containing a small amount of a deuterated solvent for the deuterium lock can also be used as an eluent. In this case the eluent signals should be eliminated by applying WET

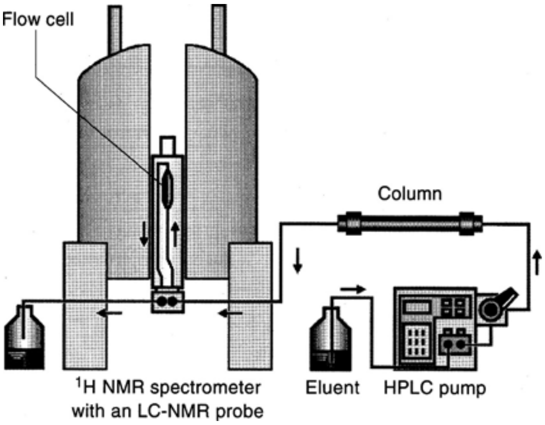

Fig. 1. Schematic diagram of on-line LC–NMR.

(water suppression enhanced through T_1 effects) [19] in combination with the LC–NMR probe with PFG coils.

Typically, the ^{1}H NMR data are collected over the entire chromatographic peak and stored as a consecutive series of n coadded scans. If the repetition time is t seconds, a series of NMR spectra are obtained every nt seconds and thus the time resolution of the chromatogram is nt seconds. In on-line LC–NMR measurements, the NMR spectral quality depends on the flow rate. The effects on the resolution and signal-to-noise (S/N) ratio are summarized in Table 1 as examined for $CHCl_3$ in $CDCl_3$ on a 750 MHz NMR instrument [18]. The resolution of the spectrum is slightly improved as the flow rate increases up to 0.5 ml/min and the broadening is observed at flow rates larger than 0.5 ml/min. The S/N ratio of the resonance decreases gradually with increasing flow rate as the residence time (τ) of the sample within the NMR cell before signal detection decreases. At flow rates larger than 0.5 ml/min, the S/N decreases to about one-fifth that in the non-flow state, mainly due to insufficient premagnetization of the sample. When a 90° pulse is used, the residence time has to be five times longer than the largest T_1 for a quantitative determination. For the signal with T_1 of 0.5 s at the flow rate of 0.5 ml/min, the volume of 0.021 ml has to be located in the front of the detection part of the flow cell.

Table 1: Effects of flow rate on the ^{1}H NMR signal of $CHCl_3$ in $CDCl_3$ (5/95 v/v) measured at 750 MHz using an LC–NMR probe with a 60 µl flow cell[*]

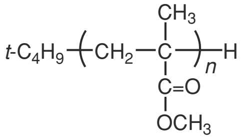
When the chromatographic separation of a polymer mixture is insufficient, the post-analysis of SEC–NMR data by the multivariate curve resolution can resolve the individual components and thus enable one to extract each NMR spectrum from the SEC–NMR data set according to intensity profiles [20].

Molecular Weight Determination of Polymers

Determination of molecular weight by SEC requires a calibration curve, which is usually prepared using a set of standard polymer samples with narrow MWD. Quantitative analysis of end groups of a polymer by NMR spectroscopy can provide the $\bar{M}_n$, provided that the chemical structures of the polymer including the end groups is well defined. *it*-PMMAs containing one t-C_4H_9 group at the end of the chain (Equation 1) was analyzed by SEC–NMR and the $\bar{M}_n$ was determined from the relative intensities of the ^{1}H NMR signals due to the t-C_4H_9 and α-CH_3 groups.



$$t\text{-}C_4H_9\left(CH_2-\underset{\underset{OCH_3}{|}}{\underset{C=O}{|}}\overset{CH_3}{\overset{|}{C}}\right)_n H \tag{1}$$

Figure 2 shows the SEC–NMR data of the *it*-PMMA with $\bar{M}_n$ of 3270. The signals due to the $-OCH_3$, CH_2, α-CH_3, and t-C_4H_9 protons resonate at 3.60, 2.13 and 1.52, 1.20, and 0.86 ppm, respectively. All the cross-sections at the peak positions give ^{1}H NMR-detected SEC chromatograms. The ^{1}H NMR-detected SEC chromatograms from the α-CH_3 signals of the four PMMA samples are shown in Figure 3 together with those recorded using a refractive index (RI) detector. The peak profiles of the ^{1}H NMR-detected and RI-detected chromatograms are very similar to each other. The

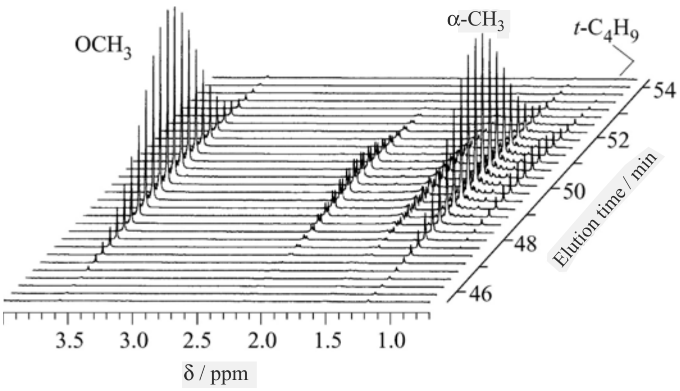


Fig. 2. The 750 MHz on-line SEC–NMR data of isotactic PMMA. ($\bar{M}_n$ from ^{1}H NMR = 3270, sample A in Figure 3) [18]. Eluent CDCl$_3$, flow rate 0.2 ml/min, amount of sample 1.0 mg, pulse width 90°, pulse repetition 2.25 s.

differences in elution times are due to differences in the void volume of the connecting path.

Figure 4 illustrates the ^{1}H NMR spectrum of the PMMA (Sample A) stored as a single file for elution times from 50.1 to 50.4 min (Figure 3) that has S/N ratios large enough to determine the $\bar{M}_\mathrm{n}$ values accurately, the calculated $\bar{M}_\mathrm{n}$ value being 3520. The data files for the tail parts of the chromatogram, which exhibit the t-C$_4$H$_9$ signal with a S/N less than 10, are added with two or three contiguous files so that the S/N exceeds 10. The $\bar{M}_\mathrm{n}$ of each fraction can be determined directly from the respective ^{1}H NMR data so that the $\bar{M}_\mathrm{n}$ and $\bar{M}_\mathrm{w}/\bar{M}_\mathrm{n}$ values for the whole sample are obtained without any calibration as is usually required for SEC analysis.

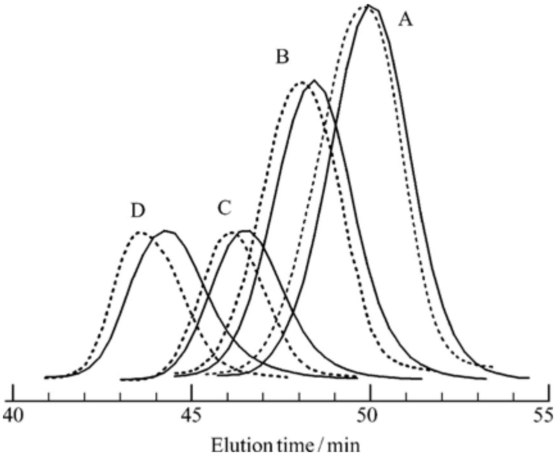

Fig. 3. The ^{1}H NMR- (solid lines) and RI-detected (dotted lines) SEC curves of isotactic PMMAs. The $\bar{M}_n$ values from ^{1}H NMR of samples A, B, C, and D are 3270, 5750, 10160, and 24220, respectively. Amounts of samples A, B, C, and D introduced to the chromatograph were 1.0, 0.8, 0.4, and 0.4 mg, respectively, and the volume of the sample solution was 50 μl [18].

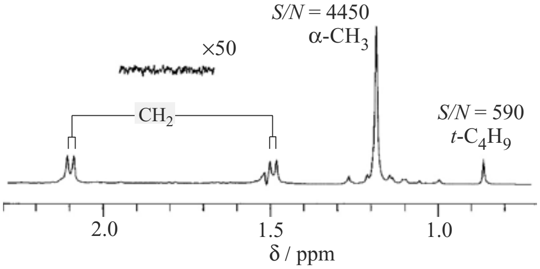

Fig. 4. The ^{1}H NMR spectrum of isotactic PMMA acquired at the elution maximum of sample A (50.1–50.4 min, Figure 3) [18].

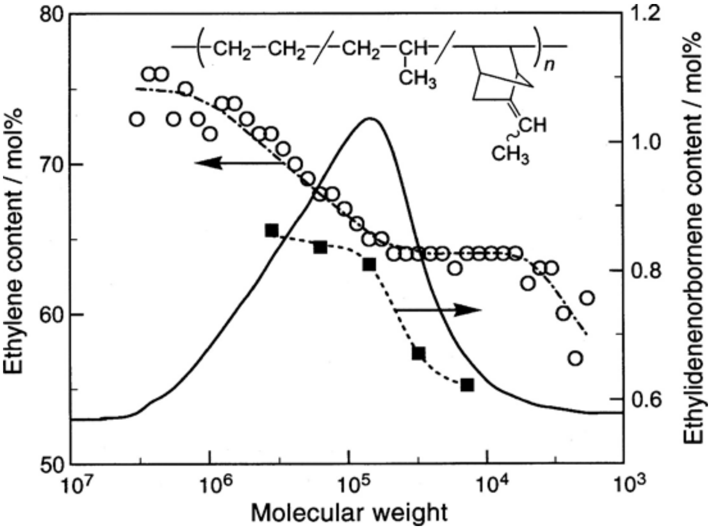
When measurements are carried out under appropriate conditions, reliable data on $\bar{M}_n$ and $\bar{M}_w/\bar{M}_n$ can be obtained up to the average degree of polymerization (DP) of about 200 [18]. Molecular weight averages of hydroxyl terminated oligo(ether sulfone)s were determined by the end group analysis. Since the hydrodynamic volumes of oligomeric substances vary considerably with irregular structures such as end groups, the molecular weight calculated by the conventional calibration procedure in SEC may deviate from the true molecular weight [21].

Molecular Weight Dependence of Copolymer Composition

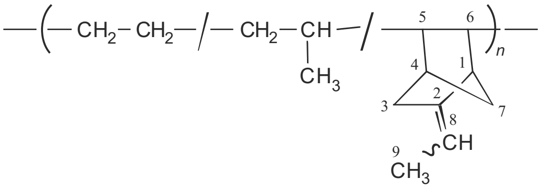
Chemical composition in a copolymer sometimes varies with molecular weight depending on the copolymerization mechanism involved. The on-line SEC–NMR technique is useful for elucidating the molecular

Fig. 5. Molecular weight dependence of comonomer compositions of ethylene-propylene-(2-ethylidene-5-norbornene) terpolymers (EPDM) as determined by SEC–NMR [24].



weight dependence of the copolymer composition, the information of which provides us with characteristics of the copolymer itself as well as the polymerization mechanism. Isotactic copolymers of *n*-butyl methacrylate and methyl methacrylate prepared with t-C_4H_9MgBr [22], poly[(acrylic acid)-*co*-(lauryl methacrylate)] [20], poly [(*n*-butyl acrylate)-*co*-styrene] [8], poly[(ethyl acrylate)-*co*-styrene] [23], ethylene-propylene-(2-ethylidene-5-norbornene) terpolymers (EPDM) [24], block-like copolymers of *t*-butyl acrylate and ethyl methacrylate by anionic mechanism [25], partially hydrolyzed poly(vinyl acetate) regarded as a pseudo-copolymer, i.e. poly[(vinyl acetate)-*co*-(vinyl alcohol)] [26]. As far as the NMR measurement conditions are appropriate, the signal intensities of the respective monomeric units in the copolymers provide their molar fractions without any calibration procedure.

As a typical example, the results for the EPDM (Equation 2), industrially important hydrocarbon elastomers, investigated by 750 MHz SEC–NMR is shown in Figure 5. Comparison of the chromatograms obtained by monitoring the CH_2 and CH_3 resonances in the terpolymer sample shows that ethylene/propylene ratio depends on the molecular weight and increases with increasing molecular weight. Molecular weight dependence of small amounts (0.6–1.1 mol%) of 2-ethylidene-5-norbornene units in the terpolymers could not be determined by the typical on-flow SEC–NMR measurement. However, the stop-and-flow measurements allow larger number of accumulations enough to determine the norbornene contents which were found to increase with increasing molecular weight in a typical commercial EPDM having a broad MWD. The *E*/*Z* ratio at C2–C8 double bond in the norbornene unit was constant (72/28) over the whole range of molecular weight [24].



(2)

Molecular Weight Dependence of Tacticity

Stereoregularity (tacticity) of polymers is one of the dominant structural characteristics, which sometimes affects their properties. NMR is uniquely sensitive to tacticity and thus SEC–NMR is applicable for elucidating the molecular weight dependence of tacticity. The information derived from the SEC–NMR analysis of tacticity is often useful for the understanding of the mechanism of stereospecific polymerization [27,28]. Polymerization of MMA with 1,1-diphenylhexyllithium in toluene at $-78\,^\circ C$ gave isotactic-rich PMMA ($mm = 85\%$) with a broad MWD. SEC–NMR analysis revealed that the high-molecular weight part of the PMMA consisted of almost 100% isotactic polymer [27]. Polymerization of MMA with t-C_4H_9Li in toluene at $-78\,^\circ C$ also gave *it*-rich PMMA with a broad but unimodal MWD. Addition of trialkylaluminum to t-C_4H_9Li changes the stereospecificity of the polymerization from isotactic-specific to syndiotactic-specific and the polymerization with

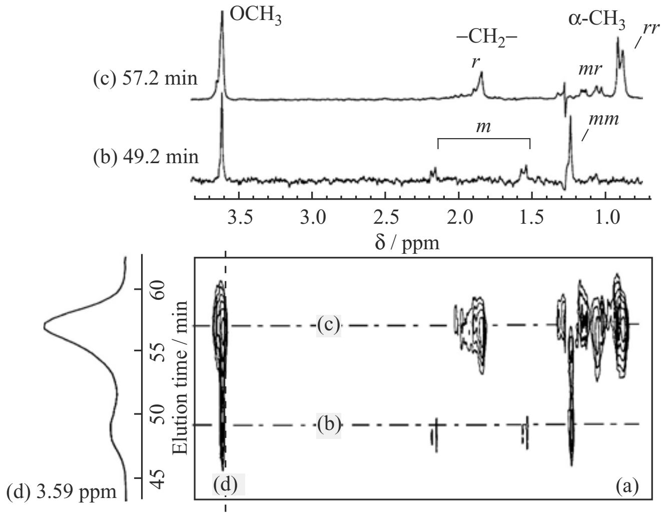


Fig. 6. A contour plot (a) and cross-sections (b–d) of the 500 MHz on-line SEC–NMR data for PMMA prepared with t-C_4H_9Li-(n-C_4H_9)$_3$Al (Al/Li = 1.0) in toluene at − 78°C [22].

t-C_4H_9Li–(n-C_4H_9)$_3$Al (Al/Li ≥ 2) in toluene at −78 °C gives highly *st*-PMMAs [28]. The t-C_4H_9Li–(n-C_4H_9)$_3$Al (Al/Li = 1) system gives a stereoblock-like PMMA in toluene at −78 °C. The contour plot of the SEC–NMR data for this PMMA is shown in Figure 6. The cross-section at the chemical shift of the OCH_3 peak (Figure 6d) indicates the polymer has a bimodal MWD. The cross-sections at elution times of 49.2 and 57.2 min (Figure 6b and c) clearly show that the lower molecular weight part of the polymer is syndiotactic and the higher molecular weight part is isotactic; that is, isotactic- and syndiotactic-specific propagating species exist concomitantly in the polymerization system at the ratio of Al/Li = 1.0.

SEC–NMR of PMMA Stereocomplex

When two kinds of polymer molecules with known molecular sizes form a complex in solution, the size of the complex is expected to be larger than the respective components. If the complex is stable enough to be differentiated by SEC from the component polymers, the SEC–NMR is a good means to gain structural information on the polymer complex.

The PMMA stereocomplex has been known as a unique polymer–polymer complex which forms on mixing *it*- and *st*-PMMAs in certain solvents such as tetrahydrofuran (THF), acetone, benzene, and *N*,*N*-dimethylformamide (DMF). Using uniform *it*-PMMA and *st*-PMMA with discrete DP, formation of the stereocomplex in solution can be observed by using SEC by appreciating the extreme narrowness of the SEC peaks of the uniform PMMAs [29]. The compositions of the associated and dissociated PMMAs, could be obtained by on-line SEC–NMR analysis [30]. Figure 7 illustrates a ^{1}H NMR-detected SEC curve of the mixture of *it*-46mer and *st*-46mer with a blend ratio *st*-/*it*- = 0.61 in acetone/acetone-d_6 (95/5 w/w) at −15 °C. The whole chromatogram is obtained by tracing the OCH_3 signals and the traces for *it*-46mer and the *st*-46mer are derived from the tacticity-sensitive α-CH_3 signals. The detection temperature (the temperature of the flow cell) was adjusted to 45 °C while the SEC column was maintained at −15 °C; when the detection temperature was set at −15 °C, the SEC–NMR spectra of the stereocomplex showed significant broadening of the resonances due to the restricted segmental mobility of the chains.

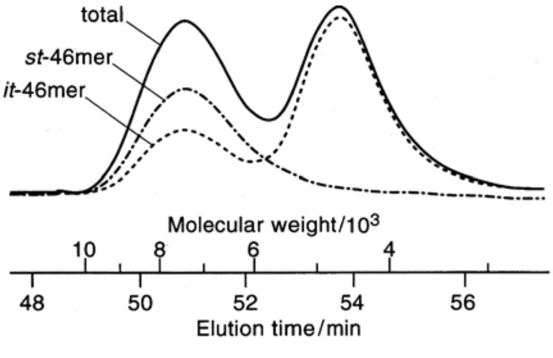

Fig. 7. The ^{1}H NMR-detected SEC curve of the mixture of *it*-46mer and *st*-46mer with a blend ratio *st*-/*it*- = 0.61 in acetone/acetone-d_6 (95/5 w/w) at −15 °C [30].

The *st*-/*it*- compositions of the stereocomplex were determined to be 1.6l–1.94. Accordingly, two types of stereocomplexes with different compositions (e.g. *st*-/*it*- = 1/1 and 2/1) should coexist in the mixtures. Both the complexes with 1/1 ($M = 9326$) and 2/1 ($M = 13{,}989$) compositions were suggested to have the hydrodynamic volumes corresponding to that of *it*-PMMA with $M = 7000$.

LCCAP–NMR

Besides SEC, there are separation modes of liquid chromatography applicable to the polymer characterization by LC–NMR. “Liquid chromatography at the critical adsorption point (LCCAP)” is a chromatographic method where size exclusion effects are balanced by interaction effects [31,32]. To maintain such a critical separation conditions, a mixture of good and poor solvents is usually employed as an eluent for separation at the CAP. Under the CAP, retention becomes independent of the length of the polymer chain and separation is accomplished according to the chemical heterogeneities of polymers, such as end groups [32] and stereoregularity [33,34]. LC–NMR in the interaction mode was used for the detection and identification of styrene oligomers. Information on the chemical structure of the end groups, DP, and the tacticity of the oligostyrene were obtained [35]. A technical poly(ethylene oxide) (PEO) was also analyzed by LC–NMR in the LCCAP mode using a mixture of acetonitrile/D_2O as the eluent. The PEO was separated according to the functional end groups, and the DP and chemical structure were determined [36,37].

If an LCCAP is able to separate a polymer according to the stereoregularity, the application of LCCAP–NMR may afford information on “tacticity distribution” in the polymer, since NMR spectrometer can be a tacticity-sensitive detector. The separation of a model poly(ethyl methacrylate) (PEMA) samples composed of four constituents with similar molecular weight ($\bar{M}_w = 14 - 16 \times 10^3$) and differing in their tacticity (*rr* triad content = 0, 33, 68, and 89%) was achieved by LCCAP with a mixed eluent composed of acetone, acetone-d_6, and cyclohexane at 35 °C. The tacticity composition within each peak eluted from the LCCAP column was determined by the NMR spectrometer in the continuous-flow mode (Figure 8). Highly isotactic, predominantly heterotactic, predominantly syndiotactic, and highly syndiotactic PEMAs were eluted from the column in that order. Tacticity distribution in a particular PEMAsample of narrow MWD ($\bar{M}_w/\bar{M}_n = 1.05$) with a tacticity *mm*/*mr*/*rr* = 2/45/53 has also been revealed by the LCCAP–NMR analysis; *rr* triad content increases from 40 to 70% and *mm* triad content decreases from 20 to 0%. The results suggest the presence of several types of propagating species with similar reactivity but different stereospecificity in the polymerization process. In the LCCAP–NMR experiments, modern solvent suppression techniques are essential, since it requires the use of a mixture of the desired good and poor solvents for the eluent [38].

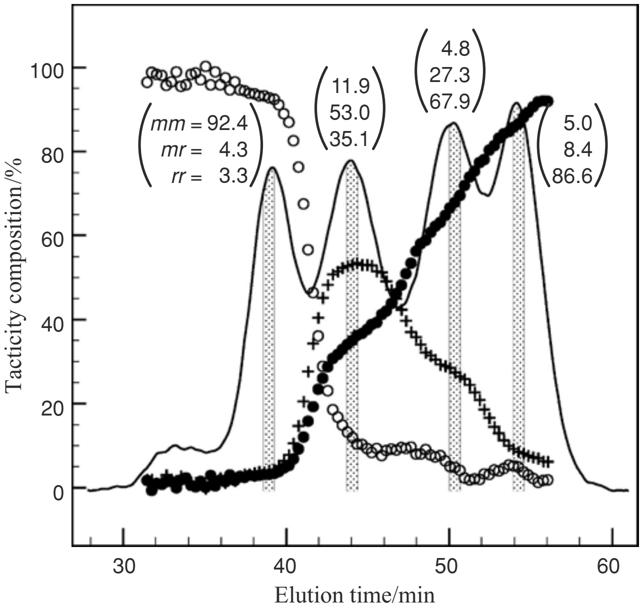

Fig. 8. The ^1H NMR-detected LCCAP trace of the model PEMA sample monitoring the CH_2 in ethoxy ester group. Tacticity compositions (*rr* (●), *mr*(+), and *mm*(○) triad contents) are also shown. Numerical tacticity values are depicted at the top of each peak [38].

Part I

NOE and Chemical Exchange

The Nuclear Overhauser Effect

Mike P Williamson
Department of Molecular Biology and Biotechnology, University of Sheffield, Sheffield S10 2TN, UK

Introduction

The nuclear Overhauser effect (NOE) is observed as a change in intensity of one resonance when the intensity of a neighboring resonance is perturbed. The effect depends strongly on the internuclear distance r, in that the rate of transmission of the NOE is proportional to r^{-6}. However, various factors conspire to reduce this dependence, making reliable quantitation of distances difficult. Nevertheless, the technique is widely used, particularly in the structure determination of biomolecules and as a routine method for conformational analysis in chemistry. The introduction of new methodology has greatly extended its use for conformational analysis, measurement of intermolecular interactions, and analysis of ligand binding. Thus, although our understanding of the theory of the NOE has not changed much in recent years, the areas of application continue to increase.

Theoretical Background

Only a brief presentation of NOE theory can be made here. A complete account of NOE theory is presented in a monograph [1], and an excellent simpler version is also available [2].

The NOE is caused by relaxation of one nuclear spin by a neighboring spin. To understand the basics of the NOE, we only need to consider two spins. In a system consisting of two NMR-active nuclei, I and S, the equilibrium magnetizations of I and S are given by I_z^0 and S_z^0, the z signifying that at equilibrium the only magnetization present is along the z-axis. The size of the z magnetization (for a spin$-1/2$ nucleus, which is the only type of spin we shall consider here) is proportional to the difference in population between the two energy levels α and β. If the z magnetization of spin S is perturbed, for example by selective saturation, or by inversion (either by a 180° pulse or by some 2D sequence), then it will subsequently return to equilibrium by relaxation processes, where *relaxation* means any process that causes exchange of a spin state between α and β. The essence of the NOE is that relaxation of S toward equilibrium can also involve I, if the two are close enough together, leading to perturbation of the populations of I and hence a change in intensity, and thus an NOE at I arising from the initial perturbation of S. This effect then allows us to detect or measure the short distance between I and S.

The reason for this is that *spontaneous* relaxation is extremely slow. The main way in which a spin can undergo a transition from one spin state to another is if that transition is *stimulated*, usually by a change in the magnetic field strength at the nucleus, which must be happening at a rate that matches the frequency of the transition. In our simple two-spin system, there are four possible energy states and six possible transitions between them (Figure 1). The transition between $\beta\beta$ and $\beta\alpha$ is a transition of spin S (hence its descriptor in Figure 1 as W_{1S}), and the energy difference between the two states (i.e. the frequency of the transition) corresponds to the frequency of spin S, for example, approximately 500 MHz for ^{1}H in an 11.7 T field. This transition is stimulated by changes in magnetic field strength at nucleus S occurring at a rate of 500 MHz. The main source of magnetic field variation at S in our simple two-spin molecule is actually spin I, and the main way in which the field can change is by a rotation of the molecule containing I and S. Thus, transition W_{1S} is stimulated by molecular tumbling at a rate of 500 MHz. This mechanism is normally referred to as *dipolar relaxation*, because it is relaxation of S by the magnetic dipole of I. This transition has no effect on the intensity of I, so does not produce an NOE. Dipolar relaxation gets weaker as the distance between I and S increases, at a rate proportional to r^{-6}.

Relaxation of S can occur by two other routes, shown on Figure 1 as W_0 and W_2. These involve the spin states of I and S changing simultaneously. W_0 involves a change between $\beta\alpha$ and $\alpha\beta$, and is often described as a "flip-flop" transition, in which the two spins I and S exchange energy. The frequency of this transition is the difference in chemical shift between I and S, so for a homonuclear system it is at most a few kHz. By contrast, W_2 involves both spins flipping together in the same direction, and its frequency is the "double quantum" frequency of 1000 MHz.

At equilibrium, the population of $\beta\beta$ is less than that of $\alpha\beta$ and the population of $\beta\alpha$ is less than that of $\alpha\alpha$. Saturation of S implies equalization of the populations of $\beta\beta$ and $\beta\alpha$, and also of $\alpha\beta$ and $\alpha\alpha$. Relaxation of S

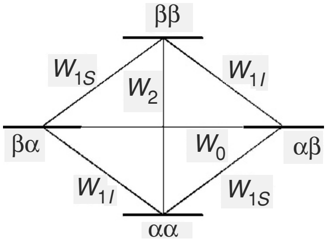

Fig. 1. Energy levels and transitions of a two-spin system. Each spin can be in spin state α or β. The total spin state is described by listing the state of I first and then S, so, for example, state $\alpha\beta$ is the state in which I is in α and S is in β.

by W_0 acts to restore S magnetization toward the equilibrium position, and thus takes spins out of $\beta\alpha$ and puts them into $\alpha\beta$. The effect of this on I is to reduce the population difference across the I transitions, and hence reduce the intensity of I. In other words, the W_0 process means that saturation of S causes a loss in intensity of I. By similar reasoning, it is easy to show that the W_2 process causes an *increase* in intensity of I. The rate of the net intensity change of I (the *cross-relaxation rate*, often given the symbol σ) is thus proportional to $(W_2 - W_0)$, and depends on how fast the molecule is tumbling in solution. If the molecule is tumbling very fast, then W_2 is more efficient than W_0, and the intensity of I increases (a positive NOE). If the molecule is tumbling very slowly, then W_0 is more efficient, and the intensity of I decreases (a negative NOE). The size of the homonuclear NOE in a two-spin system is shown in Figure 2 as a function of $\omega\tau_c$ (where ω is the spectrometer frequency expressed in rad/s and τ_c is the correlation time—the time it takes for the molecule to rotate through 1 rad), and is seen to go through zero at approximately $\omega\tau_c = 1$. This means that for small molecules the homonuclear NOE is positive, while for big molecules it is negative.

The NOE in Multi-Spin Systems

Real molecules have more than two spins. Fortunately, almost all relaxation processes only involve pairs of spins; processes involving three spins are called cross-correlation processes and can usually be ignored. This means that we can understand what happens in real molecules by a simple extension of the two-spin case. Perturbation of S leads to an effect on the intensity of I; in turn this leads to an effect on Is neighbors. Therefore, NOEs can propagate throughout the molecule. This has several consequences. In *large* molecules, the homonuclear steady-state NOE is -1 (Figure 2), meaning that saturation of S leads to complete saturation of I also. This in turn passes its saturation on to other spins in a process known as *spin diffusion*. The consequence is that all nuclei in the molecule eventually become saturated, and the steady-state experiment is uninformative. Consequently, all NOE experiments in large molecules (e.g. proteins) are carried out as transient experiments, usually by versions of the 2D NOESY experiment.

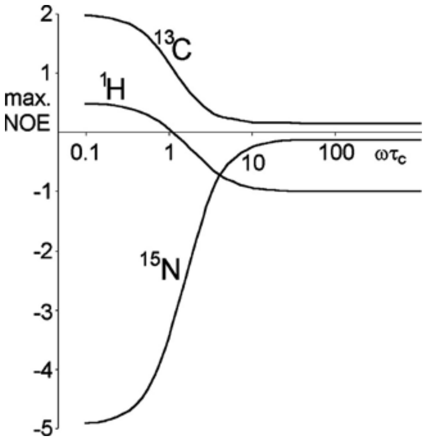

Fig. 2. The dependence of NOE intensity on $\omega\tau_c$ for an ideal two-spin system following steady-state saturation of S. The zero crossing point for homonuclear NOEs is at $\omega\tau_c = 1.12$. The curves are shown for X{^{1}H} with X = ^{1}H (homonuclear NOE), ^{13}C and ^{15}N. The curve for ^{19}F is very similar to that for ^{1}H, because of the similarity in their gyromagnetic ratios.

In small molecules, saturation of S leads to an increase in the intensity of I, with a maximum of $+50\%$, though in practice it is usually much smaller than this. An increase in I is passed on to its neighbors as a decrease in their intensity. Thus, in small molecules multi-spin effects lead to alternations in the sign of the NOE along a chain. In practice the effect is not observed for more than three spins in a row. It is therefore possible to carry out steady-state NOE experiments on small molecules, and the effects are approximately related to distance. However, calculation of sizes of NOEs requires detailed knowledge of geometries (and usually of dynamics as well), and steady-state NOEs are not (and should not be) normally interpreted in more than a qualitative manner. Nevertheless, they are extremely useful for the assignment of geometries around double bonds, and for stereochemical assignments, particularly in rigid systems such as fused ring systems. NOEs have in the past been much used to connect molecular fragments together in natural product identification. However, with the advent of heteronuclear correlation experiments such as HMBC, most problems of this type can now be addressed more simply, leaving only a few stereochemical details to be addressed by specific NOE experiments [3].

Although exact calculation of steady-state NOEs in multi-spin systems is generally not worthwhile, a few guidelines are useful for their interpretation. Protons that are very close together (for example, methyl and methylene protons) relax each other very efficiently. This means that NOEs *into* such groups are usually small. (The NOEs are small on a fractional basis. In absolute terms, an NOE to a methyl group can still be easily observed because there are three protons in a methyl group, and because the signal is often sharp.) NOEs to isolated protons can often be misleadingly large.

Time Dependence of the NOE

For the reasons given above, NOE experiments in large molecules are always done as transient (2D) experiments. In a transient experiment, the NOE first builds up (at the cross-relaxation rate), and then decays away, at roughly the spin–lattice relaxation rate ($1/T_1$). As the size of the molecule increases, the cross-relaxation rate increases proportionately (except of course for a hiatus around $\omega\tau_c \approx 1$, where the NOE goes from positive to negative), and so (approximately) does the decay rate. Thus for proteins, the transient NOE reaches its maximum at around 300 ms, and NOESY experiments are often carried out using NOE mixing times of 50–100 ms. By contrast, for small molecules, the NOE maximum can occur at several seconds. One consequence of this is that in experiments with proteins, one does not need to be too concerned about unwanted sources of relaxation. By contrast, with small molecules it is very helpful to remove things that can cause unwanted relaxation, because these can seriously reduce the size of NOE observed. In particular, it is common practice to take care to remove paramagnetic impurities such as metal ions (using chelating agents) and oxygen (by bubbling through with nitrogen or argon, or by repeated freeze–thaw cycles).

The big advantage of transient experiments is that quantitative distance measurement is much simpler. An unknown distance r_{IS} can be estimated from the intensity of the transient NOE $f_I\{S\}$ using a known reference distance r_{ref} and reference NOE f_{ref} using the simple equation

$$r_{IS} = r_{\text{ref}}\left[\frac{f_I\{S\}}{f_{\text{ref}}}\right]^{-1/6}$$

This equation is only valid for short buildup times (typically $\leq$100 ms for proteins and $\leq$0.5 s for organic molecules), when spin diffusion is insignificant. It is also only valid if the molecule tumbles rigidly and isotropically. Real molecules do neither, and although one can calculate the effect of internal motion and anisotropic tumbling, this usually requires motional details that are not experimentally accessible. For these reasons, it is always sensible to allow some margin of error in the application of this formula.

Heteronuclear NOE

The NOE can be observed between heteronuclei. Like the homonuclear NOE, it has a strong dependence on $\omega\tau_c$, as shown in Figure 2. The size of the NOE depends on the gyromagnetic ratios of the two nuclei concerned: the NOE at I on saturation of S is proportional to the ratio γ_S/γ_I. Because the gyromagnetic ratio of ^{1}H is higher than any other except ^{3}H, this means that an X{^{1}H} NOE (i.e. observation of an NOE on X after saturation of ^{1}H) is usually much larger than a ^{1}H{X} NOE (Figure 2), and can be a valuable way of increasing the intensity of the signal from X. This means that for example ^{13}C spectra of organic molecules acquired using ^{1}H decoupling often contain large NOEs of up to a factor of 2, which are, however, non-uniform across the molecule because protonated carbons receive a larger NOE than non-protonated carbons, because of their shorter distance to protons.

NOEs involving ^{15}N are interesting because the ^{15}N gyromagnetic ratio is negative, meaning that ^{15}N NOEs are always negative (Figure 2). They are also of interest because they are used extensively in studies of dynamics in proteins. Relaxation of ^{15}N in ^{15}N-labeled proteins is dominated by the attached ^{1}H, which is at a fixed distance and therefore allows measurement of the extent of local motion, as well as the overall correlation time [4].

Applications of the NOE

Quantitatively the biggest use of the NOE is in determining the structures of biomolecules. A typical protein structure determination requires the assignment and quantitation of approximately 2000 NOEs. This is usually done from 3D and sometimes 4D heteronuclear-edited NOESY spectra, and increasingly the picking of peaks and their assignment is done automatically, with increasingly sophisticated algorithms to account for (and usually spot and eliminate) the inevitable wrong assignments and consequential structural distortions [5]. NOEs are often sorted into three categories (strong, medium, and weak, corresponding to distances, for example, of <2.5 Å, <3.5 Å, and <5 Å, respectively), because of the many ways in which the relationship between NOE intensity and distance can be distorted, of which the principal ones are spin diffusion and peak overlap.

The other common use is to aid structure determination in organic molecules. Here the most common technique is a steady-state experiment (or more commonly a pseudo-steady-state experiment, in which the presaturation period is limited to 1–2 s, to speed up the experiment without significant loss of information), though the simplicity of setting up and interpreting 2D NOESY experiments has made this a popular experiment here too. For molecules of intermediate size, the NOE goes through zero (Figure 2), and an alternative experiment is used, ROESY, which does not go through zero [1].

In recent years, the DPFGSE-NOE experiment has become deservedly popular [6]. This is a 1D transient experiment, which achieves both selective saturation of the target spin and very clean removal of artifacts by use of gradient pulses. It is simple to use once set up and is becoming the method of choice for rapid measurement of selective and transient NOEs in organic molecules [3].

An increasingly popular application of the NOE is to detect intermolecular association, for which it is quick and unambiguous, and can often give details about the orientation of complexes [2]. It has had wide application for elucidating the structures of metal complexes [7,8]. Quantitative determinations are difficult because of problems in knowing the intermolecular correlation time, and because of conformational averaging, but elegant structural results have been obtained, particularly with the use of heteronuclear NOEs such as the heteronuclear 2D ^{1}H–^{19}F NOESY experiment, HOESY. Similar experiments have also been done to study site-specific solvation [9].

The NOE has been used for many years for studying the conformation of ligands when bound to macromolecular receptors, using an experiment known as the transferred NOE (trNOE). This is based on the idea that NOE buildup in a complex is much faster than in the free ligand. Hence, a NOESY spectrum of a ligand that is in excess over its receptor and in fast exchange will be dominated by NOEs arising from the bound state. Further discussion of the trNOE can be found elsewhere in this Handbook [10]. A number of related experiments are now appearing and promise to be extremely useful in drug design. Two are worth mentioning here. The first is known as saturation transfer difference (STD), and involves saturation of the receptor. Spin diffusion spreads the saturation over the receptor and onto any ligand that is bound to it. Subsequent exchange of the ligand into the free state gives rise to partial saturation of the free ligand, and thus identifies molecules that bind to the receptor [11]. The second is designed to detect whether two ligands bind to the same site, and if so to determine their relative orientations. Ligand A binds to the receptor, and gives rise to NOEs from ligand to receptor. If this ligand then dissociates, and ligand B binds in the same site, NOEs build up between receptor and ligand. The net result is an apparent NOE between ligand A and ligand B, not only demonstrating that they bind to the same site, but also providing their relative orientation [12].

Solute–Solvent Interactions Examined by the Nuclear Overhauser Effect

J.T. Gerig

Department of Chemistry and Biochemistry, University of California, Santa Barbara, CA 93106, USA

Background

The nuclear Overhauser effect (NOE) can be defined as the change in the observed intensity of a NMR signal that results when the magnetization associated with another spin is perturbed [1]. The NOE is a consequence of the nuclear spin–nuclear spin dipole–dipole interactions that contribute to spin-lattice (T_1) relaxation. Measured NOEs are typically of the order of a few percent or less but are readily determined with modern instrumentation.

Spin-lattice relaxation is due to the presence of local magnetic fields that fluctuate at frequencies at or near the Larmor frequency of the spins undergoing relaxation. The major sources of these local fields are other spins of the sample. The interactions of nuclear spin dipoles follow essentially the same physics as a set of small bar magnets; it is the relative motion of the magnets that lead to relaxation. A quantitative understanding of the dipole–dipole interaction requires a description of both the spatial aspects of the interaction and the molecular motions that modulate the interaction [2].

Intramolecular NOEs

When two interacting spin dipoles A and B, both assumed to be spin 1/2 nuclei here, are contained in the same molecule, their mutual interaction is changed by the reorientation of the molecule that holds them. It is common to imagine that spin A is at the center of a sphere of radius r_{AB}, the distance between the two spins. Spin B "skates" on the surface of the sphere as the sphere reorients in solution, changing the orientation of the A–B internuclear vector. It is often assumed that reorientation is governed by the hydrodynamics of a sphere supported in a medium that has viscosity η. The reorientation of the molecule is then described in terms of a rotational correlation time τ_R which is approximately the time required for the molecule to rotate in any direction through an angle of about 1 rad [3]. The rotational correlation time in this model is related to molecular size:

$$\tau_R = \frac{\eta V_M}{kT}$$

where V_M is the molecular volume ($= 4\pi r^3/3$ for a sphere), k is Boltzmann's constant, and T is the temperature. Typical values of τ_R for small molecules are 1–100 ps. For macromolecules of a size that can be studied by high-resolution solution NMR experiments, τ_R typically lies between 0.1 and 10 ns.

The experimental intramolecular NOE for a pair of interacting spins depends on the cross-relaxation rate σ_{AB}, given by

$$\sigma_{AB} = \frac{\gamma_A^2 \gamma_B^2 \hbar^2}{10 r_{AB}^6} \left(\frac{6\tau_R}{\left(1 + (\omega_A + \omega_B)^2 \tau_R^2\right)} - \frac{\tau_R}{\left(1 + (\omega_A - \omega_B)^2 \tau_R^2\right)} \right) \qquad (1)$$

where r_{AB} is the distance between A and B, γ_A and γ_B are the gyromagnetic ratios of the spins, ω_A and ω_B are the corresponding Larmor frequencies, and $\hbar$ is Planck's constant divided by 2π. The strong dependence on internuclear distance in Equation (1) is important: only neighboring spins (those for which $r_{AB} \sim 2 - 5$Å) contribute appreciably to σ_{AB}. Another aspect of Equation (1) to be noticed is that the value of σ_{AB} can be negative, zero or positive depending on the values for ω_A, ω_B and τ_R. (When experimental conditions conspire to make σ_{AB} near zero, the rotating frame Overhauser experiment (ROE) can be useful [4].) Intramolecular NOE experiments basically involve evaluation of σ_{AB}. Because σ_{AB} is dependent on internuclear distances, evaluation of σ_{AB} plays an essential role in determination of the structures of small molecules as well as biological macromolecules.

While it is surprisingly useful, the representation of the intramolecular interaction of spins A and B discussed above can be criticized as over-simplified. There are many theoretical descriptions of relaxation due to intramolecular dipolar interactions available that are based on somewhat more realistic models [5,6].

Intermolecular NOEs

When the interacting spins A and B are on different molecules, their dipolar interaction is modulated by mutual diffusion of the two molecules. The simplest description of the interaction in this situation assumes that the spins are contained within two spherical molecules that have radii r_A and r_B, respectively. The closest the two spins can approach each other is $r_A + r_B = a$. The time dependence of the interaction of the spheres is assumed to be described by the mutual diffusion coefficient $(D = D_A + D_B)$ where D_A and D_B are the corresponding translational diffusion coefficients. The correlation time (τ) for the interaction of A and B is usually taken as the time required to diffuse the distance a $(\tau = a^2/D)$ [7–9]. The cross-relaxation rate σ_{AB} for the intermolecular interaction of the spins A and B when the signal for spin A is observed is

$$\sigma_{AB} = \frac{3\gamma_A^2\gamma_B^2 h^2 N_B}{10\pi Da}[6J_2(\omega_A + \omega_B) - J_2(\omega_A - \omega_B)] \quad (2)$$

where the spectra density function $J_2(\omega)$ is [7]

$$J_2(\omega) = \left(\frac{\omega\tau + \left(5/\sqrt{2}\right)(\omega\tau)^{1/2} + 4}{(\omega\tau)^3 + 4\sqrt{2}(\omega\tau)^{5/2} + 16(\omega\tau)^2 + 27\sqrt{2}(\omega\tau)^{3/2} + 81\omega\tau + 81\sqrt{2}(\omega\tau)^{1/2} + 81} \right) \quad (3)$$

and N_B is the number of molecules per ml containing spin B. If $(\omega\tau)^{1/2} = (\omega a^2/D)^{1/2} \ll 1$, the cross-relaxation rate due to the intermolecular interaction of spin B with A is

$$\sigma_{AB} = \frac{8\pi\gamma_A^2\gamma_B^2\hbar^2 N_B}{27Da} \quad (4)$$

Equations (2) and (4) convey the important information that the cross-relaxation at spin A due to interactions with molecules containing spin B depends on the concentration of the B-containing molecules, the mutual diffusion of both molecules and the distance of closest approach of A and B.

Further elaborations of the theory for the intermolecular dipole–dipole interaction take into account the rotational motions of the molecules containing spins A and B [7,9,10]. If the interacting spins are not located at the center of their representative spheres, rotation of the molecules will have the effect of altering the spin–spin interaction distance as the molecules approach each other. Other treatments consider situations where the local diffusion of the molecules when they are in close proximity may not be the same as diffusion in the bulk of the solution [10]. A method has been suggested to take into account the shape of the molecule containing spin A as it interacts with a spherical molecule containing spin B [11].

Magnitudes of Intramolecular and Intermolecular NOEs

Figures 1 and 2 compare computed intramolecular and intermolecular cross-relaxation rates for the interaction of two protons calculated using Equations (2) and (1) under conditions that would typically be present in aqueous solutions of small molecules (Figure 1) and large molecules (Figure 2) at room temperature. The calculations show that an intramolecular dipole–dipole interaction is expected to be about an order of magnitude larger than an intermolecular interaction of the same spins. The figures emphasize the short-range nature of the intramolecular interaction and show the relatively weak dependence of intermolecular cross-relaxation on distance. It should be kept in mind that a substantial portion of the intermolecular cross-relaxation arises from molecules that are appreciably separated from the spins under examination.

Solute–Solvent Interactions

Many reactions of chemical and biochemical interest take place in solutions. Interactions of solvent molecules with a solute can be critical in defining the rate of a reaction and its stereochemical outcome. Most of the common reaction solvents contain hydrogen or other spin 1/2 atoms on their surface; nuclear spin dipole–dipole interactions should thus be present as solvent molecules and solute molecules encounter one another. Although it is anticipated that intermolecular interactions will lead to relatively small cross-relaxation rates, experimental cross-relaxation rates could provide information about the "exposure" of a given solute atom to solvent and, thus, provide indications of the three-dimensional structure of the solute. It may be the case that one component of a mixed solvent system preferentially interacts with a solute; such specific solvation should be apparent in observed cross-relaxation rates since the local concentration of the solvent component that preferentially interacts with the solute will be different than the measured (bulk) concentration of that component. Lastly, the solvent–solute cross-relaxation rate is dependent on the details of translational and rotational

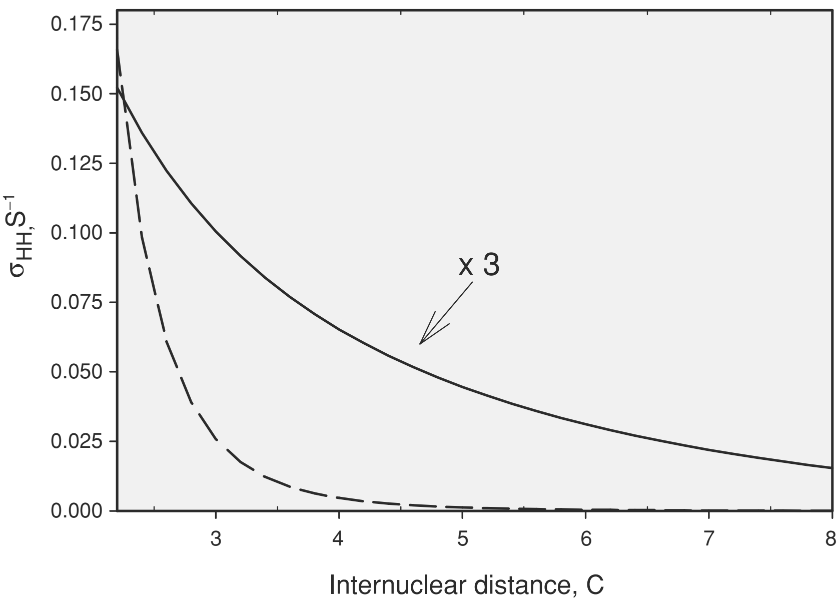

Fig. 1. Calculated ^{1}H{^{1}H} cross-relaxation rates for a small molecule dissolved in water as a function of internuclear distance. The solid line represents data for the intermolecular interaction between water protons and a proton of the small molecule while the dashed line corresponds to an intramolecular interaction. For the calculations, it was assumed that the rotational correlation time (τ_R) of the small molecule is 0.1 ns and that the translational diffusion coefficients of water and the small molecule are 1.9×10^{-9} m^2/s and 5.6×10^{-10} m^2/s, respectively. These parameters are characteristic of glucose dissolved in water [53].

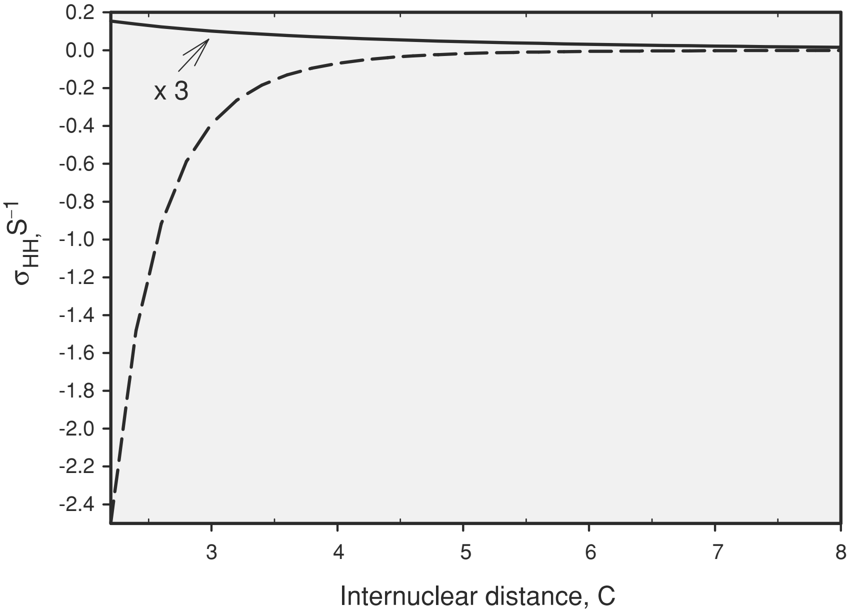

Fig. 2. Calculated ^{1}H{^{1}H} cross-relaxation rates for a large molecule dissolved in water as a function of internuclear distance. The solid line represents data for the intermolecular interaction between water protons and a proton of the large molecule while the dashed line corresponds to an intramolecular interaction. It was assumed that the rotational correlation time of the large molecule (τ_R) is 5 ns and that the translational diffusion coefficients of water and the large molecule are 2.3×10^{-9} m^2/s and 1.2×10^{-10} m^2/s, respectively. These parameters are characteristic of the enzyme lysozyme in aqueous solution [54,55].

motions of both partners and evaluation of σ_{AB} may provide insight into the nature of these processes.

Experimental Detection of Intermolecular Cross-Relaxation

The intensity of a solute NMR signal (spin A) depends on the z-component of the magnetization corresponding to A prior to application of the RF pulse that leads to the detected signal of A. Following a perturbation of the magnetization due to spin B in the solvent molecules, the initial change in the solute signal intensity with time is described by Equation (5) [12],

$$\frac{\mathrm{d}A_z}{\mathrm{d}t} = -\sigma_{\mathrm{AB}}\left(B_z(0) - B_z^0\right) \tag{5}$$

where A_z is the z-component of the spin A magnetization. The quantity $B_z(0)$ is the initial value of the solvent spin z-magnetization, B_z^0 is the z-component of the solvent magnetization when the system is at equilibrium, and σ_{AB} is the cross-relaxation rate due to the dipolar interactions of the solvent and solute spins. Equation (5) tells us that a plot of the intensity of the solute signal after perturbation of the solvent magnetization as a function of time after the perturbation (the mixing time) has an initial slope $2\sigma_{AB}$, assuming that the solvent magnetization was completely inverted at the start of the experiment $\left[B_z(0) = -B_z^0\right]$.

Some attention must be paid to experimental details when evaluating σ_{AB} arising from intermolecular solvent–solute interactions using Equation (5). The molar concentration of solvent spins is typically high and B_z^0 is large relative the solute magnetization. Thus, suppression of the solvent signal by a method that does not involve pre-saturation is usually required when collecting spectral data. Radiation damping effects may be present and lead to unexpected relaxation behavior of the solvent magnetization during the mixing time [13–15]. Difference (subtraction) methods are typically used to detect the (weak) NOE on the signal intensity of spin A. Such methods put a premium on instrument stability, particularly phase stability, and the linearity of the detection system. Control of the dipolar field associated with the solvent spins is also important [16,17].

Using a C.W. technique, Kaiser observed an intermolecular Overhauser effect between protons of cyclohexane (solvent) and chloroform (solute) in a mixture of these components [18]. Many years later, Macura and Ernst demonstrated the same interaction by means of a two-dimensional NOE experiment [19]. There have been many studies of solvent–solute interactions using the intermolecular NOE since those pioneering studies. A representative sample of these will be mentioned below. The purpose here is didactic and no attempt has been made to provide a comprehensive review of the literature.

Xenon–Solvent Interactions

Xenon-129, a solute consisting of only a single atom, dissolves in water and organic solvents to a sufficient extent that high-resolution NMR spectra of the atom can be readily obtained. Dimitrov *et al*., have determined that the cross-relaxation rate between the protons of solvent water and ^{129}Xe (σ_{XeH}) is about 3.2×10^{-3}/s [20]. Interpretation of the results suggested that the average xenon–proton distance in an aqueous solution of the gas is about 2.7 Å, an estimate that was recognized by the authors to be rather crude. The van der Waals radius of an Xe atom is 2.2 Å [21] while that of a covalent hydrogen is 1.2 Å [22], leading to an estimated distance of closest approach of 3.4 Å. The experimental cross-relaxation rate is thus consistent with a “tight” interaction between Xe and solvent molecules.

Intermolecular $^{129}\mathrm{Xe}\{^1\mathrm{H}\}$ NOEs have been detected for xenon dissolved in phosphatidylcholine (PC) vesicles. After correcting for the relative number of protons of each type in PC, the cross-relaxation rate for interaction of xenon with the protons of the choline methyl groups is about three times larger than σ_{XeH} for interactions between dissolved xenon and the CH_2 protons of the aliphatic parts of the phospholipids [23]. It was concluded that dissolved xenon is localized near the amphiphilic surface of the PC vesicles. This may be relevant to the mode of action of xenon as a general anesthetic.

Small Molecule–Water Interactions

The interactions of water protons with dissolved solute has been explored by heteronuclear intermolecular NOEs. Yu and Levy demonstrated $^{31}\mathrm{P}\{^1\mathrm{H}\}$ cross-relaxation between the phosphorus nuclei of ATP and water by a two-dimensional NOE experiment [24]. All signals from the triphosphate group are enhanced by interactions with water protons, although the γ-phosphorus at the end of the triphosphate group shows the largest effect, presumably because it is most accessible to water. Seba and Ancian found water proton $^{13}\mathrm{C}\{^1\mathrm{H}\}$NOEs to all carbon atoms of 1-methyl-2-pyridone dissolved in water [25]. Water interactions with this solute likely involve hydrogen bonds to the polar part of the molecule in addition to non-specific contacts.

Micelle–Water Interactions

Hydration of micelles of sodium octanoate and sodium dodecanoate has been explored by detecting intermolecular $^1\mathrm{H}\{^1\mathrm{H}\}$ NOEs between water protons and protons of these molecules. The results have been interpreted to indicate that water protons on average are located 3–4 Å from the carboxylate carbons in such aggregates [26]. Intermolecular $^{19}F\{^1H\}$ NOEs between water protons and the fluorines of micellar cesium perfluorooctanoate are observed for the fluorines in the CF_2 groups adjacent to the carboxylate head group but also for the other CF_2 groups of the surfactant [27]. The latter NOEs may be the result of spin diffusion or may suggest that water molecules not only contact the polar head groups but also other parts of the perfluoroalkyl chain in the micelles.

Interpretation of NOEs in micellar systems is complicated by the highly dynamic nature of these structures [28]. In addition to participating in a purely intermolecular effect, as represented by Equation (2), it is possible that in some cases water molecules interact strongly enough with the solute that the water–micelle interaction is best thought of in terms on an intramolecular molecular interaction [Equation (1)]. The rate of exchange of such strongly interacting waters with the bulk solvent molecules is an additional complication. While NOE data for the micellar systems mentioned were analyzed in terms of long-lived water–surfactant interactions, because of these additional considerations, the estimates of solvent proton–solute spin distances in these systems have to be regarded as very approximate.

Small Molecule-Organic Solvent Interactions

Our lab has determined solvent spin–solute spin NOEs for 1,3-di-*t*-butylbenzene dissolved in tetramethylsilane (TMS). Molecular models suggest that proton H_2 of the solute should be shielded from interactions with solvent molecules by virtue of the bulky *t*-butyl groups next to it. The remaining aromatic hydrogens (H_4, H_5, H_6) and those of the *t*-butyl groups are more accessible to direct interactions with solute molecules. It was found that solvent proton–solute proton $^1H\{^1H\}$ cross-relaxation rates were reasonably well predicted by a numerical procedure that incorporated the shape of the solute through its Connolly molecular surface and used the experimental diffusion coefficients of the solvent and solute. Thus, there was no evidence for special interactions between the solute and TMS.

Similar experiments were carried out with 1,3-di-*t*-butylbenzene dissolved in perfluoro-*t*-butanol. In that case, cross-relaxation rates for the protons of this solute with the OH proton of the solvent were very different from those predicted. Perfluoro-*t*-butanol is a fairly strong acid, probably with a $pK_a < 10$ [29] and 1,3-di-*t*-butylbenzene is expected to be a reasonably strong π-base. The observations suggest the formation of long-lived solute-perfluoro-*t*-butanol complexes in which fluoroalcohol molecules are hydrogen-bonded to the aromatic ring. If such complexes persist longer than the time $\tau\ (= a^2/D, \sim 0.03 - 0.1\ \text{ns})$ that characterizes diffusive encounters, dipolar interactions of solvent OH and, to a lesser extent, solvent fluorine with the aromatic protons will be modulated to some extent by rotational motion of the complex, as would be the case for an intramolecular interaction.

Determination of the enantiomeric composition of a mixture of chiral materials is a continuing problem in synthetic chemistry. This is often accomplished by recording NMR spectra of the mixture dissolved in a chiral solvent. Diastereoisomeric solvent–solute complexes form which can often be distinguished by means of their chemical shifts [30]. The structures of such solute–solvent complexes have been investigated by intermolecular NOEs [31,32]. For example, a 1:1 mixture of the S-isomer of alcohol I and acid II showed clear chemical shift differences between the R and S forms of II. Large intermolecular $^1H\{^1H\}$ NOEs were reported for the interactions of proton H_1 and the methyl protons of II with protons H_8 and H_{11} of I, with the NOEs for these interactions in the (S)I/(R)II mixture being about three times larger than the NOEs observed for the (S)I/(S)II case. Molecular dynamics (MD) simulations of these and related systems suggested that average distances between proton H_1 of II and protons H_8 and H_{11} of I are ~4.8 Å in the (S)I/(R)II system and somewhat larger (~5.2 Å) in the (S)I/(S)II complex, qualitatively consist with the intermolecular NOE results. The chemical shift differences and the relative stabilities of the diastereoisomeric complexes formed are presumably due to π-stacking interactions.

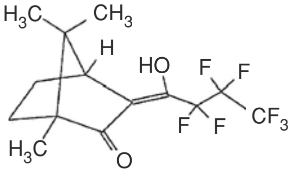
Selective Solute Interactions in Mixed Solvent Systems

Intermolecular NOEs have been used to demonstrate that one component of a solvent mixture can interact preferentially with a solute. For example, $^1H\{^1H\}$ intermolecular NOEs show that phenol dissolved in 50/50 water–acetonitrile or 50/50 water–dimethylsulfoxide mixtures is primarily solvated by the organic component of each solvent mixture [33]. In contrast, there appears to be no selective interaction of dioxane, as a solute, with either solvent component in a 50/50 ethanol–chloroform mixture.

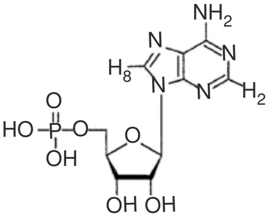
Experiments to detect selective solvent interactions usually involve determining the solute spin–solvent spin cross-relaxation rate after perturbation of the magnetization of the solvent spins. If one is willing to sacrifice information about the site-specificity of solute–solvent interactions, the inverse experiment (detect solvent spins and perturb solute spins) can also be used to investigate preferential solvation in a multi-component solvent. Thus, Bagno *et al*., demonstrated selective interactions between the protons of dissolved glucose and the protons of water in water–acetonitrile and water–dimethylsulfoxide mixtures by perturbing the magnetizations of the glucose molecules and observing intermolecular NOEs on the proton signals of the components of the solvent mixture [34].

Our laboratory has recently reported a study of selective solvent interactions in a "fluorous" reaction system [35]. Mixtures of chloroform and perfluoro(methylcyclohexane) can be used as solvents for "fluorous" biphasic reactions since they exist as two separate phases at low temperature but become a single phase at higher temperatures. The ability of such non-aqueous systems to exist as two phases at low temperature but as a single phase at higher temperature has led to development of strategies for doing chemical synthesis that rely on the temperature-dependent phase behavior to achieve separation of reactants from products and reaction catalysts [36]. Intermolecular NOEs were used to study the interactions of the chloroform and perfluoro(methylcyclohexane) solvent components with the protons and fluorines of 3-heptafluorobutyrylcamphor in both phases of the biphasic system at 25° as well as the single phase at 54°. The results indicate that, at 25° in the perfluorocarbon-rich phase, the hydrocarbon part of the solute is selectively solvated by chloroform molecules. However, there are no indications of unusual interactions of either solvent component with the solute in the chloroform-rich phase and only weak indications of selective solvation in the high-temperature (homogeneous) phase. There is appreciable regio-selectivity of chloroform interactions with the hydrocarbon part of the solute in all phases.



3-heptafluorobutyrylcamphor

Selective interactions of biologically significant molecules with solvent components within water–organic mixtures appear to be a recurring feature of these systems. Mixtures of trifluoroethanol (TFE) and water were observed over 40 years ago to stabilize helical conformations of peptides and proteins [37]; solutions of fluoroalcohols have been routinely used since to induce structure in peptides, proteins and nucleic acids [38]. Berger and coworkers have demonstrated selective interaction of TFE molecules with the aromatic protons of adenosine and adenosine monophosphate in 35% TFE [39]. Their results confirm the expectation that proton H_8 in both molecules should be more shielded from interaction with either solvent component than is proton H_2.



Adenosine 5'-monophosphate

The same group has studied solvent interactions with a tetrapeptide (*N*-acetylserylphenylalanyl-valylglycine methyl ester) in TFE–water and ethanol–water mixtures [40]. Intermolecular $^1H\{^1H\}$ and $^1H\{^{19}F\}$NOE observations indicate preferential solvation of the peptide by TFE in the TFE–water mixtures; proton–fluorine cross-relaxation rates increase as the proportion of TFE in the mixture increases while cross-relaxation due to water protons concomitantly decreases. In contrast, there are no indications of selective interactions of the solvent components when the peptide is dissolved in ethanol–water mixtures. Conclusions from the NOE experiments were reinforced by measurements of diffusion rates in the systems studied and by MD simulations.

Quantitative interpretation of selective interactions of fluoroalcohols with peptides is complicated by the tendency of the alcohols to aggregate in water [41,42]. Given the magnitude of the $^1H\{^{19}F\}$ intermolecular NOEs observed in the peptide systems studied so far it is probable that peptide molecules are submerged in or surrounded by aggregates of fluoroalcohol molecules leading to local exclusion of solvent water molecules. It appears, at least in some peptide–fluoroalcohol systems, that long-lived complexes of the peptide and fluoroalcohol molecules are formed [43,44]. There is evidence that TFE accumulates at the surface of proteins as well; relaxation dispersion studies of β-lactoglobulin in TFE–water mixtures indicate substantial interactions of the fluoroalcohol at the surface as well as the interior of the protein [45].

Biomolecule–Water Interactions

Solvent water molecules may interact strongly enough with biological molecules that they become immobilized

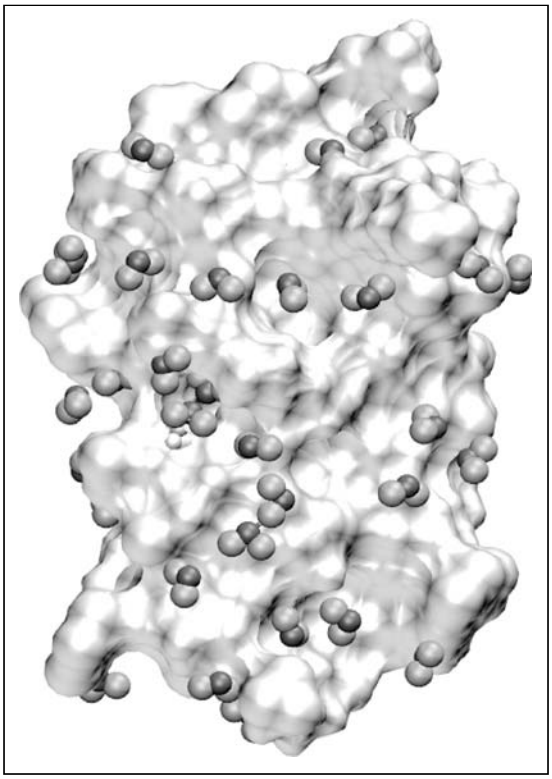


Fig. 3. Hydration of the small protein bovine pancreatic trypsin inhibitor (BPTI) in the crystalline state. The figure is based on high-resolution X-ray and neutron diffraction data [56]. In the study cited, 63 water molecules were found to be sufficiently immobilized in the crystal that they contributed to the diffraction pattern. There are many more water molecules in the crystal that are not so immobilized. Note that some of the water molecules are significantly internalized by the protein structure. (See also Plate 47 on page XXXV in the Color Plate Section.)

on the surface and within the structure to such an extent that the positions of water molecules can be determined by crystallographic methods (Figure 3). An understanding of the properties of water and other species at the surface of macromolecules is essential since biological processes such as enzymatic catalysis and macromolecular association take place at the interface between the bulk solution and the macromolecule. It is only relatively recently that experimental and computational tools have emerged to probe the interactions of water molecules at or near the surface of macromolecules. Most experimental information about hydration dynamics has come from intermolecular $^{1}H\{^{1}H\}$ NOEs between water protons and protons of the macromolecule or from NMR relaxation dispersion measurements [46,47]. The subject has a large literature; a recent article by Modig *et al.* indicates the current status of the field [48].

Interpretation of observed intermolecular NOEs between water protons and protons at the surface of a protein is complicated by the presence of solvent-exchangeable protons and by the wide range of rates for dissociation of water–macromolecule complexes. By working in supercooled solutions (–25 °C) it is possible to slow exchange dynamics, affording conditions that permit unambiguous detection of the dynamics of intact water molecules with the surface [48]. For the cyclic peptide hormone oxytocin and the small globular protein bovine pancreatic trypsin inhibitor (BPTI) it appears that most water–protein interactions at the surface under these conditions involve water molecules that are slightly retarded in their diffusive motion, consistent with MD simulations that indicate most water in the hydration layer of a protein is only weakly affected by the protein [49].

It might be anticipated that water–protein intermolecular NOEs would simply report direct interactions between the solvent and the solvent-exposed protons of the protein. Thus, the number and magnitude of $^{1}H\{^{1}H\}$ NOEs observed between water protons and protein protons should be proportional to the surface exposure of a protein proton. However, due to the wide variety of potential water molecule interactions at the surface of a biological macromolecule and the timescales for these interactions, it is unlikely that water proton–macromolecule proton NOEs will be cleanly diagnostic of "solvent exposure." A more profitable approach to identification of surface protons appears to be the use of paramagnetic relaxation agents in the solution [50,51].

Cistola and Hall have observed $^{19}F\{^{1}H\}$ intermolecular NOEs between water protons and fluorinated amino acids that have been incorporated into proteins such as U1A (an RNA-binding protein), dihydrofolate reductase and a fatty acid-binding protein [52]. In many instances, the fluorinated amino acid is buried within the tertiary structure but in other cases the observed fluorine nucleus is located on the surface of the protein. Water NOEs to fluorinated groups on the surface residues should not be as tightly intertwined with water proton exchange processes as are water NOEs to surface protons; this heteronuclear approach may be useful for probing surface hydration.

Summary

Solute spin–solvent spin NOEs have been demonstrated in a wide variety of systems. These NOEs generally are small compared to intramolecular NOEs but are readily detected using current instrumentation. They can be semi-quantitatively predicted when strong interactions between the solute and solvent are absent, given knowledge of the molecular structures, concentrations, and translational diffusion coefficients. Substantial deviations of the experimental effects from those predicted are, thus, indicative of unusual solute–solvent interactions. Intermolecular NOE experiments have provided new information regarding selective solute–solvent interactions in mixed solvent systems. For the limited number of systems where comparisons are possible, it appears that the results of intermolecular NOE experiments can be in agreement with the results of MD simulations. Further interplay of the results of intermolecular NOE experiments and simulations should provide new insights into solute–solvent interactions and the roles that solvent molecules play in determining reactivity in small molecule and biological macromolecule systems.

Chemical Exchange

Alex D. Bain
Department of Chemistry McMaster University West Hamilton, Ontario Canada L8S 4M1

Introduction

In magnetic resonance, the term chemical exchange has a specific meaning. It means that a chemical system is at macroscopic equilibrium, but at the microscopic level, an individual nucleus is exchanging its environment with another nucleus. The process causes no net change in the sample, but from the point of view of a particular nucleus, a chemical reaction has occurred. Another common term is Dynamic NMR (DNMR), which emphasizes the fact that molecules always have some motion associated with them. Apart from being an interesting aspect of spectroscopy, chemical exchange is important and useful for the same reasons as other types of chemical kinetics. Transition-state theory tells us that the rate is related to the thermodynamics of the barrier. Kinetics is one of the few ways we have of studying the transition state.

A standard example of chemical exchange in NMR is the type of molecule in which a *N,N*-dimethyl group is attached to a π electron system, such as in methyl 3-dimethylamino-2-cyanocrotonate (MDACC) (Figure 1). If the molecule were rigid, then the protons in the two methyl groups on the nitrogen would have different chemical shifts. If, however, there were rapid rotation about the bond joining the nitrogen to the vinyl group, only a single average environment would be observed. At rates intermediate between these extremes, the signals would first broaden, then coalesce, and eventually sharpen again, as the rate increased.

These are some of the most familiar and obvious manifestations of exchange. In this case, it is the chemical shift of the protons that changes in the exchange. In general, it can be any characteristic of the magnetic environment of the nucleus—if the resonance frequency changes, chemical exchange phenomena may appear. This chapter will review how chemical exchange affects many different types of NMR experiments. A brief survey of the theoretical description will also be given.

Chemical exchange effects in NMR were first reported by Gutowsky's group [1], and this work is in most standard texts. Two excellent books give summaries of the important work to their times [2,3]. As well, there are many reviews, both early [4,5] and more recent [6–9], and some books [10,11].

The dynamics in most NMR spectra fit one of the two extreme situations—effectively rigid or completely averaged. The protons in most methyl groups are magnetically equivalent because rotation is very fast. However, double bonds must break (formally) into a single bond in order to rotate, so we tend to regard the stereochemistry around a double bond as fixed. In the molecule in Figure 1, there is an interaction of the lone pair on nitrogen with the π system of the carbon–carbon double bond, leading to partial double-bond character in the C–N bond. If this barrier to rotation is high (compared to thermal energy), the two N-methyl groups will be distinct. We would see four methyl singlets: the O-methyl, the C-methyl and the two N-methyls. However, if we raise the sample temperature, so that the rate of exchange (in this case, the rate of rotation about the C-N bond) increases, the N-methyl signals broaden, coalesce, and eventually sharpen into a single, sharp average peak. In this particular molecule, there is a further process. The E and Z configurations around the carbon–carbon double bond have very similar energies, and both are observed in solution. The groups at one end of the C=C bond are electron-withdrawing, and those at the other end are electron-donating, creating a push-pull ethylene. The double bond is polarized sufficiently so that chemical exchange is also observed between the E and Z forms. Figure 2 shows a typical spectrum for the molecule in Figure 1.

Types of Chemical Exchange

For chemical exchange to affect an NMR experiment, its rate must be comparable to some time scale in the experiment. This time scale can range over several orders of magnitude [12], so the common phrase "the NMR time scale" can cover a very wide range. In Figure 2, the rate is comparable to the difference between the resonance frequencies of the two sites. This case is called intermediate exchange—when the lineshape is significantly affected. Slow exchange does not affect the lineshape very much, but it can interact strongly with spin-lattice relaxation. Finally, in fast exchange, only the average spectrum is observed, but there is still some residual line broadening due to exchange which can be extracted by careful measurements of T_2, the spin–spin relaxation rate.

Graham A. Webb (ed.), Modern Magnetic Resonance, 421–427.
© 2008 *Springer.*

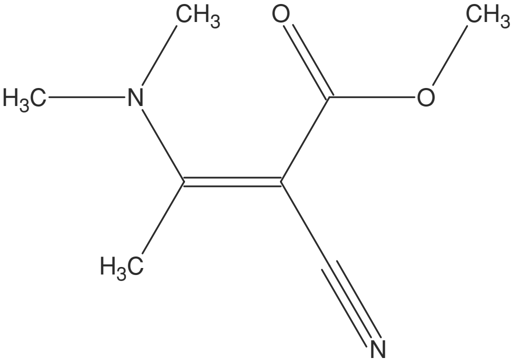

Fig. 1. Structure of MDACC. There is a process that exchanges the two *N*-methyl groups (mutual exchange), in which the molecule is identical before and after the exchange. The other process takes the *E* configuration into the *Z*. This is an example of non-mutual exchange, for which the equilibrium constant is not equal to 1.

The exchange of nuclei may change the stereochemistry of the molecule. For instance, in the push–pull ethylene MDACC, the double bond is sufficiently weakened so that the *E* and *Z* configurations can be observed to interconvert. In this case, the molecules before and after the exchange are different, and the equilibrium constant for the exchange is not equal to 1. This is called non-mutual exchange. However, this molecule also shows restricted rotation about the bond joining the *N,N*-dimethyl group attached to the ethylene. In this case, called mutual exchange, the molecule is identical before and after. Only the positions of the nuclei have been permuted, and the equilibrium constant must be 1. The chair–chair interconversion in cyclohexane is another classic example of mutual intramolecular exchange. These situations involve rearrangements within a molecule, and so are called intramolecular exchange. Intermolecular exchange also occurs—for instance the exchange between a free ligand and one bound to a transition metal complex. Labile OH and NH protons rarely show couplings to vicinal protons, due to intermolecular exchange with the solvent. The book by Jackman and Cotton [2] covers most chemical types of exchange.

Finally, there is a technical spectroscopic distinction that must be drawn, independent of the dynamics. If the spin system shows no scalar coupling (such as in a proton-decoupled natural abundance ^{13}C spectrum) there is a one-to-one correspondence between nuclei in the molecule and lines in the spectrum. When the nucleus exchanges, the line reflects this directly. However, for a coupled spin

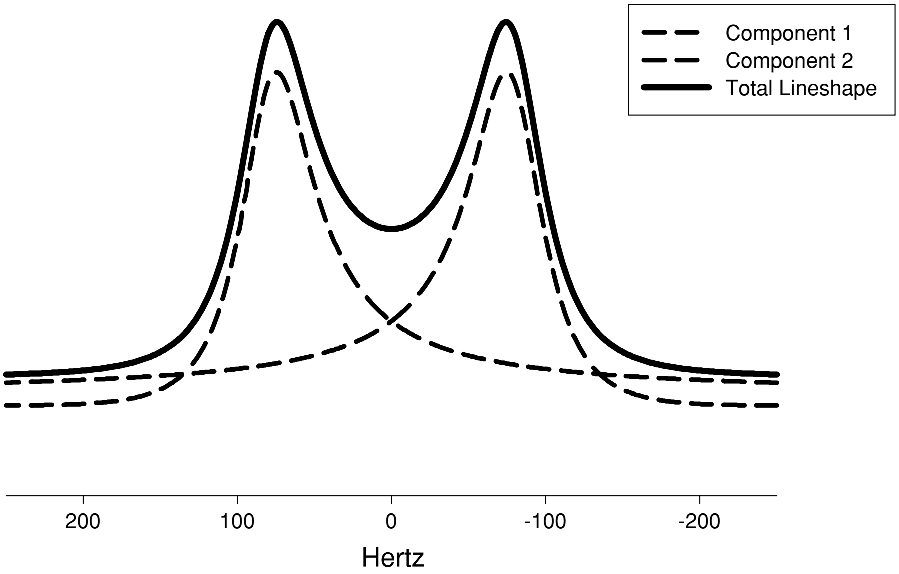

Fig. 2. 500 MHz proton NMR spectrum of MDACC in deuterated acetonitrile at $-11.3\,^{\circ}C$. The peak at 3.6 ppm represents the coalesced signal of the two *O*-methyl groups in the *E* and *Z* configurations. The peaks near 2.4 ppm are the *C*-methyl signals of the *E* and *Z* configurations, showing that the *E* configuration (signal at higher frequency) is more populated. The *N*-methyl signals of the *E* configuration near 3.2 ppm have coalesced, but those of the *Z* configuration, at 3.18 and 3.0 ppm, show two equally intense signals, typical of mutual exchange.

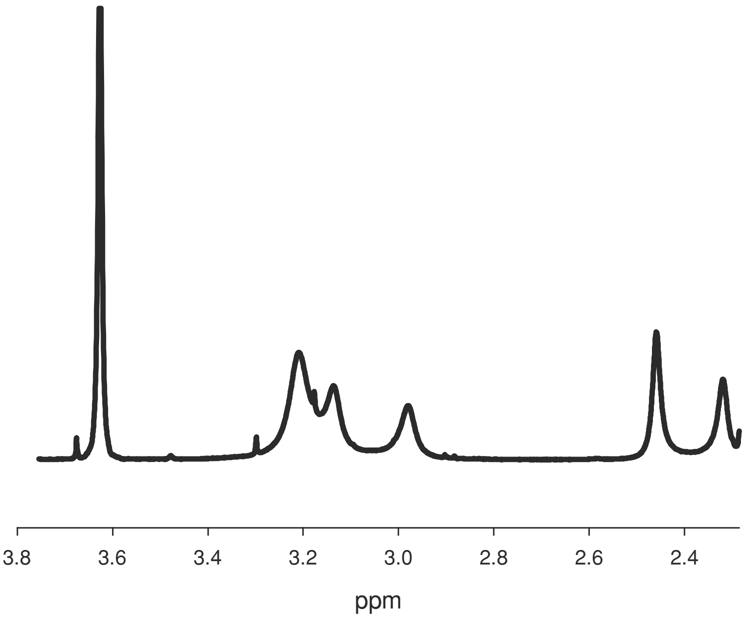

Fig. 3. Decomposition of the two-site, equally populated exchange lineshape near coalescence into two symmetric out-of-phase Lorentzian-type lines. This is a general result—any exchange lineshape can be expressed as a sum of individual transitions.

system, the correspondence is not one-to-one, and the effects on the spectrum may be much more complex. Calculating the effect of exchange on a general coupled spin system is significantly more complicated than for an uncoupled one. Therefore, the first step is to classify the system. Is the exchange intra- or intermolecular? Is it mutual or non-mutual? Is the spin system coupled or uncoupled? The answers to these questions determine the approach to be taken.

Theory

For spin systems without scalar coupling, the lineshapes for exchanging systems can be derived by setting up and solving a system of coupled Bloch equations. This theory describes the coalescence phenomenon, which is the most familiar manifestation of chemical exchange. Perhaps less familiar is the fact that the lineshape near coalescence is the sum of two transitions, just as the static spectrum clearly shows two lines. Reeves and Shaw [13] showed that the lineshape for two-site exchange can be decomposed into two out-of-phase lines (Figure 3). At roughly the same time, Binsch [14] derived a general formalism that treated all systems and formed the basis for the standard simulation program DNMR3/DNMR6. What evolved from that is the concept that exchange spectra can be expressed as a sum of individual transitions [15], just as static spectra are. In a static spectrum, there are a series of transitions with specific frequencies, whose intensities are governed by transition probabilities. Similar, DNMR spectra have transition probabilities, but they are now complex numbers. The real and imaginary parts of the complex number combine to give the intensity and phase of the line. Similarly, the frequency is also a complex number, with the real and imaginary parts giving the position and width of the line. In this way, an NMR spectrum of an exchanging system is no different from that of a static system, except that the characteristics of the transitions are complex numbers, rather than pure real ones. This principle forms the basis of simulation programs such as DNMR3 and MEXICO.

Intramolecular exchange follows first-order kinetics, since it is a unimolecular reaction. This implies that exponentials govern the time evolution. The spectrum is described by decaying oscillations in the time domain (complex exponentials), leading to the transitions making up the spectrum in Figure 3. When exchange affects the spin-lattice relaxation, the behavior is described by a multi-exponential decay. Even though intermolecular exchange involves two or more species, the NMR spectroscopy is still governed by pseudo-first-order kinetics, so the theoretical approach is the same.

Kinetics

As far as an individual nucleus is concerned, exchange is a chemical reaction. Transition-state theory, or absolute rate theory, says that the rate of a reaction, k, at a temperature,

T, is given by equation (1).

$$k = \frac{k_B T}{h} e^{-\Delta G^{\dagger}/RT} \qquad (1)$$

In this equation, k_B is Boltzmann's constant, h is Planck's constant, R is the gas constant and $\Delta G^{\dagger}$is the Gibbs free energy of activation. Since everything else is known, measuring the rate is tantamount to measuring $\Delta G^{\dagger}$. However, by measuring the rate as a function of temperature, we can extract the enthalpy and entropy of activation separately. Normally, this is done with an Eyring plot—a plot of $\ln(k/T)$ against $(1/T)$. This should yield a straight line with a slope of $-\Delta H^{\dagger}/R$. The intercept at $(1/T) = 0$ is $\ln(k_B/h) + \Delta S^{\dagger}/R$. The values of the enthalpy obtained from the slope are usually reliable, but the determination of the intercept requires a considerable extrapolation. Entropies of activation should be treated with some caution. However, if accurate rates are obtained over a wide range of temperatures, good thermodynamic data can be derived for the transition state.

Experimental Precautions

All the usual techniques for obtaining good NMR spectra should be applied. Magnetic field homogeneity is crucial if good lineshapes are to be obtained, so a sharp reference signal within the sample is extremely useful. Furthermore, stable and accurate temperatures are essential. Modern spectrometers have excellent variable-temperature controllers that will deliver temperatures that are stable to 0.1° or better. However, the temperature calibration of these units is sometimes unreliable. Temperatures should be checked, either with a thermocouple in an NMR tube, or with an NMR temperature calibration sample such as methanol.

Intermediate Exchange

Intermediate exchange is the regime where the one-dimensional spectrum strongly affected by the exchange. In this case, the rate of exchange is comparable to the difference in frequency between the two sites. Note that this is the frequency difference in Hertz, so the exchange spectra will be different at different magnetic fields, even if the temperature (and hence the rate) is the same. Similarly, the proton spectrum may show lineshapes that are well past coalescence, but the carbon spectrum may still show distinct sites.

A good deal of early work was done with coalescence temperatures. Coalescence was defined by the lineshape being flat at the midpoint—neither curved up nor down. Let $\Delta \nu$ be the difference in frequency (in Hertz) between the two sites. From the equation defining the lineshape, the rate which gives coalescence is given by equation (2)

$$k = \frac{\pi \Delta \nu}{\sqrt{2}} \qquad (2)$$

In these experiments, the temperature was varied until coalescence was achieved. Although it has been extended, the notion of coalescence is best restricted to the exchange of two equally populated uncoupled sites.

Better methods than coalescence temperatures are now available. Modern spectrometers are run by powerful general-purpose computers, and the spectrum is available in digital form. This means that the full lineshape can be fitted, using one of a number of freely available programs. This procedure can be applied to almost any dynamic system: coupled or uncoupled, equally or unequally populated. In fitting the lineshape, it is important to know that the chemical shifts (and hence, $\Delta \nu$) may change with temperature, and the equilibrium constant (if different from 1) will also change. Furthermore, each line has a natural width—the width that it would have in the absence of exchange. This must be estimated and included in the calculation. This can be done, but when the exchange is slow enough that the exchange contribution is comparable to the natural linewidth, unreliable data can result. Small changes in the assumed natural width can change the rate significantly. Furthermore, even though the changes may be small in absolute terms, it is the relative change that is important to the Eyring plot. Slow exchange is best handled by different methods. However, it is important to have data from as wide a range of temperatures as possible.

It is sometimes stated that the lineshape is most sensitive to the rate near coalescence, which is true if the frequency difference between the sites is known exactly. However, it has been our experience that the most accurate values of the rate are obtained from spectra before coalescence that still show resolved peaks, but are significantly broadened by exchange, as in Figure 2.

The study of intermediate exchange is inherently a one-dimensional experiment. The broad lines imply short relaxation times, so the coherence decays before it can be transferred in a multidimensional experiment. This usually precludes the study of intermediate exchange in biological macromolecules. Motion is an essential part of the study of proteins in solution, but the one-dimensional spectra are too crowded to be interpreted. Most of the protein spectroscopy relies on multiple dimensional spectra to spread out the lines, but intermediate exchange will destroy the magnetization before it is transferred. However, techniques for both slow and fast exchange are widely used to study protein dynamics [16].

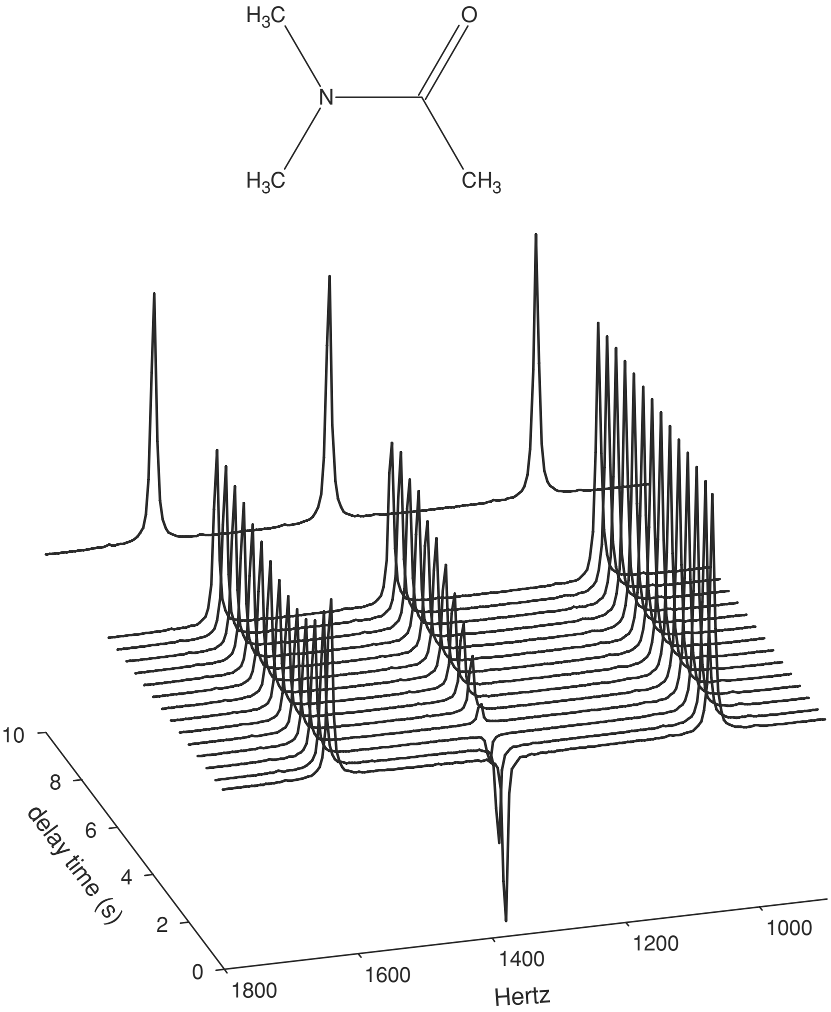

Fig. 4. Results of a selective-inversion experiment on dimethylacetamide. The signals of the two *N*-methyl groups are at high frequency. One of the signals was inverted, and then the *z* magnetizations were sampled as a function of the delay time. The inverted signal relaxes more quickly, because of exchange with the non-inverted site. The non-inverted site shows a characteristic transient decrease and then return towards equilibrium.

Slow Exchange

In this regime, the rate is not fast enough to broaden the lines significantly beyond their natural width. However, the rates are comparable to spin-lattice relaxation times. Chemical exchange has many formal similarities to dipolar relaxation, so many of the experiments that measure Overhauser effects and related phenomena can also be used to study exchange.

The analogy lies in the fact that two spins (or two sites) are involved. The basis of the methods is that the relaxation of one site depends on the state of the other. If one site is selectively inverted, it can relax back to equilibrium either by straight relaxation, or by exchanging with the unperturbed site. The inverted site will relax more quickly, due to the exchange contribution, and the unperturbed site will show a characteristic negative transient (Figure 4). The transient Overhauser effect is exactly analogous, but in this case it is the double-quantum and zero-quantum relaxation terms that couple the relaxation. Similarly, saturation of one site will cause a change in the steady-state intensity of the other, in both exchange and dipolar relaxation.

The analogy extends to multidimensional experiments. The EXSY experiment, using the same pulse sequence as NOESY, displays cross-peaks between sites that are connected by exchange. This is an excellent way to determine qualitatively which sites are exchanging with which. It can also be made quantitative, by calculating the volume of the cross-peak compared to the diagonal peak [17], with the assumption that the exchange has not proceeded too far. In principle this gives a rate, but it is good practice to repeat the experiment as a function of the mixing time.

It is the author's opinion that one-dimensional selective inversion experiments are more efficient in obtaining rates in slow exchange. One site is selectively inverted and then the system is allowed to relax for some time. Selective pulses are available on all modern spectrometers. The z magnetizations are then sampled with a $\pi/2$ pulse, as in a standard inversion-recovery experiment (Figure 4). In the time required for a single two-dimensional experiment, a number of selective inversion experiments can be done, with a range of relaxation delays. The data analysis requires a non-linear least-squares fit, but there are no assumptions made The selective inversion experiment is more complex to set up and analyze than the EXSY experiment, but we feel it gives much better data. The selective inversion experiment, also called a zz experiment, is readily expanded to indirect detection methods used for studying proteins. It has been widely used to study slow protein dynamics.

Fast Exchange

In fast exchange, the spectrum has collapsed into a single line, and so less information can be obtained. In principle, only the linewidth due to exchange, given by Equation (3), is available. Furthermore, unless $\Delta\nu$ is known, we can not get a value for the rate.

$$width \propto \frac{(\Delta\nu)^2}{k} \tag{3}$$

In practice, the effect is usually measured in a T_2 experiment, using either a CPMG or a $T_{1\rho}$ technique. If $\Delta\nu$ is available, the rate can be extracted. However, if the rate is not too fast, it can be extracted without the need for a value of $\Delta\nu$. Both these T_2 experiments have inherent time scales: the rate at which refocussing pulses are applied in a CPMG, or the rate of precession around the spin-lock field in a $T_{1\rho}$ experiment. If the timescale is slow with respect to the rate of exchange—i.e. the system has time to exchange between refocussing pulses—then the measured T_2 will reflect the exchange contribution. However, if the spins are refocussed before they can exchange, then the experiment will give a T_2 which reflects the static sites [18]. As a function of the rate of the application of the pulses, the apparent T_2 will change, and from this the absolute rate can be extracted. For this method to work, the rate of application of pulses must be greater than the exchange rate, and hardware often limits how quickly pulses can be applied. Therefore, there is an upper limit on the rates that can be measured.

If the rate is measured in this way, then the frequency difference between the sites can be obtained from Equation (3). More precisely, it is the square of this value, so that the sign is lost. However, if multiple-quantum transitions can be observed, then it is possible to use them to get the sign of the frequency difference as well [19].

Summary

Almost all molecular systems exhibit some sort of dynamic behavior. If this dynamics affects the magnetic environment of a nucleus, then it may well be accessible to measurement by NMR. The motion can be rotation around a bond, it may be an intermolecular reaction, it may be reorientation of a molecule in an anisotropic environment, or many other types. Typical timescales run from seconds down to nanoseconds. By matching the timescale of the NMR experiment to the dynamics, sensitive, and accurate measurements of the rates can be made. In many cases, magnetic resonance is the only way of obtaining these rates. The theory is well-developed and the experiments are relatively easy to implement on modern spectrometers. This means that chemical exchange will continue to play a major role in modern magnetic resonance.

Separated Detection of H-Transfer Motions in Multi-H-Bonded Systems Studied by Combined ^{1}H NMR and ^{35}Cl NQR Measurements

Ryuichi Ikeda
National Institute for Materials Science, Tsukuba 305-0003, Japan

Introduction

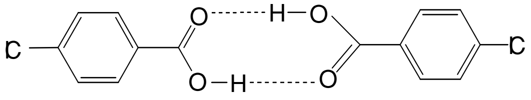
Intermolecular H-bonding has widely been observed in condensed systems, where the H-transfer through H-bonds formed between molecules enables charge and energy transfers in solid and biological systems, and marked physicochemical properties on the macroscopic scale, such as ferro- and antiferroelectrics [1], dipolar glasses [2], molecular solitons [3], etc., have been studied at the microscopic level of H-motions.

Various techniques for characterizing the H-dynamics have been applied for this purpose, i.e. measurements of vibration spectra, neutron scatterings, magnetic resonances, dielectric constants, and so on. Among these, ^{1}H NMR has quite effectively been used for a long time, because moving protons can directly be monitored and relaxation data due to the H-transfer are readily available. A well-known example for which this technique was fairly applied is the double H-transfer in dimeric units of benzoic acid (BA) in the solid [4]. The observed asymmetric minimum of the ^{1}H NMR spin-lattice relaxation time ($T_{1\mathrm{H}}$) was explained well by combined contributions from the classical BBP-type H-jumps and the quantum mechanical H-tunneling assisted by lattice phonons in an asymmetric double-well potential. On the other hand, a serious disadvantage of this technique is its low sensitivity for detecting H-movements that can cause only a slight fluctuation of local magnetic field at neighboring resonant protons, because the displacement of H-positions through jumps is small and of the order of 10 pm. Accordingly, H-jumps in H-bonds usually give rise to long $T_{1\mathrm{H}}$ values of the order of 100 s, which can easily be masked by other relaxation processes such as molecular motions.

As a complementary approach to this problem, we intended to apply NQR relaxation measurements for the detection of intermolecular H-transfer motions. We noted NQR, which has been used as a quite sensitive probe enabling one to detect even subtle changes of charge distributions in solids [5], and applied to detailed studies on phase transitions [6], lattice and molecular motions [5], etc. In this article, as a new sensitive method for detecting H-transfer in H-bonded systems, I propose ^{35}Cl NQR relaxation measurements combined with ^{1}H NMR relaxation studies. Applications of this technique were performed for the intermolecular H-transfer in an H-bonded two molecular systems where double H-transfer is expected, and in H-bonded three molecular systems where complicated H-transfer modes not studied so far are possible.

High Sensitivity of NQR Shown in 4-Chlorobenzoic Acid

Since no NQR attempt for this purpose has been reported, in the first step, we carried out the confirmation of the sensitivity of this technique for H-transfer motions. We introduced a chlorine atom as a NQR probe into a BA molecule which is a well-known H-transfer system studied in detail [4]. We measured ^{1}H NMR and ^{35}Cl NQR relaxation times on 4-chlorobenzoic acid (4-ClC$_6$H$_4$COOH) [7] that forms a dimeric structure in the solid [8] analogous to that in BA as given by



Temperature dependences of $T_{1\mathrm{H}}$ and the ^{35}Cl NQR spin-lattice relaxation time ($T_{1\mathrm{Q}}$) in Cl–BA are shown in Figure 1. An asymmetric $T_{1\mathrm{H}}$ curve observed by NMR is quite analogous to that in BA [4], indicating the occurrence of the double H-transfer motion in the H-bonded dimer unit given above. The asymmetry of $T_{1\mathrm{H}}$ curves could be explained well by introducing the combined contributions from classical BBP-type H-jumps and the quantum mechanical H-tunneling assisted by lattice phonons in an asymmetric double-well potential for the H-transfer mode shown by Skinner and Trommsdorff [4].

This protonic motion was also detected clearly by the ^{35}Cl NQR relaxation time measurement as shown

Graham A. Webb (ed.), Modern Magnetic Resonance, 431–438.

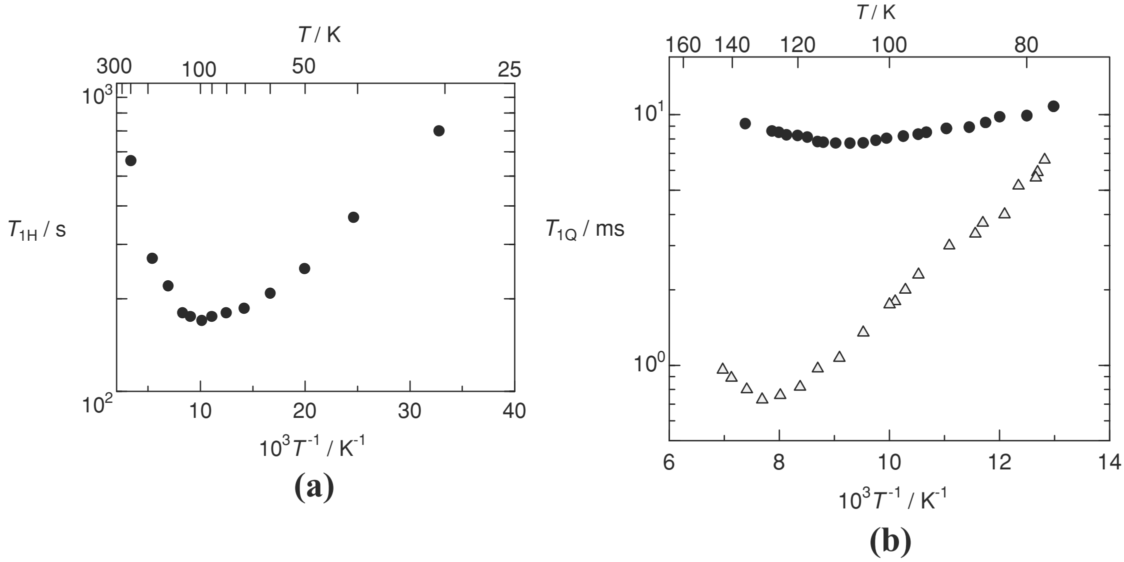

Fig. 1. ^{1}H NMR (a) and ^{35}Cl NQR (b) spin-lattice relaxation times (T_{1H}, T_{1Q}) observed for (●) 4-ClC$_6$H$_4$COOH, at an NMR Larmor frequency of 54.3 MHz, and (Δ) 4-ClC$_6$H$_4$COOD.

Figure 1(b). This is because the T_{1Q} minimum was observed at almost the same temperature as that in T_{1H}, and a marked isotope effect on T_{1Q} was observed in a partial deuterated analog, 4-ClC$_6$H$_4$COOD. As for the sensitivity of NQR, we should notify short T_{1Q} values compared with T_{1H}. If we compare the minimum values, ^{35}Cl NQR can be considered to be 10^4 times more sensitive than ^{1}H NMR. This highly sensitive detection is not surprising and can be explained as follows. In case H-jumps from one molecule to the other, it moves as a proton. This implies that the rest of the molecule, in this case, the carboxyl group changes its electronic structure by exchanging the mutual positions of C=O and C–O groups accompanied by the double H-transfer in a dimer unit. This change of the electronic structure should give a fluctuation of electric field gradient (EFG) at the resonant Cl nuclei. The presence of the π-conjugated phenyl ring is the important reason why a marked EFG change is transferred from the remote position far from the NQR nuclei.

Separated Detections of H-Transfer Modes in Multi-H-Bonded Systems

Multi-H-Transfer Motions in (Chloranilic Acid)(1,4-diazine) 1:2 Molecular Complex

Since NQR has been shown to have a high sensitivity for the detection of intermolecular H-transfer motions in solids, we applied this method to new H-bonded three molecular systems that are expected to contain multi-H-transfer processes. As the first target, we selected a 1:2 molecular complex of chloranilic acid with 1,4-diazine, [C$_6$Cl$_2$O$_2$(OH)$_2$](1,4-C$_4$H$_4$N$_2$)$_2$ (abbreviated to 1,4-complex), in which symmetric two OH–N-type H-bonds are formed. Since disordered H-positions and a short OH–N distance of 259.0 pm were reported [9], we can expect the observation of the H-transfer motion in this system.

^{35}Cl NQR Frequencies

A temperature dependence of ^{35}Cl NQR frequencies observed in the 1,4-complex is shown in Figure 2 [10]. The frequency of 36.3997 ± 0.0005 MHz observed at 77 K is markedly shifted from 37.15 MHz reported for chloranilic acid, C$_6$Cl$_2$O$_2$(OH)$_2$ [11] and also ca. 35.2 MHz (averaged value) for its sodium salt C$_6$Cl$_2$O$_2$(ONa)$_2$ [11] at 77 K. These differences are too large to be explained by differences in lattice charges and thermal vibrations, and some changes in the electronic structure should take place in the chloranilic acid molecule. Since the observed frequency in the 1,4-complex comes in the intermediate region between those in neutral acid (0) and divalent salt (2–), we can presume that chloranilic acid in the 1,4-complex takes a valency close to a monovalent (1–) state. This can be supported by the theoretical calculation of EFG at Cl nuclei in a neutral molecule and two kinds of ionic states of chloranilic acid shown in Table 1 performed by W. C. Bailey (personal communication). The absolute

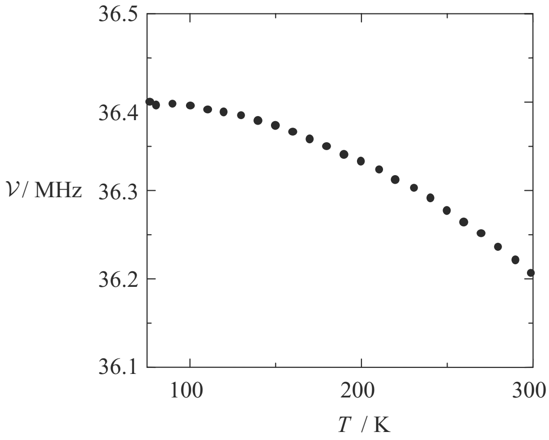

Fig. 2. A temperature dependence of ^{35}Cl NQR frequencies observed in $[C_6Cl_2O_2(OH)_2](1,4\text{-}C_4H_4N_2)_2$.

values themselves cannot be directly compared with the observed values, because no effects from thermal vibrations and charges in neighboring molecules in crystals are included in the calculation. If we note relative values, we can see that the monovalent ion gives a frequency close to the average of those in the neutral and divalent species supporting the present interpretation.

Accordingly, the most probable structure of the 1,4-complex in crystals can be expressed as either of the following two structures I and II derived from the centrosymmetric crystal structure of the present system. The formation of these ionic structures can be supported from pK_{a1} values of chloranilic acid and 1,4-diazinium in solutions to be 0.76 and 0.57, respectively [12].

(II)

Table 1: Theoretical values of quadrupole coupling constants (e^2Qq), asymmetry parameters of electric field gradients (η) and resonance frequencies (ν) calculated for a neutral chloranilic acid molecule, and monovalent and divalent chloranilate ions in isolated states

Species (charge)	e^2Qq (MHz)	η	ν(MHz)
Neutral molecule (0)	−77.8	0.11	38.98
Monovalent ion (1−)	−72.3	0.09	36.20
Divalent ion (2−)	−64.4	0.12	32.38

^{1}H NMR Relaxation Time (T_{1H})

A temperature dependence of the ^{1}H NMR relaxation time (T_{1H}) observed in the 1,4-complex is shown in Figure 3 [10]. The long T_{1H} minimum at ca. 135 K was attributed to the H-transfer motion OH–N ↔ O$^-$–HN$^+$ for the following two reasons: one is that the 1,4-complex containing deuterated acidic hydrogen gave a T_{1H} minimum much longer than 500 s; and the other is that the calculated T_{1H} minimum is close to the observed value. Since the most populated structure of chloranilic acid was shown to be monovalent (1−), the H-transfer is expected to take place between the two structures I and II given above and expressed as I ↔ II. This mode named "correlated H-transfer" can retain the most stable structure throughout the motion. The observed T_{1H} minimum became a little asymmetric giving activation energies of 3.9 and

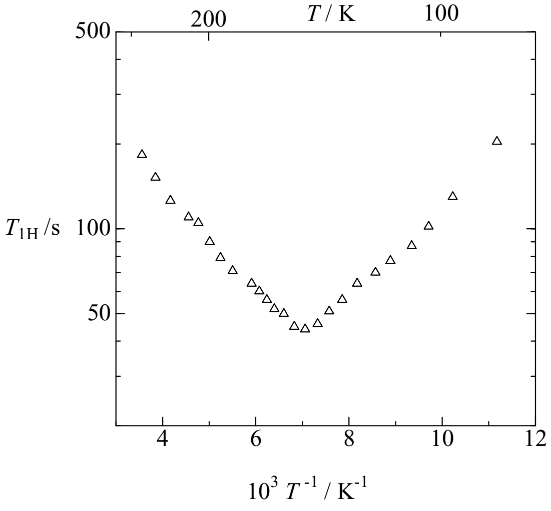

Fig. 3. A temperature dependence of ^{1}H NMR spin-lattice relaxation time T_{1H} observed in $[C_6Cl_2O_2(OH)_2](1,4\text{-}C_4H_4N_2)_2$ at 54.3 MHz.

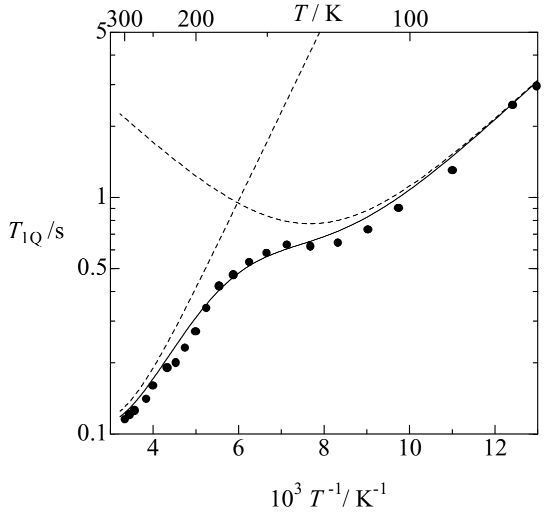

Fig. 4. A temperature dependence of ^{35}Cl NQR spin-lattice relaxation time T_{1Q} in $[C_6Cl_2O_2(OH)_2](1,4\text{-}C_4H_4N_2)_2$. The solid curve is the best-fitted calculated values superimposed by two components shown by broken lines.

3.2 ± 0.5 kJ/mol for the high and low temperature sides of the minimum, respectively, by assuming the classical BPP-type thermal activation model [13]. The lower energy at low temperatures is explainable by the contribution from the H-tunneling [4], which is quite small compared with that in BA and Cl-BA giving marked asymmetric T_{1H} curves. This is because the tunneling H-exchange in the present system is strongly hindered in the highly asymmetric double-well potential made by OH–N H-bonds. The activation energy of 3.9 kJ/mol for the classical H-jumps is acceptable, if one compares this value with 5.5 kJ/mol for the double H-transfer in BA [4], which has the OH–O distance of 263.3 pm [14] a little longer than 259.0 pm of OH–N in the 1,4-complex.

^{35}Cl NQR Spin-Lattice Relaxation Time (T_{1Q})

A temperature dependence of the ^{35}Cl NQR spin-lattice relaxation time (T_{1Q}) observed in the 1,4-complex is shown in Figure 4 [10], giving a shallow T_{1Q} minimum at ca. 120 K and a decrease above 200 K. Assuming the presence of two relaxation processes, the observed curve was expressed by a superposition of the following Debye-type relaxation curve [15]:

$$T_{1Q}^{-1} = C[\tau_c/(1 + \omega_Q^2 \tau_c^2)], \quad (1)$$

and

$$\tau_c = \tau_0 \exp(E_a/RT), \quad (2)$$

where C, τ_c, ω_Q, and E_a denote the motional constant, the motional correlation time, the NQR angular frequency, and the activation energy, respectively. The best-fitted calculated T_{1Q} is given in Figure 4. Since the minimum temperature of ca. 120 K is close to 135 K for T_{1H} and also the obtained E_a of 3.2 kJ/mol agrees with that from T_{1H}, this minimum corresponds clearly to the H-transfer motion obtained by ^{1}H NMR, namely, the correlated H-transfer between structures I and II. NQR and NMR relaxations were analogous with each other up to ca. 150 K, however, they became quite different in the high-temperature range. The other relaxation process observed in NQR showed no sign in NMR, which gave a linear increase and quite long T_{1H} of ca. 200 s at room temperature. As this relaxation mechanism occuring in NQR, we propose "uncorrelated H-transfer" in which two protons in the symmetric two OH–N H-bonds in a complex perform independent jumps. It is noted that this uncorrelated transfer takes place by accompanying changes of electric charges on chloranilic acid, because the formal charge on a chloranilic acid molecule can be divalent (2−), monovalent (1−), and neutral (0), in the case where two H-motions occur uncorrelatedly. Since the monovalent state was shown to be most stable, it is quite reasonable to consider that the neutral and divalent states are excited by the uncorrelated H-transfer at elevated temperature.

From the above consideration, the total motional scheme of the H-transfers can be given in Figure 5. In the high-temperature range, two possible modes, i.e. those between monovalent and divalent states, and between monovalent and neutral states, can take place. In the present measurement of T_{1Q}, however, since no minimum was observed in the range up to 300 K, the T_{1Q} decrease observed above ca. 200 K is assignable to one of these two modes or possibly both.

A surprising result in the present study is that the uncorrelated H-transfer motion could not be detected by ^{1}H NMR, although the correlated H-transfer was clearly observed. This mystery can be explained well by considering differences of the relaxation mechanisms in NMR and NQR by the following reason.

In ^{1}H NMR for the present system, as was described above, the H-jumps in H-bonds make only a weak magnetic field fluctuation. This is the reason why the correlated H-transfer afforded a quite long T_{1H}. After the onset of the correlated H-transfer, the uncorrelated motions start upon heating. Since the magnetic field fluctuation by the H-transfer has already been averaged at low temperatures, even if the uncorrelated H-transfers are excited at high temperatures, further fluctuations should be quite small, because the fluctuation at the diazine protons in this mode comes from those on the opposite side of the chloranilic acid molecule separated by several 100 pm. Using the reported crystal structure data [9], it was roughly estimated

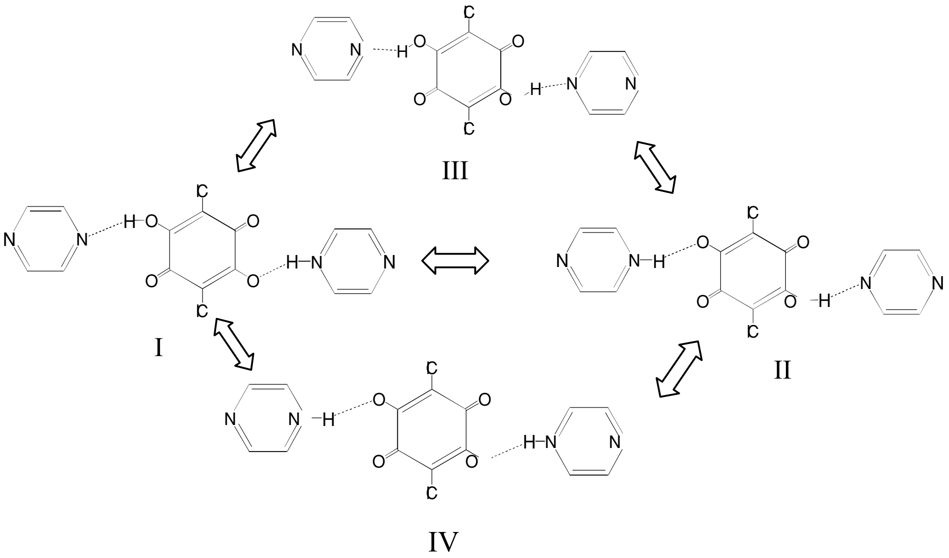

Fig. 5. An H-transfer model in $[C_6Cl_2O_2(OH)_2](1,4\text{-}C_4H_4N_2)_2$. The correlated transfer mode I ↔ II keeps the monovalent state of acid, while the uncorrelated transfer modes I ↔ IV (or II ↔ VI) and I ↔ III (or II ↔ III) are accompanied by changes of the formal charge on acid molecules.

that the T_{1H} minimum due to the uncorrelated H-transfer becomes ca. 400 times longer than that from the correlated motion. This implies that its T_{1H} becomes several thousand seconds and will be completely masked by the relaxation from the correlated motion.

On the other hand in NQR, the uncorrelated motions result in changes of the formal charges on chloranilic acid molecules as shown in Figure 5. This implies that the charge distribution on the phenyl ring, i.e. EFG at the resonant chlorine nuclei, fluctuates during the uncorrelated motions. This fluctuation seems to be much stronger than that in the correlated motion which keeps the monovalent structure of the acid molecules. This is the reason why the marked shortening of T_{1Q} was observed for uncorrelated H-transfers. The above NQR data clearly indicate that the sensitivity for the detection of intermolecular H-transfers in the NQR method is much higher than that of ^{1}H NMR, of course, NMR can provide complementary important information.

Multi-H-Transfer Motions in (Chloranilic Acid)(1,2-diazine) 1:2 Molecular Complex

In the previous section, different modes of H-transfers in a multi-H-bonded system were shown to be separately detected by the NQR relaxation measurement [10]. This work is the first study so far reported, where different H-transfer modes were separated. In the previous 1,4-complex, however, only two relaxation processes were observed by NQR, although three H-transfer modes are predicted. This is because the high-temperature process afforded only a T_{1Q} decrease and no minimum up to room temperature, and, hence, we could not distinguish motional modes, even if more than one mode contribute to the relaxation. To improve the situation, we measured an analogous multi-H-bonded system, but different H-bonded structures are expected. A new system is (chloranilic acid)(1,2-diazien) 1:2 complex, $[C_6Cl_2O_2(OH)_2](1,2\text{-}C_4H_4N_2)_2$ abbreviated to 1,2-complex, in which two symmetric H-bonds analogous to those in the 1,4-complex are formed in crystals, and an OH–N H-bond length of 258.2 pm [16] shorter than 259.0 pm in the 1,4-complex [9], was reported. It is noted that the pK_{a1} value of 2.24 in 1,2-diazinium ions in solution [12] is much higher than 0.57 in 1,4-diazinium, indicating the stability of high ionic states of chloranilic acid in the 1,2-complex, if one refers $pK_{a1} = 0.76$ and $pK_{a2} = 2.72$ in chloranilic acid [12]. This implies the easier formation of chloralilate (1−) and (2−) ions, suggesting that different H-transfer modes from those in the 1,4-complex are expected in this system.

^{35}Cl NQR Frequencies

The observed ^{35}Cl NQR frequencies for the 1,2-complex are shown in Figure 6 [17]. We should note that $\nu = 34.940 \pm 01$ MHz at 77 K is much lower than 36.400 MHz in the 1,4-complex [10]. This frequency is close

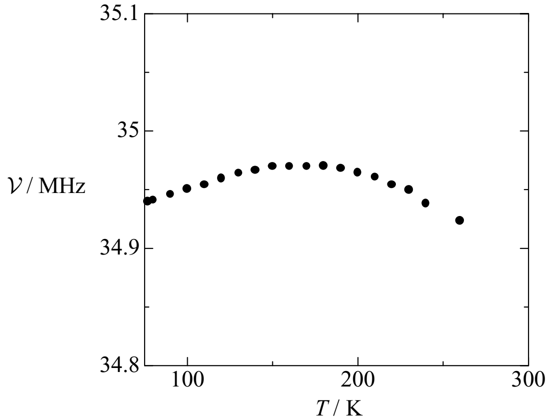

Fig. 6. A temperature dependence of ^{35}Cl NQR frequency (ν) observed in solid $[C_6Cl_2O_2(OH)_2](1,2\text{-}C_4H_4N_2)_2$.

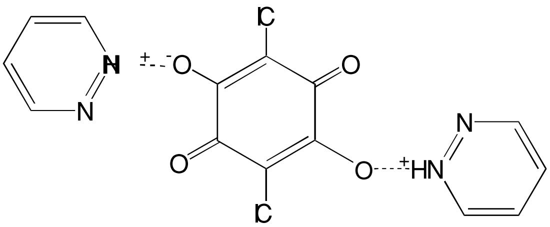
to 35.2 MHz in the divalent salt, sodium chloranilate $[C_6Cl_2O_2(ONa)_2]$ [11]. This indicates, as expected from the pK_a values of the acid and base, that the divalent ionic state of chloranilic acid given below is the most stable in crystals, in contrast to the monovalent structure mostly populated in the 1,4-complex.



^{1}H NMR and ^{35}Cl NQR Relaxation Times (T_{1H} and T_{1Q})

The observed ^{1}H NMR and ^{35}Cl NQR relaxation times are shown in Figure 7(a and b), respectively [17]. A shallow single T_{1H} minimum analogous to that in the 1,4-complex was observed at ca. 110 K, indicating the onset of an H-transfer motion. Slopes of a slight asymmetric T_{1H} curve afford activation energies of 3.8 and 3.2 ± 0.5 kJ/mol, on the high and low temperature sides of the minimum, respectively. These values are quite close to those in the 1,4-complex. On the other hand in NQR measurements of T_{1Q}, at least three relaxation processes were observed in the temperature range studied. Analogously to the analysis in the 1,4-complex given above, three T_{1Q} components were fitted by Equations (1) and (2), and the best-fitted curve is given in Figure 7, where the lowest temperature relaxation was attributed to the same motion detected by ^{1}H NMR, and its T_{1Q} curve was fitted by use of the ^{1}H NMR data.

Analogously to the 1,4-complex, the H-exchanging scheme in the 1,2-complex can be expressed in Figure 8. Since the most populated structure of chloranilic acid was shown to be divalent given by I, the first excitation at low temperatures occurs inevitably to the states monovalents II and III. If we accept this model, the possible relaxation in the intermediate-temperature range can be attributed between II and III, and the high-temperature one to the neutral structure IV from II and III. The latter process is expected to have a higher barrier, because the time-averaged most stable structure is close to the divalent I state that needs a high energy for producing the neutral structure. This can also be shown from a marked difference between the pK_{a1} and pK_{a2} values in chloranilic acid. In this complex, accordingly, we could obtain one-to-one correspondences between the observed data and the expected H-transfer modes.

In the present complex, only a single relaxation process was observed in the NMR spectrum, whereas three processes were clearly detected by NQR supporting the foregoing discussion for the differences of the relaxation mechanisms found by NQR and NMR on the 1,4-complex.

Conclusion

In the present combined studies of NMR and NQR relaxations on intermolecular H-transfers in multi-H-bonded systems, it is clearly shown that NQR can be a new technique for the separated detection of respective H-motions successively excited with temperature. Individual intermolecular H-transfer motions were clearly detected by observing the conventional NQR spin-lattice relaxation time. Such detailed H-transfer modes have not been successfully observed by other techniques within my knowledge. The ^{1}H NMR relaxation measurement always provided only a single process for the lowest temperature H-transfer mode but can be useful as a complementary technique giving evidence for H-motions and enabling the theoretical analysis of relaxation.

A characteristic feature of NQR has well been understood to be the high sensitivity for detecting electric charge distributions in the neighborhood of the resonant nuclei in crystals and has been used for observing subtle changes in crystal lattices at phase transitions undetectable by other techniques. If we notify this advantage of NQR, it can be easily accepted that the intermolecular H-transfer as a proton resulting in the charge transfer between molecules gives a huge effect on the NQR relaxation.

As an experimental technique, the present method is quite simple and applicable to systems with complicated H-transfer modes by applying the multi-NQR method,

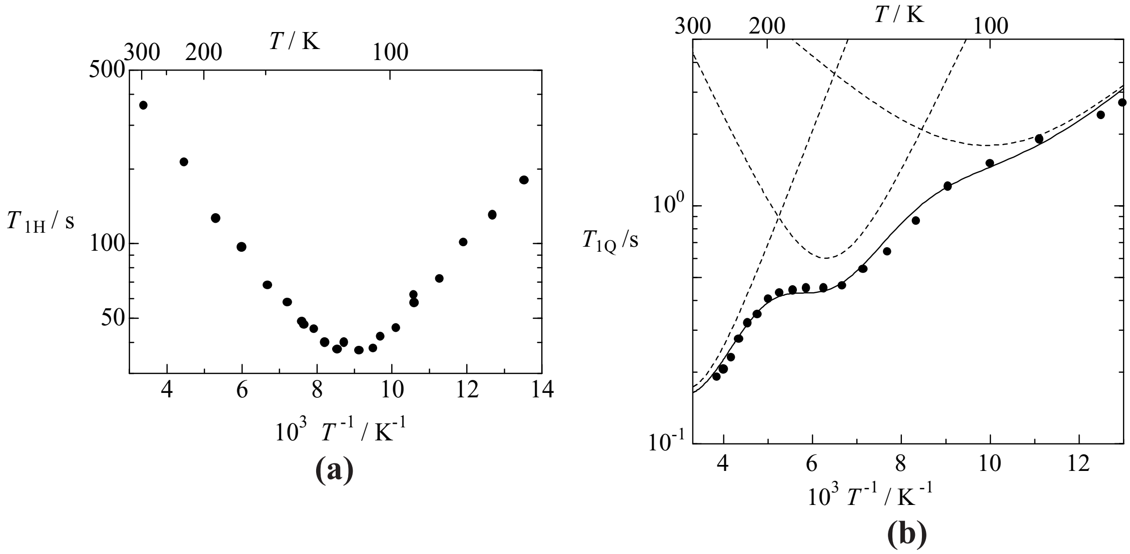


Fig. 7. Temperature dependences of (a) ^{1}H NMR spin-lattice relaxation time (T_{1H}) observed at 54.3 MHz and (b) ^{35}Cl NQR relaxation time (T_{1Q}) in solid $[C_6Cl_2O_2(OH)_2](1,2\text{-}C_4H_4N_2)_2$. Broken lines show calculated three relaxation processes and the solid line shows the best-fitted calculated values.

EPR: Principles

Bruce R. McGarvey
Department of Chemistry and Biochemistry, University of Windsor, Windsor, Ontario N9B 3P4, Canada

The basic methodology and development of the spin Hamiltonian method as well as the terminology and symbols used in EPR developed out of atomic spectroscopy. Therefore it is useful to review how atomic spectroscopy of atoms and ions dealt with the Zeeman effect, which is the effect of a magnetic field on atomic spectra. This is all covered in the classic work by Herzberg [1].

Angular Momentum

All magnetic properties of materials have their origin in angular momentum of electrons, nuclei, and molecules. Since the quantum mechanics of angular momentum is identical for all species, we will review the important elements of the quantum mechanics for the nuclear spin. The three operators of nuclear spin about the three coordinates are $\hat{I}_x$, $\hat{I}_y$, and $\hat{I}_z$. These operators are in units of $\hbar$. From the commutation properties of these three operators, it can be shown that the nuclear spin functions are eigenfunctions of the total angular momentum operator $(\hat{I}_x^2 + \hat{I}_y^2 + \hat{I}_z^2)$ and one of the three basic operators, generally chosen as $\hat{I}_z$. This is summarized below:

$$\begin{aligned} \left(\hat{I}_x^2 + \hat{I}_y^2 + \hat{I}_z^2\right) |I, M_I\rangle &= I(I+1)\, |I, M_I\rangle \\ \hat{I}_z\, |I, M_I\rangle &= M_I\, |I, M_I\rangle \end{aligned} \qquad (1)$$

where $|I, M_I\rangle$ is the ket notation for the spin function with eigenvalues I and M_I. Each nucleus has a specific value for I which must be integer or half-integer, while M_I can have the values $M_I, (M_I - 1), (M_I - 2), \ldots, -M_I$. Two other relations to know, if you are to solve spin Hamiltonians are the raising and lowering operators $\hat{I}_\pm$:

$$\begin{aligned} \hat{I}_\pm &= \hat{I}_x \pm i\hat{I}_y \qquad (2) \\ \hat{I}_\pm\, |I, M_I\rangle &= \sqrt{I(I+1) - M_I(M_I \pm 1)}\, |I, M_I \pm 1\rangle \end{aligned}$$

where the imaginary number $i = \sqrt{-1}$.

For electrons, the spin operator symbol is $\hat{S}$ and the quantum numbers are S and M_S. For a single electron it is conventional to use a lower case s and the quantum numbers $s = 1/2$ and $m_s = \pm 1/2$. For orbital angular motion it is conventional to use the symbol L for multiple electron systems and 1 for a single electron. Due to the spatial origin of this angular momentum property, only integer values of L and 1 are allowed.

Spin–Orbit Interaction

The angular motion of the electrons generates a magnetic field that interacts with the magnetic moment of the electron's spin, so there is a spin–orbit interaction that must be included, which has the form: $\hat{H}_{LS} = \lambda \hat{L} \cdot \hat{S}$. The spin–orbit interaction parameter, λ, is of the order of 10–100 cm^{-1} for low atomic numbers and increases to better than 10,000 cm^{-1} in the lanthanide series and is positive when a given p, d, or f shell is less than half filled and negative when the shell is more than half filled. This spin–orbit interaction which links $\hat{L}$ and $\hat{S}$ mixes up the $(2L+1)(2S+1)\, LS$ states to produce states defined by the total angular momentum operator $\hat{J} = \hat{L} + \hat{S}$ which have the J quantum numbers $|L+S|$, $|L+S-1|, \ldots |L-S|$ and energies

$$E_{LS} = \frac{\lambda}{2}\left[J(J+1) - (L(L+1) - S(S+1)\right] \qquad (3)$$

Zeeman Interaction

The magnetic moment operator for the angular motion of the electrons is $\beta_e \hat{L}$, where β_e is the Bohr magneton. The magnetic moment operator for electron spin is $g_e \beta_e \hat{S}$, where $g_e = 2.0023$ and for the nuclear spin it is $g_N \beta_N \hat{I}$, where β_N is the nuclear magneton. For an atom or ion with both orbital angular momentum and spin the Hamiltonian operator for the interaction with a magnetic field B is

$$H_Z = \beta_e(\hat{L} + 2\hat{S}) \cdot B \qquad (4)$$

which can be rewritten for a given J state as

$$\begin{aligned} H_Z &= g_J \beta_e \hat{J} \cdot B \\ g_J &= \frac{3J(J+1) + S(S+1) - L(L+1)}{2J(J+1)}. \end{aligned} \qquad (5)$$

Graham A. Webb (ed.), Modern Magnetic Resonance, 439–444.
© 2008 *Springer.*

g_J is called the Landé g factor. From Equation (4) we derive that the magnetic interaction splits the J state into $(2J + 1)$ states with energies

$$E_{M_J} = g_J \beta_e B M_J. \tag{6}$$

Spin Hamiltonian

EPR deals with magnetic systems that have a degenerate or nearly degenerate ground state whose energy levels are changed in the presence of an applied magnetic field and EPR spectroscopy deals with the magnetic transitions between these energy levels, which are induced by electromagnetic radiation of the system. Magnetic systems in this definition refer to materials that have traditionally been called paramagnetic, ferromagnetic, and anti-ferromagnetic materials and not the weakly magnetic materials studied by NMR spectroscopy, which are traditionally called diamagnetic. Magnetic transitions in the definition refer to transitions induced by the interaction of the oscillating magnetic field of the electromagnetic radiation with the magnetic dipole of the material being studied. No definition can be perfect, so it must be mentioned that there are a few examples in the literature where electronic transitions are also observed in what has been called EPR spectroscopy.

Since the early days of EPR, the spectra have been interpreted [2] in terms of the Spin Hamiltonian appropriate to the system being studied. A Spin Hamiltonian is a Hamiltonian that has only electron spin and nuclear spin operators plus constants and the magnetic field. The constants when properly chosen will give energy levels that will match the energy levels of the system and their dependence upon the applied magnetic field.

$S = {}^1\!/_2$ Systems

The concept is best illustrated by considering the simplest system which has only a doubly degenerate ground state and is represented by an $S = {}^1\!/_2$ spin Hamiltonian. What follows will seem rather elaborate when one considers a simple free radical, which is easily seen to be $S = {}^1\!/_2$, but we will consider, later, two systems in which the $S = {}^1\!/_2$ will be considered more as a “fictitious” spin.

Consider we have a system, which in the absence of a magnetic field, is doubly degenerate. We will label the wave functions as ψ_+ and ψ_-. When we apply the Zeeman operator, H_Z, as given in Equation (4), degenerate perturbation theory asks us to solve the 2×2 determinant

$$\beta_e \begin{vmatrix} \left\langle \psi_+^* \right| (L_z + 2S_z) B_z \left| \psi_+ \right\rangle - E & \left\langle \psi_+^* \right| (L_x + 2S_x) B_x + (L_y + 2S_y) B_y \left| \psi_- \right\rangle \\ \left\langle \psi_-^* \right| (L_x + 2S_x) B_x + (L_y + 2S_y) B_y \left| \psi_+ \right\rangle & \left\langle \psi_-^* \right| (L_z + 2S_z) B_z \left| \psi_- \right\rangle - E \end{vmatrix} = 0 \tag{7}$$

If we now consider the spin Hamiltonian

$$\begin{aligned} \mathcal{H} &= \beta_e \hat{S} \cdot g \cdot B \\ &= \beta_e (g_x S_x B_x + g_y S_y B_y + g_z S_z B_z) \end{aligned} \tag{8}$$

for the $S = {}^1\!/_2$ functions, $|S, M_S\rangle = \left|\frac{1}{2}, \pm\frac{1}{2}\right\rangle$, we obtain the following determinant

$$\beta_e \begin{vmatrix} \frac{1}{2} g_z B_z - E & \frac{1}{2}(g_x B_x - i g_y B_y) \\ \frac{1}{2}(g_x B_x + i g_y B_y) & -\frac{1}{2} g_z B_z - E \end{vmatrix} = 0. \tag{9}$$

Comparison of the two shows that the spin Hamiltonian parameters g_x, g_y, and g_z are obtained from

$$\begin{aligned} g_z &= 2 \left\langle \psi_+ \right| L_z + 2S_z \left| \psi_+ \right\rangle \\ g_x &= 2 \left\langle \psi_+ \right| L_x + 2S_x \left| \psi_- \right\rangle \\ g_y &= -2i \left\langle \psi_+ \right| L_y + 2S_y \left| \psi_- \right\rangle \end{aligned} \tag{10}$$

Equation (10) tells us how to calculate the g parameters in the $S = {}^1\!/_2$ spin Hamiltonian. For the mathematical purist, it should be noted that the g matrix has nine parameters which reduces to six because the off diagonal elements are symmetrical and this matrix can be reduced to a diagonal matrix with only three parameters when one chooses what has come to be called the principal axes. In the above equations we have assumed x, y, and z to be in the principal orientation.

Solution of the determinant in Equation (9) gives the following equation for the two energy states

$$\begin{aligned} E &= \pm \tfrac{1}{2} g \beta_e B; \\ g &= \sqrt{(g_x^2 \sin^2\theta \cos^2\phi + g_y^2 \sin^2\theta \sin^2\phi + g_z^2 \cos^2\theta)} \end{aligned} \tag{11}$$

where θ and ϕ are the polar angles for the orientation of the magnetic field. Note that the sign of the g matrix elements cannot be determined from the energy difference that is measured in the spectrum.

We shall now apply these equations to three examples.

Organic Free Radicals

In these free radicals the orbital angular momentum is essential quenched so there is no $\hat{L}$ contribution and they can be considered to be simple $S = {}^1\!/_2$ systems which would have $g = g_e$. The fact that the g values are slightly different is due to small admixtures of some excited states with electron angular momentum into the ground state through the spin–orbit interaction. These correction factors are small for organic free radicals due to the small values of the spin–orbit interaction parameter for C, N, and O atoms and the high energies of these excited states.

NO˙ Molecule

In the gaseous NO˙ molecule the ground state is $\sigma^2\pi^4\pi^{*1}$, which places the unpaired electron into the fourfold degenerate π^* orbital. The π^* orbital can be written as $(\pi^*)^{\pm}_{\pm 1}$, where the upper ± refers to the two orientations of the electron spin and the lower ± 1 refers to the two orientations of the orbital angular momentum of the π^* orbital.

$$\hat{S}_z(\pi^*)^{\pm}_{\pm 1} = \pm\frac{1}{2}(\pi^*)^{\pm}_{\pm 1} \quad \hat{L}_z(\pi^*)^{\pm}_{\pm 1} = \pm 1(\pi^*)^{\pm}_{\pm 1}$$

The spin–orbit $\lambda\hat{L}\cdot\hat{S}$ interaction creates two states

$$^2\Pi_{\frac{1}{2}} \quad E = -\frac{1}{2}\lambda \quad \psi = (\pi^*)^{+}_{-1}, (\pi^*)^{-}_{+1}$$

$$^2\Pi_{\frac{3}{2}} \quad E = \frac{1}{2}\lambda \quad \psi = (\pi^*)^{+}_{+1}, (\pi^*)^{-}_{-1}$$

and since $\lambda \approx 100\ \text{cm}^{-1}$ the two states are separated by $100\ \text{cm}^{-1}$. The g_z value is given by $(L_z + 2S_z)$, so for both states

$$^2\Pi_{\frac{1}{2}}\, g_z = 0; \quad ^2\Pi_{\frac{3}{2}}\, g_z = 4.0.$$

Thus the ground state is essentially non-magnetic in the gaseous state but the excited state will be thermally occupied at room temperatures and is easily detected in the gas.

If NO˙ is tied down as a ligand or trapped in the solid state or frozen solution state, the axial symmetry is likely to be removed and the orbital angular momentum quenched. Thus giving rise to an $(\pi^*)_x$, or $(\pi^*)_y$ orbital as the ground state which will be EPR active. If we assume the energy of the energy difference between the π_y orbital and the π_x orbital is Δ, without spin–orbit coupling, and then include spin–orbit coupling we obtain a Kramer's doublet ground state and excited state [3] with the energies

$$E = \pm\frac{1}{2}\lambda\sqrt{1+\omega^2};\ \omega = \frac{\Delta}{\lambda} \tag{12}$$

and the following ground state wave functions:

$$\begin{aligned}
\psi_+ &= A(\pi^*)^{+}_{+1} + B(\pi^*)^{+}_{-1}\\
\psi_- &= -B(\pi^*)^{-}_{+1} - A(\pi^*)^{-}_{-1}.\\
A &= -\frac{1}{\sqrt{2}}\left[1 - \frac{1}{\sqrt{1+\omega^2}}\right]\\
B &= \frac{1}{\sqrt{2}}\left[1 + \frac{1}{\sqrt{1+\omega^2}}\right]
\end{aligned} \tag{13}$$

Using Equation (10) with Equation (13) gives the following g values for the ground state:

$$\begin{aligned}
g_z &= 2\left[1 - \frac{1}{\sqrt{1+\omega^2}}\right]\\
g_x, g_y &= \frac{2\omega}{\sqrt{1+\omega^2}}
\end{aligned}. \tag{14}$$

In Equation (14) the value of $g_{z,x,y}$ goes from 0 to 2 as ω increases from 0. Thus for large Δ the ground state becomes the $(\pi^*)_x{}^{\pm}$ orbital. It only takes a $\Delta > 300$–$400\ \text{cm}^{-1}$ to bring $g_{x,y}$ close to 2 from 0, while g_z requires values $> 1{,}000\ \text{cm}^{-1}$. Thus, it takes only a small distortion interaction to convert a non-magnetic ground state to an active state in EPR. For NO attached to catalytic surfaces at liquid N_2 temperatures, the g values [4] are: $g_z = 2.0$ and $g_{x,y} \cong 1.9$.

The fact that the g matrix appears to have axial symmetry, when the molecule does not, is due to the fact that our calculation involves a system of only four functions and two energy states. If we include the existence of other excited states, the low symmetry will appear in the g matrix. The NO system shows some of the artificiality of the spin Hamiltonian concept. This system, is not a simple unpaired electron spin even though we are treating it as such by using the $S = 1/2$ spin Hamiltonian.

High Ligand Field d^5

In lower crystalline fields, Fe^{III}, d^5, has $S = 5/2$ but with ligands such as cyanide, porphyrins, etc. the five electrons are found in only the three t_{2_g} orbitals which in octahedral symmetry is a sixfold degenerate state. The related ions of Ru^{III} and Os^{III} are always found in this state. In this system, the electron orbital angular momentum is not quenched and the spin–orbital interaction plays an important role. It is always fitted to a $S = 1/2$ spin Hamiltonian but the g values vary from 3 to less than 1 and there has been, traditionally, a problem with what the sign of the g value should be. There have been a large number of papers in which the g values are derived but they often do not agree with each other or are difficult to compare. A

Table 1: Equations for the g matrix for the four possible cases using the $d_{\pm 1}$ and d_{xy} basis functions for t_2

Case	g_x	g_y	g_z
1a	$-2\left\lfloor -2ac + b^2 + \sqrt{2}b(a-c)\right\rfloor$	$-2\left\lfloor 2ac + b^2 + \sqrt{2}b(a+c)\right\rfloor$	$-2\left[a^2 - b^2 + c^2 + (a^2 - c^2)\right]$
2a	$-2\left\lfloor -2ac + b^2 + \sqrt{2}b(a-c)\right\rfloor$	$2\left\lfloor 2ac + b^2 + \sqrt{2}b(a+c)\right\rfloor$	$2\left[a^2 - b^2 + c^2 + (a^2 - c^2)\right]$
1b	$2\left\lfloor -2ac + b^2 + \sqrt{2}b(a-c)\right\rfloor$	$2\left\lfloor 2ac + b^2 + \sqrt{2}b(a+c)\right\rfloor$	$-2\left[a^2 - b^2 + c^2 + (a^2 - c^2)\right]$
2b	$2\left\lfloor -2ac + b^2 + \sqrt{2}b(a-c)\right\rfloor$	$-2\left\lfloor 2ac + b^2 + \sqrt{2}b(a+c)\right\rfloor$	$2\left[a^2 - b^2 + c^2 + (a^2 - c^2)\right]$

comprehensive review [5,6] has been written about this and a method of defining the parameters has been put forward to reduce the complexity. A condensed version of the theoretical results will be given here because there is some question as to whether the spin Hamiltonian concept is really proper for this system.

We will treat the problem using the following five electron functions as our starting wave functions:

$$\begin{aligned}
\left|-1, \pm\tfrac{1}{2}\right\rangle &= d_1^+ d_1^- d_{xy}^+ d_{xy}^- d_{-1}^{\pm} \\
\left|+1, \pm\tfrac{1}{2}\right\rangle &= d_{-1}^+ d_{-1}^- d_{xy}^+ d_{xy}^- d_1^{\pm} \qquad (15)\\
\left|0, \pm\tfrac{1}{2}\right\rangle &= \pm i d_1^+ d_1^- d_{-1}^+ d_{-1}^- d_{xy}^{\pm}.
\end{aligned}$$

The use of $\pm i$ in the third function is a mathematical trick to convert the two 3×3 matrices, that have to be diagonalized, from complex matrices to real matrices. The ligand field operator H_C will split the sixfold state into three different energy Kramer's doublets in lowest symmetry. It is customary to define two parameters to express the effect of the ligand field. They are;

$$\left\langle d_{xy}\right| H_C \left|d_{xy}\right\rangle = \Delta \qquad (16)$$

$$\left\langle d_{xz}\right| H_C \left|d_{xz}\right\rangle = \frac{V}{2} = -\left\langle d_{yz}\right| H_C \left|d_{yz}\right\rangle. \qquad (17)$$

Applying both the ligand field and spin–orbit interaction yields the energy determinant

$$\begin{array}{ccc}
\left|-1, \tfrac{1}{2}\right\rangle & \left|0, -\tfrac{1}{2}\right\rangle & \left|+1, \tfrac{1}{2}\right\rangle \\
\left|+1, -\tfrac{1}{2}\right\rangle & \left|0, \tfrac{1}{2}\right\rangle & \left|-1, -\tfrac{1}{2}\right\rangle
\end{array}$$

$$\begin{vmatrix}
(2\Delta - \tfrac{1}{2}\xi - E) & -\dfrac{\xi}{\sqrt{2}} & \dfrac{V}{2} \\
-\dfrac{\xi}{\sqrt{2}} & (\Delta - E) & 0 \\
\dfrac{V}{2} & 0 & (2\Delta + \dfrac{1}{2}\xi - E)
\end{vmatrix} = 0 \qquad (18)$$

and a ground state doublet of the form

$$\begin{aligned}
\psi_+ &= a\left|+1, -\tfrac{1}{2}\right\rangle + b\left|0, \tfrac{1}{2}\right\rangle + c\left|-1, -\tfrac{1}{2}\right\rangle \\
\psi_- &= a\left|-1, \tfrac{1}{2}\right\rangle + b\left|0, -\tfrac{1}{2}\right\rangle + c\left|+1, \tfrac{1}{2}\right\rangle \quad .
\end{aligned} \qquad (19)$$

What we need to consider first is how the g values are obtained from Equation (10). In the earlier examples, we knew which Kramer's doublet to call ψ_+ and ψ_- by which function had spin up or down but both functions in Equation (19) have spins of $+$ and $-$. In this case the assignment is arbitrary and has led to confusion in the literature about the sign. Further the a, b, c constants in the doublet must have the same magnitudes and relative signs to each other but are not required to have the same signs in ψ_+ and ψ_-. Thus we have four possible sets of equations for the g values which yield different combinations for the signs of g, which are set out in Table 1. In the table Case 1a is for the plus and minus labels to be assigned as shown in Equations (19) and for the two sets of mixing coefficients a, b, c having the same sign. Case 2a is the solution for interchanging the plus and minus labels but having both sets of coefficients with the same sign. Cases 1b and 2b are for the solutions in which the signs of the two set of coefficients are opposite.

When there is more than one solution to a mathematical problem, it is customary to use boundary conditions to select the more physically reasonable solution. In this case we use symmetry. For axial symmetry ($V = 0$), the coefficient $c = 0$ and we expect $g_x = g_y$. This rules out Cases 2a and 2b because they give $g_x = -g_y$. In octahedral symmetry, where $a = \sqrt{\frac{2}{3}}$; $b = \frac{1}{\sqrt{3}}$, one would expect all three g values to be identical and this can only happen for Case 1a. In this case, all three g values are -2. Experiments [7] have shown in a few instances, that the g is indeed negative for octahedral strong field d^5 systems. What is the meaning of a negative g? It tells us that the north pole of the magnetic moment for the ion is opposite to that of an electron in a given M_S state.

In this system the angular momentum dominates in octahedral symmetry so calling it a spin one half system is somewhat artificial. The actual wave functions are mixtures of up and down spin functions. We just treat it as a system with a "fictitious" $S = 1/2$ because it has only two states. The choice of Case 1a above works well for near octahedral systems but fails for large distortions. If Δ becomes very large the electron's angular momentum becomes quenched and b approaches 1. In this case 1a gives $g_z = +2$ and $g_{x,y} = -2$ but this cannot be because the magnetic moment is pure spin and all three g values should be $+2$ which is predicted by using Case 1b for calculating g. This ambiguity has plagued researchers in this field and points to a weakness in using the spin Hamiltonian representation for this system.

Hyperfine Interaction

When there is a dipole–dipole interaction between the electron and a nuclear spin a hyperfine term is added of the form

$$\hat{S} \cdot A \cdot \hat{I} \tag{20}$$

where A is a 3×3 matrix. It becomes a diagonal matrix if symmetry requires the principal axes of A to be collinear with the g matrix.

Nuclear Zeeman and Nuclear Quadrupole Interaction

The nuclear Zeeman interaction is similar to the electron's Zeeman interaction, only orders of magnitude smaller. It becomes important only when its magnitude is comparable to the hyperfine interaction of the same nucleus. For nuclear spin systems with $I > 1/2$ there is an interaction between the nuclear quadrupole moment and electrical field gradients that can be represented by a nuclear spin Hamiltonian involving second order nuclear spin operators. If x, y, and z are in the principal axis system for the quadrupolar interaction then the spin Hamiltonian can be written for both terms as

$$-g_N \beta_N B \cdot \hat{S} + \frac{e^2 q Q}{4I(2I-1)} \left\{ \left[\hat{I}_z^2 - \tfrac{1}{3} I(I+1) \right] + \eta \left[\hat{I}_x^2 - \hat{I}_y^2 \right] \right\} \tag{21}$$

where g_N is nuclear g value, β_N is the nuclear magneton, Q is the electric quadrupole moment of the nucleus, q is the electric field gradient at the nucleus, and η is an asymmetry parameter, which by definition can have values only between $-1/3$ and $+1/3$. Q is 0 for $I = 1/2$ and q is 0 for high symmetry sites such as tetrahedral, octahedral, and cubic. The quadrupole term mixes up nuclear spin states allowing forbidden double flip transitions to have finite intensities. Double flip transitions are those in which both the electron and nuclear spins change their quantum numbers simultaneously.

$S > {}^1\!/_2$ Systems

When you have a higher spin system with a degeneracy greater than 2, you must include a term of the form $\hat{S} \cdot D \cdot \hat{S}$, where D is a $(2S+1) \times (2S+1)$ matrix. The source of this spin–spin term comes from two types of interactions; first is the straight dipole–dipole interaction between two unpaired electrons, which is the main source in organic triplet states, and second is spin-orbit–orbit-spin interaction in systems like the transition metal complexes, which have large spin–orbit interaction parameters. In the principal axis system this can be written as

$$D \left\lfloor \hat{S}_z^2 - \tfrac{1}{3} S(S+1) \right\rfloor + E \left\lfloor \hat{S}_x^2 - \hat{S}_y^2 \right\rfloor \tag{22}$$

This spin-Hamiltonian is mathematically identical to the nuclear quadrupole term and the behavior is the same. For axial symmetry $E = 0$ and for symmetries that make x, y, and z identical $D = 0$. Also, if z is the main distortion axis, then $|E| \leq |D|/3$. This interaction is often called the zero field interaction because it produces an energy difference in the $(2S+1)$ spin states even in the absence of a magnetic field. In many transition complexes, this term can be much larger than the Zeeman interaction.

Higher Order Spin–Spin Terms

In higher-spin systems, it has been sometimes found necessary to include higher order spin operator terms. For $S = 3/2$ and higher a term involving $\hat{S}$ to third order and H to first order is allowed by symmetry arguments [8]. In octahedral and tetrahedral symmetry (the only symmetries where this small term has been detected) this term takes the form

$$u\beta_e \left\{ \hat{S}_x^3 B_x + \hat{S}_y^3 B_y + \hat{S}_z^3 B_z - \tfrac{1}{5} \left[3S(S+1) - 1 \right] \hat{S} \cdot B \right\} \tag{23}$$

where x, y, z are cubic axes. For $S = 2$ and greater, terms involving $\hat{S}$ to the fourth power are allowed. In cubic symmetry, it takes the form

$$\tfrac{1}{6} a \left\{ \hat{S}_x^4 + \hat{S}_y^4 + \hat{S}_z^4 - \tfrac{1}{3} S(S+1) \left[3S(S+1) - 1 \right] \right\} \tag{24}$$

For an axial distortion in the z direction the following would have to be added.

$$\tfrac{1}{180}F\left\{35\hat{S}_z^4 - 30S(S+1)\hat{S}_z^2 + 25\hat{S}_z^2 - 6S(S+1) + 3S^2(S+1)^2\right\} \qquad (25)$$

For lower symmetries other terms would have to be added. To further complicate the situation, when $S = 3$ or greater (this happens in the lanthanides and actinides), terms with $\hat{S}$ to the sixth power will be allowed.

In the past, these terms were only included in single crystal work where the position of resonance lines could be determined with high accuracy. This is no longer true with the use of high magnetic field spectrometers, where their magnitude may require inclusion in the analysis of powder and frozen solution spectra [9,10].

Alternate Form for the Zero Field Spin Hamiltonian

There is an alternate form for the zero field terms given above in Equations (22)–(25) that appears more often in the work on lanthanides and actinides. This method uses the following operator function to represent the spin–spin part of the spin Hamiltonian

$$H_{SS} = \sum_{J,M} a_{JM} T_{JM} \qquad (25)$$

where T_{JM} are irreducible tensor operators of $\hat{S}$ with $J = 2, 4, 6$ as required and the a_{JM} are the parameters to be fitted. The T_{JM} functions are operator functions related to the spherical harmonic functions. Examples and the definition can be found in one of the author's papers [11]. In various works the T_{JM} are defined with different constants. See, for example, Abragam and Bleaney [12]. A full discussion is beyond the scope of this introduction to EPR.

Zero Field NMR: NMR and NQR in Zero Magnetic Field

David B. Zax

Department of Chemistry & Chemical Biology, Cornell University, Ithaca, NY 14853-1301 USA, Tel: 1-607-255-3646, Fax: 1-607-255-4137, Email: dbz1@cornell.edu

Zero field NMR serves as the solution to a diverse grouping of very specific problems in solid state magnetic resonance. For some systems large magnetic fields interfere with the interesting phenomenon. In other cases high sensitivity may be achieved, paradoxically, not in high field but only where nuclear spins are transported from high to very low fields and back. And, finally, zero field NMR is of potential interest where the spectral resolution of dipole-dipole couplings and/or quadrupole couplings is limited by the broadening introduced to the spectrum when these nuclear spin interactions are observed in the presence of a large magnetic field. These couplings can be represented in their full form as

$$\mathcal{H}_d = -\sum_{\ell<k} \omega^d_{\ell k}\left[\frac{3(\mathbf{I}_\ell \cdot \mathbf{r}_{\ell k})(\mathbf{I}_k \cdot \mathbf{r}_{\ell k})}{r^2_{\ell k}} - \mathbf{I}_\ell \cdot \mathbf{I}_k\right]$$

where $\mathbf{r}$ is the internuclear vector and $\omega^d_{\ell k}$ the dipole-dipole coupling constant between spins ℓ and k. The coupling constant $\omega^d_{\ell k} \equiv \gamma_k \gamma_\ell \hbar \langle r^{-3}_{\ell k}\rangle$ and thus is itself structurally sensitive. Alternatively, the quadrupolar Hamiltonian is

$$\mathcal{H}_q = A_q(I)\left(3I_z^2 - I(I+1) + \eta\left(I_x^2 - I_y^2\right)\right)$$

where $A_q(I)$ reflects the distribution of electronic charges, and thus chemistry. Both $\mathcal{H}_q$ or $\mathcal{H}_d$ persist even absent any external magnetic field, and zero field studies seek to measure their characteristic frequencies. (While the Hamiltonian associated with the J coupling also survives in zero field, even in liquids, there seems little reason to seek to measure J frequencies—as except in unusually prepared spin systems it generates no splittings[1], and the same information should be available more readily in ordinary high-field experiments.) Collectively we will refer to these forms of the internal Hamiltonians in zero field as $\mathcal{H}_{zf}$.

An Historical Perspective: Field-Cycling NMR

Zero field NMR belongs to an ancient tradition in NMR studies. Pound and Purcell's[2] early demonstration of the existence of "negative temperatures"—with more spins in the excited than the ground nuclear spin state—was achieved by polarizing a sample, removing it rapidly from the field and then turning the sample upside down—and returning the sample to the magnet for detection. Soon thereafter Reif and Purcell[3] observed H_2 at very low temperature, and remarked on the observation of signals whose lineshape differed significantly depending on whether or not they were observed in the presence of a strong external field. That difference focuses our attention on the role played by the external magnetic field. Its primary function is to raise the energies of nuclear spin transitions from the exceedingly low (say, <10 MHz) to the acceptably low. Above some threshold, the resonance frequency is determined by the Zeeman interaction, and increases linearly with the field and in proportion to the magnetogyric ratio γ_k of the kth nuclear spin. The price paid for this increase in sensitivity? $\mathcal{H}_q$ or $\mathcal{H}_d$ are measured only as perturbations on the much larger Zeeman interaction; and as a perturbation, each is expressed in the NMR spectrum in modified forms, where the orientation as defined in the frame of the external field matters. The observable portions of $\mathcal{H}_q$ or $\mathcal{H}_d$ are

$$\mathcal{H}'_d = \sum_{\ell<k} \frac{\omega^d_{\ell k}}{2}(1 - 3\cos^2\beta)(3I_{z,\ell}I_{z,k} - \mathbf{I}_\ell \cdot \mathbf{I}_k)$$

$$\mathcal{H}'_q = -\frac{A_q(I)}{2}\left(3I_z^2 - I(I+1)\right)\Big((3\cos^2\beta - 1) + \eta\sin^2\beta\cos 2\alpha\Big)$$

where the angles α, β represent the Euler angles corresponding to rotations about the laboratory y- and z-axes which relate the laboratory (L) frame of reference and a consistently chosen axis system representing the internal interactions (the M frame). In disordered or powder samples this require many sets of rotation angles $\Omega \equiv \{\alpha, \beta\}$, as the necessary rotation R differs from orientation to orientation. For the sample as a whole we indicate this distribution via the symbol R_Ω, and an explicit calculation must integrate over the distribution of $P(\Omega)$. Thus the internal Hamiltonians present a distribution of energies when observed as a perturbation in a large externally applied field. This corresponds to a broadening mechanism for the high-field line—as recognized by Reif and Purcell—and removing this spectral broadening is one motivation for studying systems in zero field.

Thereafter interest in field-cycled NMR arose in a quite different application. Slichter and Hebel[4], and Anderson and Redfield[5], made critical discoveries about the nature of the superconducting state using the nuclear spins to observe the properties of superconducting electrons pairs in Al. But while nuclear spins might provide the critical confirmation of the nature of electron pairing, there was a simple experimental problem in applying NMR. The magnetic field needed to observe the spins interfered with the superconducting state—yet, absent the magnetic field, the magnetic resonance signature would be unobservably weak. The solution? Study superconductivity by monitoring the change in nuclear spin properties in zero field—but brought to zero field only for a brief period ($<T_1$) only. Samples are "prepared"—i.e. polarized—and signals detected in sufficiently high magnetic field so that the sensitivity of the experiment is reasonable; in between these two time periods the more interesting physics can be probed by removing the polarizing and detecting field. The same methodology has been adapted to the study of molecular tunneling in the rotation of methyl groups[6]; in low magnetic fields tuned radio frequency irradiation can drive the transitions between tunnelling states.

Sensitivity Enhancement of Low-γ Nuclear Quadrupole Resonance

The essence of field-cycled magnetic resonance experiments is that low-field frequencies can be detected with high-field sensitivity. Surprisingly enough, for many low-γ nuclear spins the sensitivity of the field cycling experiment exceeds that of high field spectroscopy; at least, where abundant, high-γ nuclear spins, and in particular, ^{1}H's are also available. While the spectrum is detected at high frequencies when the Zeeman interaction dominates, as $I = \frac{1}{2}$ particles with no quadrupolar field the resonance frequencies of those same ^{1}H spins in zero magnetic field are determined only by the range of dipole-dipole couplings, which typically span less than 100 kHz. Thus the demagnetized ^{1}H spins which maintain (for T_1) the polarization of high field have a very low spin temperature. For quadrupolar low-γ (X) nuclear spins, however, the situation is reversed; high field sensitivity is often low often both because the Zeeman frequency is low and/or the concentration of target nuclear spins in the sample is low. In low field, however, the quadrupolar transition frequencies are nearly always higher than the residual dipole-dipole frequencies of the spin–$\frac{1}{2}$ nuclei; thus the demagnetized X spins are nowhere near as cold.

At some magnetic field between that of the polarizing field B_0 and zero field the energy levels of the high-γ and X nuclear spins are matched. Where the two spin reservoirs come into resonance slowly, magnetization transfer equilibrates both baths to the same spin temperature, partially warming the abundant ^{1}H spins while the rarer X spins are significantly cooled. Upon returning to high field, the same level-crossing is re-encountered; as the ^{1}H and X spins have previously achieved equilibrium at exactly that field, no further transfer of magnetization is to be expected—and the ^{1}H spins, when brought back to high field, will be irreversibly warmed, leaving less magnetization for detection from that which would have been observed had there been no magnetization transfer.

Once demagnetized to zero field, various spectroscopic approaches are possible. In field-cycling spectroscopy using level-crossings[7–12], spins in zero field are irradiated and energy absorbed where the applied rf field is resonant with zero-field transition frequencies. Upon remagnetization the ^{1}H high-field signal is further decreased via the level-crossing magnetization transfer mechanism. Where the heat capacity of the X spins is low—as where they are rare—even greater sensitivity can be achieved by repeating the magnetization transfer/irradiation sequence multiple times before detection and repolarization. A plot of the detected ^{1}H magnetization found in high field as a function of irradiation frequencies in zero field shows minima wherever a resonance has been detected—and the minima, of course, correspond to the zero-field frequencies found in the two spin reservoirs. The entire experiment can then be repeated for a new zero field irradiation frequency, thus plotting out the spectrum. The advantages of level-crossing NMR? Unparalleled sensitivity, to the point where it is possible to detect ^{2}H or ^{17}O at *natural abundance* in well-chosen samples. Its disadvantages? That that sensitivity requires samples with very long T_1, so that the field cycle and multiple irradiation sequences can be carried out while the initial magnetization still lingers, and the standard disadvantages of all absorption spectroscopies—specifically, that the resolution and sensitivity cannot be simultaneously optimized.

Zero Field NMR: Experimental Details

As described above, a zero field NMR experiment can be divided into three periods: a period of initial polarization of magnetization, a period during which the field-free frequencies are probed, and a detection period. The polarization period is most typically carried out at high field, as is the detection period; that leaves only the middle period for further discussion. In the zero-field evolution period, various stratagems are possible, as illustrated in Figure 1. Below we discuss some alternatives to traditional level crossing NMR experiments[13].

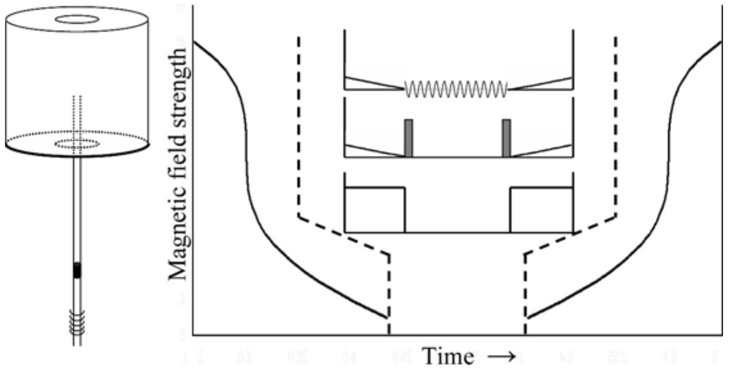

Fig. 1. Description of the time course of a field-cycling zero field experiment. Sample is polarized in high field; the experiment is initiated as the sample is transported to a low field region—here illustrated travelling in a glass tube under pneumatic control. In very low field, there are multiple options; three illustrated include, from the top: adiabatic demagnetization followed by low field irradiation, progressively swept in frequency; middle: evolution initiated by a field pulse (either tuned approximately to a transition, or at zero frequency), and interrupted by a similar pulse, and repeated for longer values of evolution time, or; bottom: signal evolution initiated and terminated by a sudden field transient. In all cases, the sample is then returned to high field for detection.

Demagnetization and Initiation of Evolution

A time-domain version of a similar experiment is possible. In high field, a density operator ρ is prepared which commutes with the Zeeman Hamiltonian $\mathcal{H}_z = -\gamma B_0 I_z$, and the truncated forms $\mathcal{H}'_d$ or $\mathcal{H}'_q$. For times short as compared to T_1, ρ may contain any and all powers of I_z; most commonly (and at equilibrium) $\rho \propto I_z$. Adiabatic demagnetization of the spins from high field, with or without level-crossings, yields a spin polarization which commutes with the zero field Hamiltonian of the spins so that $[\rho, \mathcal{H}_{zf}] = 0$ and therefore oriented in the L frame. Thus there is no macroscopic polarization to be observed along any axis after adiabatic demagnetization, unless the distribution of sample orientations is not uniform.

This fact seems paradoxical—as there is a long history of nuclear quadrupole resonance experiments[14], which manage to observe signals in samples where the only order is associated with the (disordered) alignment of the nuclear spins eigenstates of the zero field magnetic field. Observation of an NQR signal is initiated by a pulse of radiofrequency radiation applied in a coil—and that process selects a subset of orientations for excitation. Thus a detectable magnetization is created along the axis of the coil-as long as the signal is initiated by an excitation *oriented in the laboratory frame* resonant with pairs of energy levels. A similar approach has been demonstrated to initiate time-evolution of quadrupolar nuclear spin systems after adiabatic demagnetization to zero field[15].

An alternative approach abandons the easily managed adiabatic transition to zero magnetic field and instead executes a rapid demagnetization—most practically effected by a two-step process, from the polarizing field to some intermediate field (of order 0.03–0.1 T), followed by a rapid quenching of the intermediate field. Quantum mechanics invokes the sudden approximation to describe the state of the system after rapid demagnetization[16]—and, quite simply, to state that where the demagnetization occurs sufficiently rapidly the spins are unable to respond to the change in their circumstances. Where the polarizing magnetic field can be suddenly reduced so that the ordinary roles of the local Hamiltonians $\mathcal{H}_d$ or $\mathcal{H}_q$ and the Zeeman Hamiltonian $\mathcal{H}_z$ are reversed and $\mathcal{H}_d, \mathcal{H}_q > \mathcal{H}_z$ then the polarized state of magnetization proportional to I_z defined *in the L frame* no longer commutes with the Hamiltonian(s) *defined in the M frame*, and must evolve. The allowed evolution frequencies are determined by the allowed transitions in the zero field Hamiltonian $\mathcal{H}_{zf}$; the transition intensities are determined by the eigenstates of the zero-field Hamiltonian and the orientation(s) of the spin network as compared to the external magnetic field.

A free induction decay is initiated the instant that the polarizing field is removed; assuming, of course, that the loss of the polarizing field is, indeed, "instantaneous". Where the polarizing field is removed more gradually, or from an initial value not much larger than $\mathcal{H}_{zf}$ the demagnetization may instead resemble at least in part the adiabatic process described above, and some spin order will instead end up in eigenstates of $\mathcal{H}_{zf}$. Where the intermediate field too low, the free induction decay initiated after a rapid turn-off of that field is of lower overall amplitude, and with intensities which may not be entirely predictable.

Detecting the Zero Field Signal

The magnetization evolving in zero magnetic field can be described via a density operator formalism. Simplest is a description of the density operator in the case of sudden demagnetization from an "infinitely" large magnetic field; under these circumstances the density operator found at zero time in zero field is identical to that prepared in high field $\rho(0) \propto I_{z,L}$ where the subscript makes explicit that the magnetization in zero field is referenced to the z-axis of the laboratory frame. A well-chosen experiment maximizes the initial magnitude of the zero field free induction signal function $S(t) = \mathrm{Tr}[\rho(t)\mathcal{O}]$ where $\mathcal{O}$ is the detected operator. The trace can be maximized at $t = 0$, and thus the power in the zero field spectrum maximized, only where $\mathcal{O} \propto \rho(0) \propto I_{z,L}$. Thus evolving magnetization may be detected in zero magnetic field by wrapping a sensing coil about the sample along the laboratory z-axis as a Faraday-law magnetization detector—precisely as in high field NMR detectors. Such direct detection has not generally been assumed to be feasible in most field-cycling experiments, particularly where the magnetization evolution is initiated by rapid field demagnetization, as the limiting timescales for rapid transitions restrict such experiments to systems with relatively low zero field frequencies. Faraday law detectors vary in sensitivity as the evolution frequency and as a result the signals which might be induced in a solenoidal coil at 100 kHz, would be 1000-fold smaller than the signals from an equal magnetization in a coil of equal Q at 100 MHz. In a precise reversal of the demagnetization process, signal detection requires sample remagnetization, with the rapid turn-on of an intermediate field which stores some of the evolving magnetization as a Zeeman polarization followed by transport to the larger detection field so that conventional high-field NMR provides a measure of the evolved state of $\rho(t)$. Similarly where signal evolution after adiabatic demagnetization is initiated by a field pulse, P, the evolving operator at $t = 0$ is $P^{-1}\rho P$. Then $\mathcal{O}$ should be similarly designed to provide the maximum signal, and signal intensity in high field is maximized if we assume a detectable operator $\mathcal{O} = P\rho P^{-1}$; i.e. we time-reverse the process which generated the evolving magnetization. We will comment on how this might be achieved, below. Alternatively, we might imagine a zero-field detector of form quite different than the Faraday law solenoids typically found in high-field spectrometers.

Evaluation of Signals Observed in Zero Field

No universal treatment of the signals expected in zero field can be provided, as the signal intensities—as opposed to the signal frequencies—are highly dependent on the details of the demagnetization and remagnetization processes. The most straightforward discussion of experimental results arises where the transition to and from zero field happens in the "sudden" limit, and where there is no possibility of level-crossings with any magnetic nuclei. We will emphasize the detailed analysis of this case[17,18].

Magnetization arrives in zero magnetic field as a magnetic dipole of size comparable to that prepared in high magnetic field, and with the same orientation. Time evolution in zero magnetic field can be followed using the density matrix formalism. As $\rho(t) = \exp(\imath\mathcal{H}_{zf}t)$ $\rho(0)\exp(-\imath\mathcal{H}_{zf}t)$, $S(t) \equiv \mathrm{Tr}[\rho(t)\rho(0)]$. This expression, however, is deceptively simple, as ρ is prepared in the L frame, while $\exp(\imath\mathcal{H}_{zf}t)$ is most readily evaluated in the M frame where all comparable spin ensembles share the same $\mathcal{H}_{zf}$. It is simplest to transform $\rho_L \rightarrow \rho_M$; i.e to re-express the density operator of the system in the molecular frame appropriate to a local description of the problem. Two Euler angles are sufficient—and the required angles precisely reverse the transformation described above which rewrite the molecular-frame Hamiltonians $\mathcal{H}_q$ and $\mathcal{H}_d$ in the privileged axis system whose z-axis is parallel to the external magnetic field B_0; so that if R takes the M frame to the L, frame, R^{-1} executes the inverse operation. For any specific orientation our signal is $S_\Omega(t) = \mathrm{Tr}[\exp(\imath\mathcal{H}_{zf}t)R\rho_L(0)R^{-1}\exp(-\imath\mathcal{H}_{zf}t)RI_{z,L}R^{-1}] = \mathrm{Tr}[\rho_M(t), \rho_M(0)]$, and $\rho_M(t) = -\sin\beta\sin\alpha I_{x,M}(t) + \sin\beta\cos\alpha I_{y,M}(t) + \cos\beta I_{z,M}(t)$, so that

$$\begin{aligned}\mathcal{S}_\Omega(t) = {} & \cos^2\alpha\sin^2\beta\,\mathrm{Tr}\left[I_{x,M}(0)I_{x,M}(t)\right] \\ & + \sin^2\alpha\sin^2\beta\,\mathrm{Tr}\left[I_{y,M}(0)I_{y,M}(t)\right] \\ & + \cos^2\beta\,\mathrm{Tr}\left[I_{z,M}(0)I_{z,M}(t)\right]\end{aligned}$$

Where multiple orientations Ω are found, the net signal requires that we integrate over the distribution $P(\Omega)$ describing how our systems are oriented. For the common case that the sample is unoriented $P(\Omega) \propto d(\cos\beta)d\alpha$ and

$$\begin{aligned}\mathcal{S}(t) & \propto \int_0^\pi d\alpha \int_0^{2\pi} \sin\beta\, d\beta\, \mathcal{S}_\Omega(t) \\ & \propto \frac{1}{3}\sum_{p=x,y,z} \mathrm{Tr}[I_{p,M}(t)I_{p,M}(0)]\end{aligned}$$

i.e. the line intensities are given by equal weightings of each of the three possible first-rank tensor orientations of magnetization in the M frame. Normally $[I_p, \mathcal{H}_{zf}] \neq 0$ for all indices p, and all of the magnetization transported to zero field evolves. For simplicity we evaluate the trace in matrix form, making use of $\langle j|I_{p,M}(t)|k\rangle = \langle j|I_{p,M}(0)|k\rangle\exp(-\imath\omega_{kj}t)$ (where $\omega_{kj} \equiv \omega_k - \omega_j$ is the difference in frequency units between energies of the kth

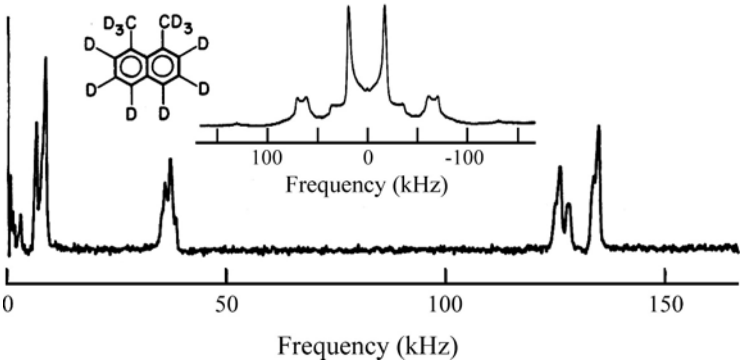

Fig. 2. High field ^{2}H NMR spectrum (inset) and zero field ^{2}H NQR spectrum, of 1,8-dimethylnaphthalene-d_{12}. The inset spectrum shows the quadrupole-echo detected spectrum, with a narrow Pake pattern (singularities at ±18 kHz) derived from the ^{2}H nuclei found in the two pairs of methyl groups, and a broader pattern corresponding to all the ring deuterons. In the zero field NQR spectrum (positive and negative frequencies are indistinguishable) we see ν_0 (at low frequencies <10 kHz), ν_- and ν_+ lines (between 120–135 kHz) from the ring deuterons, indicating substantial variability in the quadrupolar fields A_q at the different ring sites and significant asymmetry parameters η. The methyl group absorption is observed at about 36 kHz; the structure in the band is due to dipole-dipole couplings within the methyl groups.

and jth eigenstates of $\mathcal{H}_{zf}$) and

$$\mathrm{Tr}\left[I_{p,M}(t)I_{p,M}(0)\right] \propto \sum_{j,k} |\langle j|I_{p,M}(0)|k\rangle|^2 \cos\omega_{kj}t$$

For $I = 1$ nuclear spins, each of the three canonical angular momentum operators I_x, I_y and I_z corresponds to a different zero-field transition, and each of the three lines (conventionally labelled ν_0, ν_- and ν_+) is easily observed with very high resolution in Figure 2, which contrasts the high field ^{2}H spectrum of dimethylnaphthalene with its zero field counterpart. In the former, we observe a methyl group (with singularities near ±18 kHz) and a broad absorption band for the various ring sites (with singularities near ±60 kHz); in the latter with see the methyl multiplet pattern near 36 kHz split by the dipole-dipole couplings within the rotating -C^2H_3 group, as well as a series of well-resolved ring lines corresponding to the ν_- and ν_+ transitions from 125–135 kHz, and a set of ν_0 lines (below 10 kHz in the spectrum). Of course, the observed frequencies ω_{kj} and line intensities vary not only with the experiment but with the spin network being probed. No universal description can be provided, but numerous examples of spectra are available for representative spin groupings[19]. Where α and β are not uniformly distributed over the sphere, the zero field spectrum of an oriented sample yields *homogeneous* frequencies ω_{kj} but *inhomogeneous* (i.e. Ω dependent) line intensities.

Detection of the evolving density operator can either proceed directly via a coil wrapped about the sample, or by trapping the evolving magnetization and returning the sample to high field for subsequent detection. Either method registers similar information; but as described above direct detection is difficult with conventional detectors. A significant increase in the efficiency of zero field NMR utilizes Josephson-junction based Superconducting QUantum Interference Devices (SQUIDs)[20–25]. SQUIDs have lower than normal noise floors, and thus improved sensitivity to small changes in flux, as compared to ordinary semiconductor preamplifiers. SQUID-based detectors can be designed to detect either the derivative of the flux—i.e. the same quantity measured in an ordinary Faraday-law detector—or the flux itself. For low frequencies the latter is clearly preferable. Perhaps more importantly, SQUID detectors sample the evolving magnetization for all necessary evolution times in zero field in a single experiment. Where the magnetization is returned to high field for detection of the evolving zero field signal, each new time point can be observed only by trapping magnetization in the intermediate field; the next point requires an entire new polarization/depolarization sequence.

Where the demagnetization takes place adiabatically, evolution must be initiated with an external field pulse. Either a tuned low-frequency rf pulse[15] or a strong dc field pulse[26] will generate evolving magnetization. In either case some signal intensity is sacrificed, as the demagnetized state of magnetization commutes with $\mathcal{H}_{zf}$, and after *any* kind of pulse ρ will still commute in part with $\mathcal{H}_{zf}$. Detection efficiency is maximized by reversing the excitation sequence. Where the excitation and detection involve different operators—i.e. where the demagnetization is adiabatic and evolution is initiated with a field pulse, and the evolving magnetization is trapped when a large field is rapidly turned on—the signal amplitudes are tolerably large, and the zero field evolution frequencies are observed as sums of sines. Level-crossings can also be used so as to indirectly detect the frequencies of zero-field evolution, as in the indirect detection of ^{2}H nuclear resonance frequencies via the ^{1}H magnetization detected after a complete field cycle.

Extensions of Zero Field NMR and NQR

High amplitude, rapidly switched low-frequency (or dc) magnetic field pulses are required to study larger zero field splittings, whether operating in the "sudden" approximation limit, which requires that the switched field be sufficiently high so that $\mathcal{H}_z > \mathcal{H}_{zf}$ and that on-off time τ satisfies $\omega_{kj}\tau < 1$ for all eigenvalues ω_{kj} of $\mathcal{H}_{zf}$, or the adiabatic limit with pulse-initiated evolution. (It is possible to do swept-frequency experiments, though that would seem to obviate much of the advantage of the Fourier method as applied to zero field NMR.) Large pulsed fields (as high as 25–30 T) lasting for short times have been demonstrated in De Haas–van Alphen experiments[27] and similar technology would seem to be adaptable to zero field NMR, although switching large fields on and off in the fringe field of a superconducting magnet introduces unique complications. Nonetheless as implementations of zero field NMR experiments have largely focused on either dipole-dipole coupled networks—especially, ^{1}H-abundant species—or quadrupolar nuclear spin systems with relatively small coupling frequencies, such extreme pulsed fields may not be necessary. (Moreover, for the higher quadrupole frequencies where even stronger pulsed fields might be useful, a field-cycling apparatus may not be necessary, as the natural polarization levels may be sufficient.)

Other extensions include manipulation of spins in zero field. Using pulsed fields it is possible to perform high-resolution COSY[15] or NOESY-like[28] two-dimensional experiments. As the field-cycling experiment is already two-dimensional, with zero field evolution monitored point-by-point in high field, such experiments are actually three-dimensional. Correlation between the zero and high field Hamiltonians should be more time efficient, except that common line-narrowing methods including magic angle spinning (MAS) can which yield more interesting high-field spectra interferes with the resolution in zero field[29]—as the spinning of the sample introduces a new quantization axis uniquely to the laboratory frame—to say nothing of the difficulty of transporting rapidly spinning samples. More extensive manipulation of the spins in zero field is also possible. A more intriguing, though so far largely unused approach, has been to manipulate first- and second-order spin interactions using DC field pulses about three orthogonal axes[30].

Zero Field NMR and NQR: Limitations and Prospects?

An inherent limitation on zero field NMR in dipole dominated networks is that even in modest sized spin systems spectral resolution is poor. Consider N spin–$\frac{1}{2}$ particles, described by 2^N eigenstates. In high field, $m = \langle I_z \rangle$ is a good quantum number, and a single-pulse NMR experiment excites transitions only where $\Delta m = 1$. Thus the number of allowed transitions is limited, though rapidly increasing; for $N = 3$ there are no more than 15 allowed transitions, while for $N = 6$, as many as 792 transitions. In contrast in zero field there are no good quantum numbers and no selection rules, so we expect as many as $2^N(2^N - 1)$ lines; where $N = 3$, fifty six distinct lines may be observed corresponding to varying combinations of only 3 distinct dipole-dipole couplings; and for $N = 6$, four thousand thirty two transitions corresponding to only 15 coupling constants. Exacerbating the problem is that in zero magnetic field no useful distinction exists between nuclei of differing γ so all spin–$\frac{1}{2}$ nuclei participate in the network—and the coupling networks in zero field studies are larger than might be found in high field NMR experiments. (On the other hand, half-integer and integer spins couple only weakly to one another[31].) Finally, the decay of the dipolar field with distance is slow, and thus limiting a spin coupling network to N spins is rarely warranted; in fact, one of the most successful predictors of zero field line shapes is a statistical treatment due to Kubo and Toyabe[32]. Thus the highest resolution spectra, and most of the coherence transfer experiments, have focused on ^{2}H zero field spectra. For this spin-1 system, the quadrupolar frequencies of $\mathcal{H}_q$ play a role in zero field comparable to high field chemical shifts, while $\mathcal{H}_d$ is observed only as a perturbation on the larger $\mathcal{H}_q$. The majority of the remaining studies have emphasized other quadrupolar nuclei with relatively small zero field transition frequencies. The use of SQUID-based detectors to improve sensitivity, allow for direct detection of the evolving zero field magnetization and reduce measurement time will no doubt prove increasingly valuable.

Very high-resolution dipolar spectra of spin–$\frac{1}{2}$ nuclei in zero field NMR have been observed only in spin networks with very small N, and many of the early spectra focused on hydrates such as $Ba(ClO_3)_2 \cdot H_2O$ for that reason. Even in the hydrates absorption bands in zero field are broad, and significantly diminished linewidths adequate to measure a motionally-induced anisotropy in the dipolar field could be observed only once the majority of ^{1}H atoms were removed by recrystallization out of deuterated water solution[18]. That the resolution in $\mathcal{H}_d$ is poor even in zero field has substantially restricted the types of systems amenable to these field cycling studies unless isotopic dilution is used to limit the extent of the spin network (as

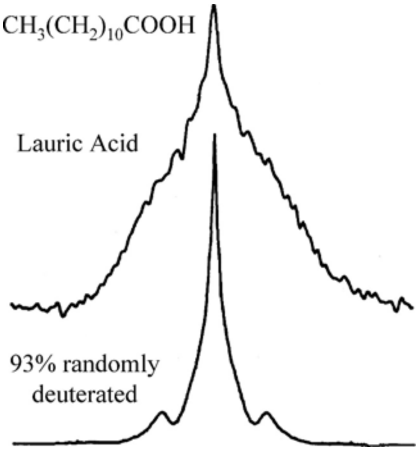

Fig. 3. Zero field ^{1}H NMR spectra of lauric acid, $CH_3(CH_2)_{10}COOH$. At top, spectrum of completely protonated material, showing lack of resolution due to extended network of similar sized dipole-dipole couplings. Below, 93% randomly deuterated lauric acid. The broad peak is substantially narrowed, leaving only isolated pairs which would appear to provide the resolved lines at about ±35 kHz.

in Figure 3). Moreover, a clever high-field-only approach to the same problem has been demonstrated, including detection of ^{13}C-^{13}C dipole-dipole couplings with H decoupling[33, 34]. Zero field NMR observes $\mathcal{H}_d$ untruncated by the magnetic field. In high field where $\mathcal{H}_d$ exists as a perturbation on the much larger $\mathcal{H}_z$, only the eigenvalues of the truncated form $\mathcal{H}'_d$ are normally measured. Averaging in both spatial and spin coordinates by simultaneously spinning and applying pulses can further average $\mathcal{H}'_d$ yielding a further averaging with the remarkable property that the new dipolar Hamiltonian is proportional to the untruncated Hamiltonian $\mathcal{H}_d$, so that a dipolar spectrum without orientational broadening can be observed, without cycling the field from high to low and back again, and observed while a resonant decoupling field is applied which removes abundant, high-γ spins from the spin network being probed. Thus newer developments in zero field NMR and NQR make it increasingly likely that future attempts to measure high-resolution quadrupolar and dipolar spectra in solids will look to avoid the field-cycling methods at the historical origin of these methods.

Organo Metallic Chemistry

Organoboron Chemistry

Bernd Wrackmeyer
Department of Inorganic Chemistry, University of Bayreuth, 95447 Bayreuth, Germany

NMR studies of organoboron compounds usually deal with ^{1}H, ^{13}C, and ^{11}B nuclei, and with few exceptions focus on solutions [1–5]. The presence of the quadrupolar ^{11}B isotope (natural abundance 80.42%; $I = 3/2$) can be exploited in several ways.

Measurements of ^{11}B NMR spectra are straightforward with modern NMR spectrometers by single pulse techniques, using short acquisition times (<0.2 s in most cases), 90° pulses, and short repetition delays (<5 ms) The NMR receptivity of the ^{11}B nucleus is high, the ^{11}B NMR signals are not too broad (often <200 Hz) in spite of the sizeable electric quadrupole moment ($Q = 4.1 \times 10^{-2}$ [10^{-28} m^{2}]). And the range of chemical shifts δ^{11}B is fairly large (Figure 1).

For broad ^{11}B NMR signals and diluted solutions, the background signals arising from boron-containing glass additives in the tubes and in the probe head can become a problem. However, in most cases, chemical shifts δ^{11}B are readily determined, even from diluted reaction solutions, and the line widths $h_{1/2}$ of the ^{11}B NMR signals, a measure on the quadrupolar spin relaxation time $T^{Q}(^{11}\mathrm{B})$ [$h_{1/2} = (\pi T^{Q})^{-1}$], provide further valuable information. In principle, ^{10}B NMR can also be measured. However, the NMR properties of ^{10}B are less favorable, since its natural abundance is lower (19.58%), magnetic moment is smaller by a factor of 3, and nuclear spin $I = 3$.

One of the most significant features of δ^{11}B data is the marked difference for boron nuclei with coordination numbers three and four, the latter being more shielded. This means that dynamic equilibria can be studied by ^{11}B NMR with respect to the surroundings of the boron atom. In general, it is possible, even by using moderate field strengths B_0, to distinguish between various boranes present in reaction solutions as shown in Figure 2 for a mixture of diborane(6) derivatives [6].

Two-dimensional (2D) NMR experiments involving ^{11}B nuclei are mainly used for polyboranes, carboranes, other heteroboranes, and their metal complexes in order to establish the ^{11}B/^{11}B connectivity in the clusters. These are simple ^{11}B/^{11}B COSY experiments with simultaneous ^{1}H decoupling [7] or combinations of ^{11}B/^{1}H shift correlations and ^{1}H/^{1}H COSY experiments with simultaneous ^{11}B decoupling [8].

Another important consequence of the presence of ^{11}B concerns effects on the NMR spectra of spin-1/2 nuclei, which in the case of organoboranes are predominantly ^{1}H and ^{13}C nuclei, and less often ^{19}F, ^{31}P, ^{29}Si, or ^{119}Sn nuclei to name a few examples of other spin-1/2 nuclei. If these nuclei are linked directly to boron, their NMR signals will be severely broadened owing to scalar relaxation of the second kind, caused by the spin dynamics of the quadrupolar ^{11}B nucleus which averages scalar ^{11}B–X spin–spin coupling (X = spin-1/2 nucleus). In the case of slow ^{11}B nuclear spin relaxation, splitting of the X NMR signals can be observed. Slight broadening of X NMR signals may also be noticeable in some cases if the ^{11}B nucleus is separated by two or three bonds from X. Heteronuclear decoupling experiments of the type X{^{11}B} (frequently done for X =^{1}H, ^{13}C [9] as shown in Figure 3) can be used for assignments and help to establish the origin of the broadened X NMR signals [10].

The ^{1}H{^{11}B] experiments are standard on all modern NMR spectrometers, whereas the ^{13}C{^{1}H, ^{11}B} or other X{^{11}B} experiments require additional hardware. Since the quadrupole-induced nuclear spin relaxation is more efficient at low temperature, sharpening (“quadrupolar decoupling”) of respective broadened X NMR signals is typically observed by measuring the X NMR spectra at low temperature.

Organogermanium Chemistry

Bernd Wrackmeyer
Department of Inorganic Chemistry, University of Bayreuth, Bayreuth, Germany

The NMR spectroscopic characterization of organogermanium compounds is based almost entirely on ^{1}H and ^{13}C NMR measurements in the usual way.

The only magnetically active isotope of germanium is the quadrupolar nucleus ^{73}Ge with rather unfavorable NMR properties (nat. abund.7.76%, low magnetic moment, and spin $I = 9/2$). However, there are several classes of organogermanium compounds, for which meaningful ^{73}Ge NMR spectra can be measured [1–4]. These measurements require additional hardware, since the NMR frequency of ^{73}Ge ($\delta^{73}Ge(GeMe_4) = 0$ for $\Xi(^{73}Ge) = 3.488315$ MHz) is too low for the usual broadband multinuclear probe heads. In many cases, the ^{73}Ge NMR signals are fairly broad as the result of efficient quadrupole-induced nuclear spin relaxation [$T^{Q}(^{73}Ge)$ is short], and the detection of ^{73}Ge NMR signals can become rather difficult by using simple single pulse methods. This is the consequence of "acoustic ringing" [5], typical of low-γ nuclei, which causes a rolling base line (Figure 1, lowest trace) and thus may obscure the real signal if this is also broad.

Various pulse sequences have been developed in order to overcome this problem [6–8]. However, usually a compromise has to be found among loss of sensitivity, long spectrometer time, and a clean or distorted base line. In the future, Hadamard excitation [9] or related techniques could help to solve this problem.

Considering the limited number of known chemical shifts $\delta^{73}Ge$, the overall range for this parameter is not easy to predict. However, the comparison [10] with chemical shifts $\delta^{29}Si$ and $\delta^{119}Sn$ of comparable silicon and tin compounds, respectively, indicates a range of about 2500 ppm. Although, the range of $\delta^{73}Ge$ is larger than that of $\delta^{29}Si$, the pattern follows closely, in most cases, the trends well known for silicon compounds. Less pronounced as for tin compounds, there is a tendency of germanium to increase its coordination number. This is reflected, expectedly, by a considerable increase in ^{73}Ge nuclear shielding [11], and also by changes in the line widths of the ^{73}Ge NMR signals [12].

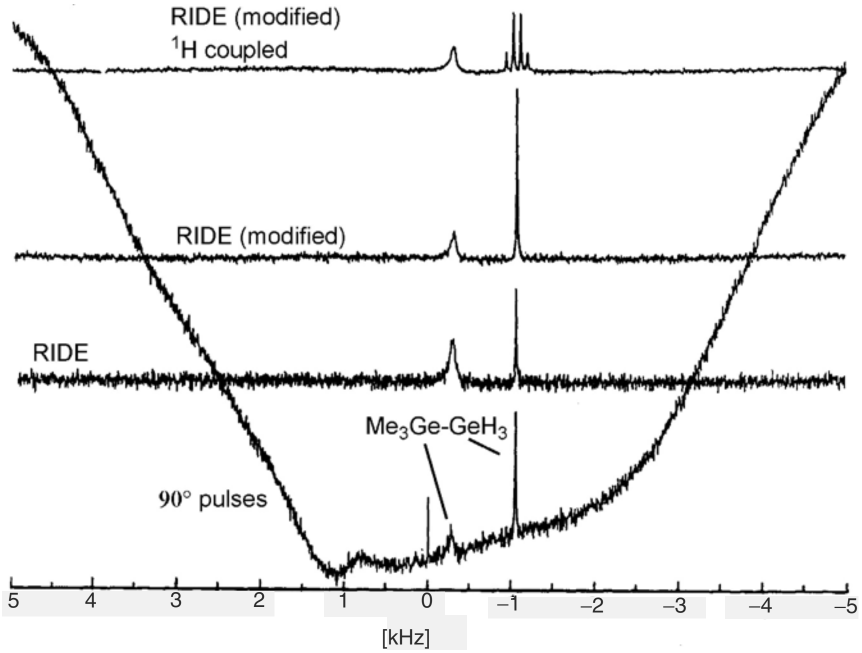

Fig. 1. 3.13 MHz ^{73}Ge NMR spectra of 1,1,1-trimethyldigermane [6]. The lowest trace shows the spectrum obtained by using single pulse mathods. In the middle traces, pulse sequences [6,7] were appied to eliminate the acoustic ringing. The upper trace shows the ^{1}H-coupled spectrum, confirming the assignment of the ^{73}Ge NMR signals.

Organotin Chemistry

Bernd Wrackmeyer

Department of Inorganic Chemistry, University of Bayreuth, 95447 Bayreuth, Germany

NMR studies of organotin compounds in solution deal in most cases with ^{1}H, ^{13}C, and ^{119}Sn nuclei. In some fields of organotin chemistry, solid-state ^{119}Sn NMR measurements become increasingly important [1]. The fact that both ^{119}Sn (8.58%) and ^{117}Sn (7.61%) are spin-1/2 nuclei with appreciable natural abundance (in contrast to ^{115}Sn: 0.35%; $I = 1/2$), and that they are fairly sensitive toward the NMR experiment (factors 25.7 and 19.2 relative to ^{13}C!) creates an attractive situation for ^{119}Sn NMR measurements [2–6], in particular if the molecules in question contain two or more tin atoms.

Measurements of routine ^{119}Sn (or ^{117}Sn) NMR spectra are straightforward using single pulse techniques, acquisition times in the order of 1 s, pulse angles of about 30°–45°, and short repetition times (10 ms). Since the gyromagnetic ratio γ for ^{119}Sn (also for ^{117}Sn) is negative, the NOE (upon ^{1}H decoupling) may cause a problem if it comes close to canceling the ^{119}Sn NMR signal. Therefore, it is advisable to check, for each class of compounds in question, whether ^{119}Sn{^{1}H} and ^{119}Sn{^{1}H-inverse gated} experiments give the same results. Frequently, longitudinal ^{119}Sn nuclear spin relaxation is governed by spin–rotation interactions (T_1^{SR}) or, in particular, at high field strengths B_0, by the chemical shift–anisotropy mechanism (T_1^{CSA}), and then ^{119}Sn–^{1}H dipole–dipole interactions (T_1^{DD}; reasonable for the NOE) play a minor role. A significant gain in the performance of ^{119}Sn NMR is achieved by the application of INEPT experiments [5,6], taking advantage of scalar ^{119}Sn–^{1}H spin–spin coupling, for which a large data set is available from ^{1}H NMR spectra. The most efficient way to obtain ^{119}Sn NMR signals even from very diluted solutions is provided by ^{1}H–^{119}Sn heteronuclear shift correlations (HMQC, HSQC, and HMBC), selecting ^{119}Sn–^{1}H spin pairs and detecting the ^{1}H NMR signals [7].

The chemical shifts δ^{119}Sn cover the large range of about 6500 ppm (Figure 1). The multifaceted chemistry of tin is reflected by a great variety of different surroundings of the tin atoms. It is remarkable that the ^{119}Sn nuclear magnetic shielding is found to be very low for two-coordinate tin(II) compounds bearing organic substituents and rather high again for tin(II) compounds, however, with η^{5}-bonded cyclopentadienyl ligands. A range of about 600 ppm is covered by simple organotin compounds containing tetra-coordinate tin atoms. For these compounds, changes in the δ^{119}Sn values follow closely the trends set by δ^{29}Si or δ^{207}Pb values for comparable silicon or lead compounds [8,9].

The facile change in the coordination number of tin, as a result of the pronounced Lewis-acidic character of many tin compounds can be seen by changes in ^{119}Sn nuclear shielding. Any increase in the coordination number of tin causes shifts of the ^{119}Sn resonances to lower frequencies, even if such interactions are weak (Figure 2). There is a wealth of ^{119}Sn NMR studies of compounds with Sn–O bonds, including cage structures, biologically active species, all in which the tin atoms can have quite different coordination numbers [10,11]. The most useful approach in this field is the combination of X-ray crystallography, solid-state ^{119}Sn NMR and solution-state ^{119}Sn NMR [12].

Many coupling constants $^{n}J(^{119}\mathrm{Sn}, \mathrm{X})$ are readily measured either from ^{119}Sn NMR spectra (Figures 3 and 4) or from X NMR spectra. These couplings provide important information on structure and dynamics of tin compounds [13]. Empirical correlations have been proposed in order to relate bond angles C–Sn–C with the magnitude of coupling constants $^{1}J(^{119}\mathrm{Sn}, ^{13}\mathrm{C})$ [14,15]. The measurement of isotope-induced chemical shifts, e.g. $^{n}\Delta^{12/13}\mathrm{C}(^{119}\mathrm{Sn})$ [6] is straightforward from many ^{119}Sn NMR spectra (Figure 4). Although these parameters are not well understood at present, they may become increasingly important, since they are sensitive to the nature of Sn-element bonds and the coordination sphere of the tin atom [12,16].

Paramagnetic Effects

^{1}H and ^{13}C High-Resolution Solid-State NMR of Paramagnetic Compounds Under Very Fast Magic Angle Spinning

Yoshitaka Ishii and Nalinda P. Wickramasinghe
Department of Chemistry, University of Illinois at Chicago, Chicago, IL 60607, USA

Introduction

More than one-third of the elements in the periodic table exhibit paramagnetism. Paramagnetic metal ions play a variety of significant roles in material science [1,2], bioinorganic chemistry [3–5], nanoscience [6–8], and pharmacology [9,10] as complexes with organic ligands. On the other hand, development of novel paramagnetic complexes has been often hindered by lack of efficient characterization methods, in particular, for non-crystalline solids. High-resolution solid-state NMR (SSNMR) using magic angle spinning (MAS) is a powerful technique for structural analysis of non-crystalline organic materials in solids [11–13]. However, the large dispersion of paramagnetic shifts and associated technical difficulties have impeded progress in high-resolution SSNMR studies of paramagnetic systems [14], which contrasts with recent tremendous advancement in SSNMR for diamagnetic systems including biomolecules [12,13,15–19]. ^{13}C and ^{1}H SSNMR have been the most widely used methods for organic solid materials. For paramagnetic systems, however, because of the large shift dispersion, insufficient ^{1}H or ^{1}H–^{1}H RF decoupling with the limited RF fields available in a conventional probe typically results in severe loss of resolution in ^{1}H and ^{13}C SSNMR spectra. Also, large paramagnetic shifts mask the diamagnetic shifts that are characteristic of chemical groups, making signal assignment difficult. Recent studies demonstrated that ^{2}D labeling eliminates the requirement of ^{1}H RF decoupling, and selective ^{13}C labeling offers resolution and reliable assignments in ^{13}C SSNMR for small paramagnetic systems [20–25]. On the other hand, isotope labeling is costly and often not justified for analysis of small compounds, resulting in applications of SSNMR to only a handful of paramagnetic systems. Moderate MAS around 10 kHz was reported to provide modest resolution in ^{1}H and ^{13}C SSNMR for unlabeled paramagnetic systems [22,26]. Although a path for SSNMR analysis of unlabeled paramagnetic systems has been opened by these studies, applicability of this approach is limited to systems having small ^{1}H–^{1}H dipolar couplings due to large ^{1}H shift dispersion or motions. Also, procedures for assignments in unlabeled paramagnetic systems have not been established. As a result, ^{13}C and ^{1}H SSNMR of paramagnetic systems have been largely unexplored.

Recently, our group demonstrated that a new approach using very fast MAS (VFMAS; spinning speed $\omega_R/2\pi >$ 20 kHz) permits excellent resolution/sensitivity and signal assignments in ^{13}C and ^{1}H SSNMR even for unlabeled systems [27,28]. Although MAS over 50 kHz is currently available [29], we define VFMAS as MAS at $\omega_R/2\pi > 20$ kHz because spinning over 20 kHz induces crucial changes in spin dynamics for organic solids by eliminating the majority of ^{1}H–^{1}H and ^{1}H–^{13}C dipolar couplings. As will be discussed, this change by VFMAS forms the foundation of our approach. This review outlines the principles and recent applications of this VFMAS approach for paramagnetic complexes.

One-Dimensional (1D) ^{1}H SSNMR for Paramagnetic Systems

Spinning Speed Dependence and Sensitivity of ^{1}H MAS NMR

Figure 1 shows spinning speed dependence of ^{1}H MAS NMR spectra of unlabeled Cu(II)(DL-Ala)$_2$·H$_2$O (a–c) and Mn(III)(acac)$_3$ (d–f). Clearly, VFMAS significantly improves the sensitivity and resolution. In Figure 1(c and f) at 5 kHz MAS, no signals are identified because of line broadening due to large ^{1}H–^{1}H couplings and ^{1}H anisotropic paramagnetic shifts. In contrast, under VFMAS, excellent sensitivity and resolution are displayed for Cu(DL-Ala)$_2$ at 24 kHz (a), demonstrating that VFMAS efficiently removes broadening due to ^{1}H–^{1}H dipolar couplings and ^{1}H paramagnetic shifts [28]. Although only weak signals for NH$_2$ are observed at −44 and −78 ppm, this is because the NH$_2$ protons are directly coordinated to Cu(II) and subject to significant anisotropic paramagnetic shifts [22]. As will be described below, the assignments were obtained by separate two-dimensional

Graham A. Webb (ed.), Modern Magnetic Resonance, 467–474.

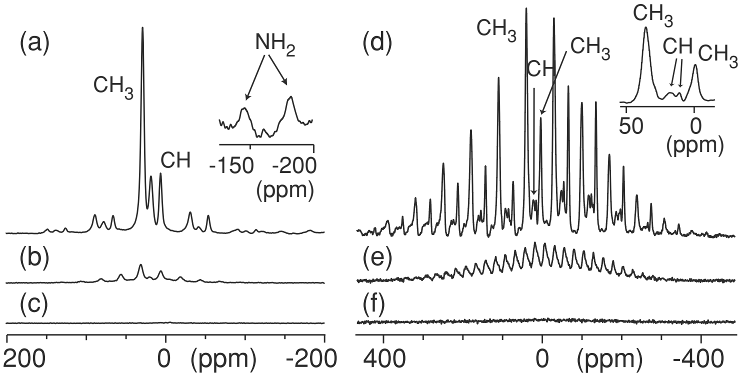

Fig. 1. ^{1}H MAS spectra of Cu(DL-Ala)$_2$·H$_2$O (a–c) and Mn(acac)$_3$ (d–f) at spinning speeds (a) 24 kHz, (b and e) 10 kHz, (c and f) 5 kHz, and (d) 27.8 kHz obtained at ^{1}H frequency of 400.2 MHz with 1-pulse excitation and a rotor synchronous echo (τ_R–π–τ_R). The two insets in (a) and (d) are the expanded regions of NH$_2$ signals in (a) and centerlines in (d). The sample amount was 17 (a–c) and 14 mg (d–f). Total experimental times were only 18 (a–c) and 12 ms (d–f) with four scans for each spectrum.

(2D) ^{13}C–^{1}H chemical shift correlation NMR under VFMAS except for NH$_2$, for which we adopted the assignment by Liu *et al.* using ^{2}D SSNMR [22]. For Mn(acac)$_3$, in spite of numerous sidebands remaining even under VFMAS at 27.8 kHz in Figure 1(d), the center peaks are well resolved, as shown in the inset. It is worth pointing out that anisotropic paramagnetic shifts are generally proportional to $(S+1)S/R_{IS}^3$, where S is an electron spin number, and R_{IS} is the distance between the nuclear spin I and the electron spin S at a paramagnetic center [14,26]. Because the spin numbers S for Mn(III) and Cu(II) are $5/2$ and $1/2$, respectively, it is reasonable that more sidebands were observed for Mn(acac)$_3$. The line widths in (a and d) are comparable to those for diamagnetic systems. Large dispersion of ^{1}H chemical shifts provides excellent resolution, which permits characterization using 1D ^{1}H SSNMR.

The other important feature of ^{1}H SSNMR for paramagnetic systems under VFMAS is its high sensitivity. For this reason, ^{1}H VFMAS is usually the first experiment we typically attempt for systems previously uncharacterized by SSNMR. Short ^{1}H T_1 values of paramagnetic compounds (~ms) allow us to acquire signals rapidly. Because of the excellent sensitivity of ^{1}H VFMAS SSNMR, the ^{1}H spectra in Figure 1(a and d) were obtained in total experimental times of only 18 and 12 ms, respectively.

There has been a popular conception that the sensitivity of SSNMR for paramagnetic systems is significantly lower than that for diamagnetic systems because of paramagnetic broadening. However, because the sensitivity in Figure 1(a and d) under VFMAS appears excellent, we theoretically reexamined this conception. Sensitivity of FT NMR with a matched window function is generally given by [30]

$$\xi = \langle s(t)^2 \rangle^{1/2} (t_{\max}/T)^{1/2} / \rho_N, \qquad (1)$$

where $s(t)$ is an envelope function of an FID, $t_{\max}$ is an acquisition period of a FID, T is a recycle time or an interval between two scans, ρ_N is the r.m.s. noise amplitude in a unit bandwidth. The factor $\langle s^2 \rangle$ is the average signal power. For simplicity, we assumed that $s(t)$ is given by an exponential decay, as $s(t) = \exp(-t/T_2)$. When $t_{\max}$ is matched to T_2, as $t_{\max} = cT_2$ for a given constant c, $\langle s^2 \rangle$ is independent of T_2. Thus, the sensitivity, ξ, depends only on the receiver duty factor ($t_{\max}/T$). In SSNMR experiments, T is usually adjusted to $3T_1$, and hence, $t_{\max}/T = (c/3)T_2/T_1$. For ^{1}H SSNMR of diamagnetic systems, $t_{\max}/T$ is only about 0.03–0.1% ($t_{\max} \sim$ 1 ms and $T \sim$1–3 s). On the other hand, for paramagnetic systems, $t_{\max}/T$ is as large as 10–30% ($t_{\max} \sim$ 0.5–1 ms and $T \sim$ 3–5 ms) because of enhanced resolution by VFMAS and short T_1 values. Hence, when sidebands are sufficiently suppressed by VFMAS, the theoretical sensitivity of ^{1}H SSNMR for paramagnetic systems is greater than that for diamagnetic systems by a factor of 10–30 with VFMAS.

Microanalysis by ^{1}H SSNMR

This exceptional sensitivity can be utilized in a form of ^{1}H SSNMR microanalysis of unlabeled paramagnetic systems. We applied this ^{1}H VFMAS method to two crystal forms of polycrystalline Cu(II)(8-quinolinol)$_2$ [CuQ$_2$] in order to examine whether polymorphs of paramagnetic drugs or materials can be distinguished in a nanomole scale by ^{1}H SSNMR. CuQ$_2$ is an apoptosis inducer in human leukemia cells [31], and its β-form is known to be thermally more stable [32]. Figure 2 shows the ^{1}H VFMAS spectra of 20 nmol of (a) α- form and (b) β-form CuQ$_2$. The sensitivity is excellent after only 10 min of signal accumulation. Clearly, these spectra are distinguishable on the basis of the line positions and line widths even without signal assignment. Considering the fact that ^{1}H SSNMR rarely displays sufficient resolution to distinguish polymorphs for diamagnetic systems and

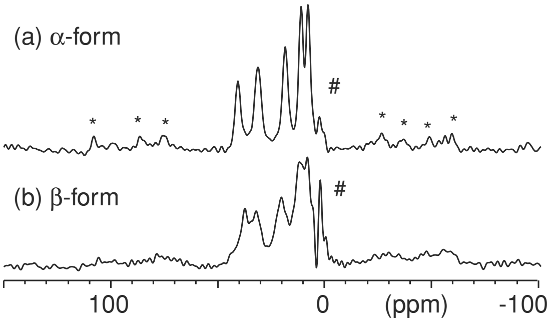

Fig. 2. ^{1}H MAS spectra of (a) α-form and (b) β-form of Cu(II)(8-quinolinol)$_2$ obtained at ^{1}H frequency of 400.2 MHz with 1-pulse excitation at $\omega_R/2\pi = 27.03$ kHz. Only 20 nmol (7 μg) of the sample was used for each spectrum. A total of (a) 36,560 and (b) 98,304 scans were recorded with recycle delays of (a) 15 ms and (b) 5 ms. The total experimental time was 10 min each. Background signals were suppressed by subtracting a spectrum obtained for a rotor without the sample. Residual background signals and spinning sidebands are marked by # and *, respectively.

that various small paramagnetic metal complexes function as drugs [10,31,33] and materials [8,34], the present data suggest unique possibility of distinguishing molecular packing or supramolecular structures for paramagnetic complexes by ^{1}H SSNMR. As will be discussed, the high resolution in ^{1}H SSNMR attained by VFMAS can be combined with 2D NMR with suitable polarization transfer methods.

1D ^{13}C VFMAS SSNMR for Paramagnetic Systems

Spinning Speed Dependence of ^{13}C MAS Spectra

Figure 3(a–c) shows the spinning speed dependence of the ^{13}C MAS SSNMR spectra of unlabeled Cu(DL-Ala)$_2$ obtained with high-power CW ^{1}H RF decoupling (100 kHz). In Figure 3(a), at $\omega_R/2\pi = 5$ kHz, only one peak that corresponds to CH$_3$ can be identified. In contrast, Figure 3(c) at $\omega_R/2\pi = 24$ kHz clearly displays three peaks for CH$_3$ (172 ppm), CO (−191 ppm), and CH (−276 ppm) groups in Cu(DL-Ala)$_2$ with improved resolution and sensitivity. Figure 3(d) shows the ^{13}C VFMAS spectrum at $\omega_R/2\pi = 24$ kHz without ^{1}H RF decoupling. The resolution in (d) is superior to that in (c), in particular, for the CH signal. This is well explained by the fact that VFMAS effectively removes ^{1}H–^{13}C dipolar coupling regardless of ^{1}H resonance offsets and anisotropic shifts due to large paramagnetic shifts, while the efficiency of ^{1}H RF decoupling is strongly affected by these parameters.

Sensitivity Enhancement by Cross-Polarization

Polarization transfer by cross-polarization (CP), one of the vital techniques in ^{13}C SSNMR, has been ineffective for most paramagnetic systems because of large paramagnetic shift dispersion. In a few successful cases, including the initial high-resolution ^{13}C SSNMR for paramagnetic systems by Bryant and coworkers [35], signals within a limited bandwidth (∼200 ppm) were observed at lower field (^{1}H frequency ∼200 MHz) [23,35,36]. For systems having larger paramagnetic shift dispersion, CP transfer efficiency is suppressed because large resonance offsets cause deviations from the Hartmann–Hahn condition with the limited RF intensities that are available in a conventional MAS probe.

We recently demonstrated that further sensitivity enhancement in ^{13}C SSNMR spectra for paramagnetic systems can be obtained using polarization transfer from ^{1}H spins with the strong RF fields available in VFMAS probes [27]. Figure 3(e) shows the ^{13}C CP-VFMAS spectrum of Cu(DL-Ala)$_2$ obtained with high-power ramped CP. Because of short ^{1}H T_1 values, it is possible to acquire a larger number of scans within a given experiment time. Clearly, the sensitivity was significantly enhanced in Figure 3(e), compared with (d). The sensitivity enhancement factors in Figure 3(e) are 2.2–3.6 and 1.2, compared with the spectra in Figure 3(d) for protonated and non-protonated ^{13}C signals, respectively. Compared with the spectrum in (b) under moderate MAS at 10 kHz, which was utilized in previous ^{13}C SSNMR studies for paramagnetic systems [22], the enhancement factors are 4–5. As a result, the excellent sensitivity and resolution in Figure 3(e) was obtained in only 1 min. We will discuss signal assignment of the spectrum in a later section.

It has long been a problem for synthetic chemists that solution NMR of small paramagnetic systems is often subject to severe paramagnetic broadening because of a long electron spin relaxation time for isolated paramagnetic molecules in solution [37]. Since excellent sensitivity was identified in the above ^{13}C SSNMR spectra under VFMAS, we compared the sensitivity between SSNMR and solution NMR in order to examine the potential of ^{13}C SSNMR for analysis of paramagnetic systems as an alternative to ^{13}C solution NMR. Figure 3(f) shows preliminary results of ^{13}C solution NMR spectra of saturated Cu(DL-Ala)$_2$ in D$_2$O. To compensate for the low solubility of this sample (3.8 mg in 0.7 ml D$_2$O), we acquired the signal for 3 h (102,400 scans) rather than 1 min. Apparently, no signals were identified in (f). Although further studies are needed to examine applicability of SSNMR to other paramagnetic systems, it is encouraging that ^{13}C high-resolution SSNMR spectra were obtained for the sample, for which solution NMR is not effective.

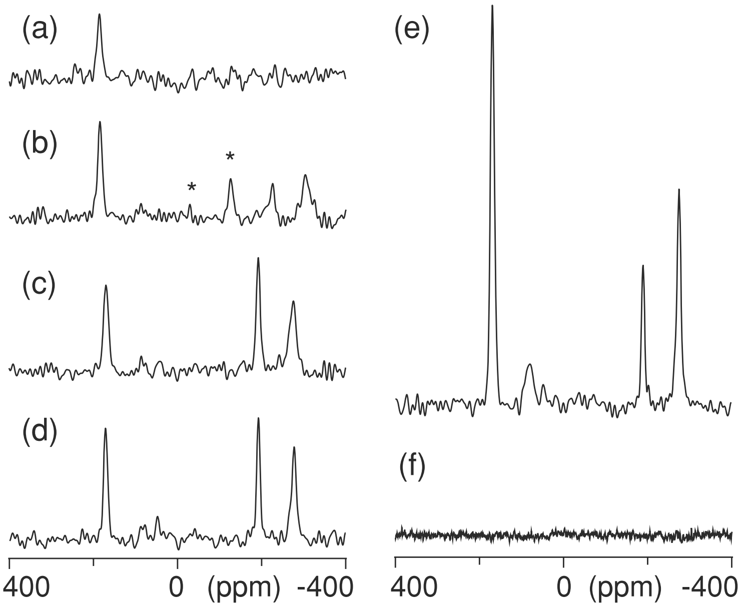

Fig. 3. ^{13}C MAS spectra of Cu(DL-Ala)$_2$·H$_2$O obtained with (a–d) 1-pulse excitation, and (e) adiabatic-CP, together with (f) ^{13}C solution NMR spectra of a saturated Cu(DL-Ala)$_2$ solution in D$_2$O. ^{13}C NMR frequency was 100.6 MHz for all the spectra. The spectra in (a–c) were acquired at $\omega_R/2\pi$ of (a) 5 kHz, (b) 10 kHz, and (c) 24 kHz with ^{1}H CW RF decoupling (100 kHz) with a recycle delay (τ_d) of 0.1 s. The spectra in (d and e) were acquired without ^{1}H RF decoupling and with τ_d of 0.1 s, and 50 ms, respectively; (f) was obtained by 1-pulse excitation with WALZ 64 decoupling. For each of spectra (a–e), an experimental time was 1 min with (a–d) 614, and (e) 1200 scans, while in (f) an experimental time was 3 h with 102,400 scans. The spectrum in (e) is scaled so that the spectra (a–e) display a common noise level in the figure. τ_d for (a–d) was matched to three times of ^{13}C T_1 values. τ_d in (e) was restricted by an RF duty factor (1%) to prevent a probe arcing. The ^{13}C pulse widths for $\pi/2$ and π pulses were 2.5 and 5.0 μs, respectively. In the CP experiment, the ^{13}C RF field was swept from 107.5 to 124.5 kHz during a contact time of 0.5 ms, while the ^{1}H RF field was kept constant at 92 kHz. The spinning sidebands are indicated by * in the spectra. The sample amount for (a–e) was 15 mg. For (f), 3.8 mg of the sample was dissolved in 0.7 ml D$_2$O.

^{1}H Decoupling Dependence of ^{13}C VFMAS Spectra

In Figure 4, we show ^{1}H decoupling dependence of ^{13}C MAS spectra of Cu(DL-Ala)$_2$ (a–d) and Mn(acac)$_3$ (e–h). The spectra were obtained with (a and e) no ^{1}H RF decoupling (decoupling by VFMAS), (b and f) ^{1}H high-power CW decoupling, (c and g) ^{1}H TPPM decoupling, and (d and h) XY-8 π-pulse train decoupling [38], with a common number of scans for each sample. For Cu(DL-Ala)$_2$, the spectrum obtained with no RF decoupling in (a) displays the resolution higher than that obtained with TPPM or CW RF decoupling. This is because majority of ^{1}H–^{13}C dipolar couplings are removed by VFMAS over 20 kHz. We also tested π-pulse train decoupling, which was successfully applied to ^{19}F decoupling [38]. In the π-pulse train, one π-pulse was rotor synchronously applied in one rotation cycle in order to avoid interference between the RF decoupling and the averaging of ^{13}C–^{1}H dipolar coupling by VFMAS. Our result in (d) shows the π-pulse train decoupling does not enhance sensitivity compared with no decoupling in (a). For Mn(acac)$_3$ in Figure 4(e–h), CW or TPPM decoupling sequences caused loss of signal or substantially reduced resolution. As already discussed, ^{1}H anisotropic shifts for this system reach 700 ppm ($\pm$140 kHz in ^{1}H 400 MHz); hence, it is reasonable that ^{1}H RF decoupling is ineffective. In contrast, with no RF decoupling in (e) or with a π-pulse train in (h), well-resolved signals were identified, although sidebands were not completely suppressed. It is also noteworthy that CW and TPPM decoupling substantially increases the RF duty factor and limits the maximum repetition rate. In contrast, dropping RF decoupling permits fast repetition for samples having short ^{13}C T_1 such as Mn(acac)$_3$.

As recently reported by Ernst [39], average Hamiltonian analysis for an isolated I–K two spin system

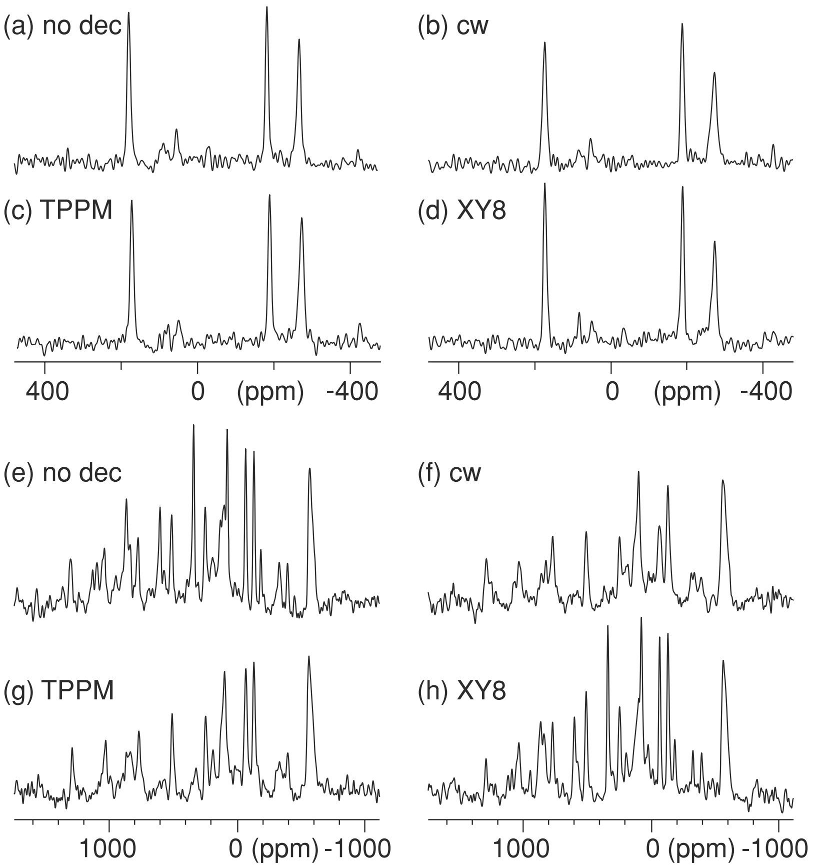

Fig. 4. ^{1}H decoupling dependence of ^{13}C VFMAS spectra of (a–d) Cu(DL-Ala)$_2$·H$_2$O and (e–h) Mn(acac)$_3$ at ^{13}C NMR frequency of 100.6 MHz. The spectra were obtained by 1-pulse excitation with (a, e) no ^{1}H RF decoupling, (b and f) CW, (c and g) TPPM, and (d and h) XY-8 π-pulse train ^{1}H decoupling. The spinning speed in (a–d) and (e–h) was set to 24.00 and 26.31 kHz, respectively. The spectra for each sample are displayed in a common scale. In CW or TPPM decoupling, a ^{1}H RF field of 100 kHz was applied. In XY-8 decoupling, an XY-8 π-pulse train of a (d) 5-μs or (h) 3.4-μs pulse width was rotor synchronously applied with a π-pulse per rotation cycle. For Cu(DL-Ala)$_2$, each spectra were recorded with common numbers of scans (1024 scans), recycle delays (τ_{d}) of 0.1 s, and total experimental times of 1.8 min. For Mn(acac)$_3$, the experimental times after 40,960 scans were (e, h) 11 and (f, g) 31 min with τ_{d} of (e, h) 15 or (f, g) 45 ms. The sample amount was (a–d) 15 and (e–h) 13.5 mg.

($I = {}^{1}$H and $K = {}^{13}$C) shows that the second-order cross term between ^{1}H–^{13}C dipolar coupling and ^{1}H anisotropic shifts under high-power ^{1}H CW RF decoupling is given by

$$H_{\text{CS-D}}^{(2)} = \sum_{\substack{m=-2 \\ m\neq 0}}^{2} \frac{\omega_{IK}(-m)\omega_{I}(m)}{\omega_1} 2I_y K_Z, \qquad (2)$$

where we assumed that the nutation frequency due to ^{1}H RF decoupling, $\omega_1/2\pi$, is much larger than the spinning frequency, $\omega_{\text{R}}/2\pi$ ($\omega_1 \gg \omega_{\text{R}}$). In Equation (2), $\omega_{\text{IK}}(n)$ and $\omega_I(n)$ are Fourier coefficients for the frequency of $n\omega_{\text{R}}/2\pi$ in time-dependent heteronuclear dipolar coupling and anisotropic shift for the I spin, respectively. When $\omega_I(m)$ due to the paramagnetic anisotropic shift is comparable to ω_1, $|H_{\text{CS-D}}^{(2)}|$ becomes comparable to $|\omega_{\text{IK}}(-m)|$, where $|H_{\text{CS-D}}^{(2)}|$ denotes the norm of $H_{\text{CS-D}}^{(2)}$. Hence, ^{1}H RF decoupling *reintroduces* ^{1}H–^{13}C dipolar couplings for systems having large anisotropic shift, rather than removes the couplings, as shown in Figure 4 (f and g). On the other hand, VFMAS eliminates all the higher order terms for the isolated I–K two-spin system, regardless of anisotropic shifts or resonance offsets. Therefore, we conclude that eliminating ^{1}H RF decoupling is the best option for small paramagnetic systems at this point. If ^{1}H–^{13}C J couplings need to be removed, an XY-8 π-pulse train is an alternative.

Signal Assignments and Multi-dimensional NMR

1D Assignment Method

Signal assignments in SSNMR spectra of paramagnetic systems are often problematic because large paramagnetic shifts mask diamagnetic shifts, which are used to assign signals to specific chemical groups. To address this issue, we recently proposed a signal editing method for paramagnetic systems based on ^{13}C–^{1}H dipolar recoupling using ^{1}H–^{13}C REDOR pulse sequence shown in Figure 5(a). With the two ^{1}H π pulses (filled squares), this sequence reintroduces ^{13}C–^{1}H dipolar couplings, selectively dephasing protonated ^{13}C signals; on the other hand, without these π pulses the sequence functions as a simple rotor synchronous echo sequence. In a control experiment for L-valine, we observed $S/S_0 = 90$, 47, and 8% for CO_2^-, CH_3, and CH, respectively, where S and S_0 denote the signal intensities obtained with and without the ^{1}H π pulses, respectively. It is reasonable that dephasing for a CH_3 group is less than that for a CH group because CH_3 rotation along the symmetry axis partially truncates ^{13}C–^{1}H dipolar couplings. Figure 5(b and c) shows ^{13}C spectra of Cu(DL-Ala)$_2$ obtained (b) without and (c) with ^{1}H π pulses using the pulse sequence shown in (a). $S/S_0 = 52$, 83, and 12% for the peaks at 173, −183, and −269 ppm, respectively. The assignment based on this result is indicated in Figure 5(b); this assignment agreed well with that by Liu *et al.* using selective ^{13}C and ^{2}D labeling [22]. Compared with the previous assignment methods using selectively labeled samples, signal editing using dipolar recoupling under VFMAS provides reliable signal assignments for small amounts of unlabeled samples.

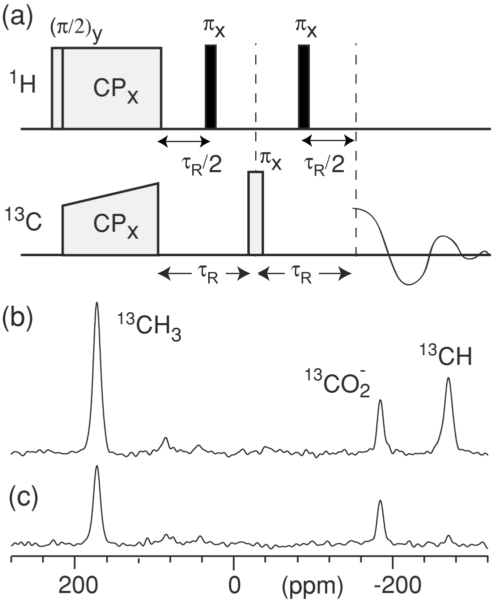

Fig. 5. (a) A ^{1}H–^{13}C REDOR pulse sequence for ^{13}C–^{1}H dipolar filter signal editing. When the two ^{1}H π pulses (filled boxes) are applied, ^{13}C–^{1}H dipolar couplings are restored under VFMAS. ^{13}C CPMAS spectra of Cu(DL-Ala)$_2\cdot$(H$_2$O) obtained (b) without and (c) with ^{13}C–^{1}H dipolar dephasing using the pulse sequence in (a) at $\omega_R/2\pi = 22.989$ kHz ($\tau_R = 43.5$ µs). ^{1}H and ^{13}C π-pulse widths were set to 5 µs.

Assignment by 2D ^{13}C–^{1}H Heteronuclear Correlation NMR

2D chemical shift correlation SSNMR has been useful for characterization of materials and biomolecules [12,30]. However, applications of this fundamental technique to paramagnetic compounds have been limited to ^{13}C-labeled materials even for small molecules because of limited sensitivity and difficulty in broadband polarization transfer. The VFMAS approach efficiently removes ^{1}H–^{1}H and ^{1}H–^{13}C dipolar couplings, permitting high-resolution ^{1}H and ^{13}C SSNMR for paramagnetic complexes. Hence, with efficient broadband CP under VFMAS, it is possible to correlate high-resolution ^{13}C and ^{1}H SSNMR for unlabeled paramagnetic compounds in 2D ^{13}C–^{1}H correlation SSNMR.

Figure 6(a) and (b) shows 1D ^{13}C CPMAS and 2D ^{13}C–^{1}H chemical shift correlation SSNMR spectra of V(III)(acac)$_3$,(acac =CH_3–CO–CH–CO–CH_3), respectively. In (B), six lines and three lines, which are overlapping in the 1D spectrum in (A), are resolved around ^{13}C shifts of −180 and 100 ppm. With ^{13}C–^{1}H dipolar dephasing, the six lines and the three lines were assigned to CH_3 and CH groups, respectively [27]. Based on this result, we concluded that it is most likely that V(acac)$_3$ has three magnetically non-equivalent ligands because of distortion away from the symmetry of the isolated molecule and the signals for CO are broadened out by strong hyperfine couplings. The result agrees well with recent high-resolution X-ray crystallography data, in which non-equivalence of the three ligand molecules was identified [40]. The 2D spectrum in Figure 6 also provides the assignments in ^{1}H SSNMR.

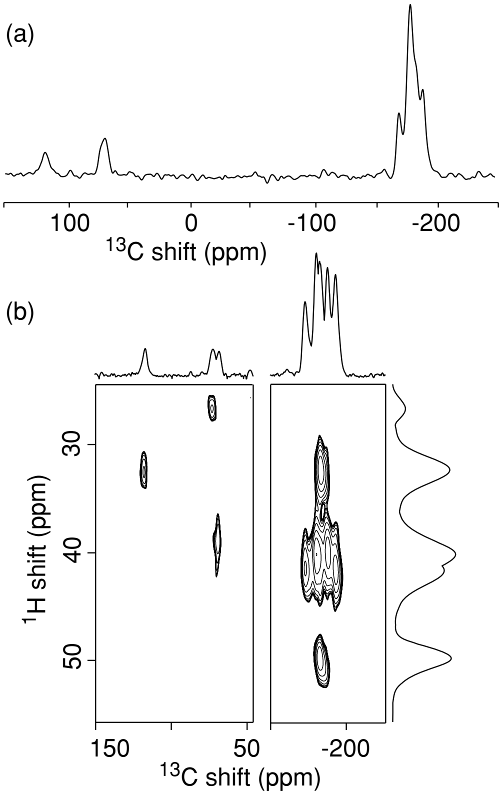

Fig. 6. (a) 1D ^{13}C CP-VFMAS and (b) 2D ^{13}C–^{1}H correlation VFMAS NMR spectra of V(III)(acac)$_3$ obtained with ramped CP with a contact time of 0.5 ms, together with 1D skyline projections in (b). The spinning speed is 22.99 kHz. In the ramped CP, the ^{13}C RF field was swept from 74 to 82 kHz, while ^{1}H RF field was kept constant at 101 kHz. The recycle delay was 0.1 s after each 2 ms of signal acquisition. In (a), only 1024 scans were collected within a total experimental time of 1.8 min. In (b), 25 t_1 complex points were recorded with t_1 increments of 43.5 μs and total of 1536 scans were collected for the real or imaginary components of each t_1 point. The total 2D experimental time was 2.2 h.

Experimental Aspects

All the SSNMR data were recorded at 9.4 T with a Varian Infinityplus 400 spectrometer equipped with a Varian T3 3.2-mm MAS double-resonance probe and a home-built 2.5-mm MAS double-resonance probe. All the SSNMR spectra obtained by 1-pulse excitation or CP were acquired with a rotor synchronous echo sequence prior to signal acquisition. Since the spectral width of the paramagnetic complexes is large (up to 200 kHz at 9.4 T), it is difficult to obtain a flat baseline without the echo sequence. To minimize receiver dead times, short sampling intervals (2–5 μs) were employed. After phase corrections, the baselines were corrected by the built-in polynomial correction function at Varian Spinsight software. It is well known that paramagnetic isotropic shifts have a $1/T$ dependence (Curie's law). Because of this, severe line broadening can be induced by the temperature distribution over a sample heated by fast spinning. To suppress the broadening, cooling air (-10 to 23 °C) was used at the flow rate of 140–160 (ft)^2/h using a Varian VT stack. A profile of the temperature distribution can be easily characterized by observing the ^{207}Pb NMR line shape of Pb(NO$_3$)$_2$ under spinning [41].

Conclusion

We presented a set of novel fundamental techniques to achieve significant sensitivity and resolution enhancement as well as signal assignments using VFMAS in 1D and 2D ^{1}H and ^{13}C SSNMR for paramagnetic complexes. The presented results in the VFMAS approach offers possibilities of analyzing a variety of unlabeled paramagnetic systems by ^{1}H and ^{13}C high-resolution SSNMR for limited sample volumes in a simple experimental setting. We also demonstrated applications of recoupling techniques on paramagnetic systems, which had not been previously attempted. Structural analysis of paramagnetic systems using the recoupling techniques will be discussed elsewhere.

Paramagnetic Effects of Dioxygen in Solution NMR—Studies of Membrane Immersion Depth, Protein Topology, and Protein Interactions

R.S. Prosser and F. Evanics
Department of Chemistry, University of Toronto, North Mississauga, ON, Canada L5L 1C6

Abstract

Oxygen offers several advantages as a paramagnetic reagent. Picosecond electron spin–lattice relaxation times, the absence of charge, and a rapid diffusion rate in water and membrane interiors, mean that oxygen is both an effective paramagnetic shift reagent (^{19}F or ^{13}C NMR applications) or spin–lattice relaxation agent (applications involving high gamma nuclei, such as ^{19}F and ^{1}H). Moreover, oxygen is well known to possess a marked solubility gradient along the immersion depth axis in lipid bilayers and detergent micelle systems. The consequent paramagnetic gradients (both in terms of spin–lattice relaxation rates and contact shifts) can be used to discern immersion depth of membrane additives (membrane peptides, drugs, or lipids). In studies of transmembrane α-helical and β-strand proteins, oxygen paramagnetic effects are used to discern information on protein topology. Applications involving studies of water-soluble proteins are also reviewed. Oxygen permeation in heme proteins, local preferences for oxygen on protein surfaces, or binding interfaces in protein–protein complexes may be uniquely studied using either chemical shift perturbations or spin–lattice relaxation rate enhancements.

Introduction

Conventional wisdom has long argued against the use of oxygen in most NMR applications. Even at ambient concentrations, oxygen is known to degrade long-range NOEs and contribute to line broadening, thereby masking weak scalar couplings. However, there are instances where oxygen provides unique opportunities, particularly in the study of membranes, membrane proteins, and protein interactions. This chapter highlights some of the recent applications involving oxygen in NMR. We will begin with a brief description of the salient equations for spin–lattice relaxation enhancement and chemical shift perturbations, associated with a freely diffusing paramagnet such as oxygen. The intention in the examples which follow is to convey to the reader the wide variety of applications and where possible, prospects for future studies.

Spin–Lattice Relaxation

Paramagnetic interactions may be manifested in terms of line broadening, enhancement of spin–lattice relaxation, or chemical shift perturbations. Oxygen electronic spin–lattice relaxation times, $T_{1\mathrm{e}}$, are relatively short for paramagnetic species [1]. This has two consequences. Firstly, other correlation times such as oxygen diffusion, or intra- and intermolecular reorientations, which might be expected to modulate the paramagnetic dipolar interaction, are longer than $T_{1\mathrm{e}}$, and thus less relaxation-effective. Secondly, oxygen is a relatively weak paramagnetic relaxation agent. Consequently, oxygen concentrations can frequently be found where line broadening effects are weak, relative to the natural line widths, while spin–lattice relaxation enhancements are relatively large, at least in the macromolecular limit where $T_1 \gg T_2$.

For a purely dipolar interaction between a nuclear spin, I, and a paramagnetic spin, S, the relaxation rate may be described by the classic equation [2, 3]

$$R_1^{\mathrm{P}} = \frac{2}{15}\gamma_I^2\gamma_S^2\hbar^2 S(S+1)\{J_0(\omega_S-\omega_I) + 3J_1(\omega_I) + 6J_2(\omega_I+\omega_S)\}\,. \quad (1)$$

For a freely diffusing paramagnet such as oxygen, the dipolar interaction is modulated principally by translational diffusion and by fast electronic spin relaxation. Consequently, the classic dipolar relaxation equations [4] do not apply, nor are the above spectral density functions necessarily Lorentzian. The problem of a freely diffusing paramagnet, with electronic relaxation times, T_1^S and T_2^S, has been previously treated [3] wherein the spectral

Graham A. Webb (ed.), Modern Magnetic Resonance, 475–483.
© 2008 *Springer.*

density function is described by

$$J_k(\omega) = \frac{8}{27}\frac{N_{\mathrm{A}}[\mathrm{O}_2]}{bD} \times \mathrm{Re}\left\{\left[1+\frac{1}{4}\left(\frac{i\omega\tau+\tau}{T_k^S}\right)^{1/2}\right] \Bigg/ \left[1+\left(\frac{i\omega\tau+\tau}{T_k^S}\right)^{1/2}+\frac{4}{9}\left(\frac{i\omega\tau+\tau}{T_k^S}\right) + \frac{1}{9}\left(\frac{i\omega\tau+\tau}{T_k^S}\right)^{3/2}\right]\right\} \quad k=1,2 \tag{2}$$

where b represents the distance of closest approach for the oxygen species to the nucleus of interest and D signifies the sum of the diffusion constants of both species. Finally, τ is defined by $\tau = b^2/D$ and in the extreme narrowing limit, the spectral density function simplifies to [3,5]

$$J_k(\omega) \approx J(0) = \frac{2}{3}\frac{N_{\mathrm{A}}[\mathrm{O}_2]}{b^3} T_k^S. \tag{3}$$

Teng and Bryant have attempted to employ the above theory to the case of protein surfaces, by introducing a geometric parameter which includes both a steric term accounting for relative oxygen accessibility and a soft potential term accounting for changes in local concentrations of the paramagnet, near the nucleus of interest [6]. Their analysis of ^{1}H paramagnetic rates in ribonuclease A suggest that there is a significant range of local free energies of interaction between oxygen and protein surface residues. In particular, disordered hydrophobic pockets exhibit increased associative interactions with oxygen. Thus, although the expressions for dipolar relaxation from a diffusible paramagnet are well described for both small molecules and proteins, the presence of preferential interactions of oxygen with specific regions of a macromolecule complicates the analysis of spin–lattice relaxation enhancement by oxygen, for purposes of structure refinement.

Chemical Shift Perturbations

Chemical shift perturbations from a diffusible paramagnet have been reported on several occasions [7,8]. Prosser and Luchette [9] have examined the temperature dependence of oxygen-induced chemical shift perturbations in a ^{19}F-labeled probe immersed in methanol. After accounting for differences in oxygen solubility by simultaneously measuring spin–lattice relaxation enhancement, chemical shift perturbations were observed to be inversely dependent on temperature. The authors concluded that in situations where oxygen was freely diffusing, chemical shift perturbations were of a contact origin. Contact shifts from diffusible paramagnets are rarely used for structure refinement [10–12]. For our purposes, we propose that the chemical shift perturbation should depend on the local oxygen concentration at the nucleus of interest, $[\mathrm{O}_2]$, in addition to the collisonally accessible surface area, A_{solvent}. Therefore, we express the chemical shift perturbation, $\Delta\sigma$, as

$$\Delta\sigma = kA_{\mathrm{solvent}}\,\alpha[\mathrm{O}_2] \tag{4}$$

where k is a proportionality constant, and α reflects the relative propensity of a given nucleus to experience unpaired spin density from a diffusible paramagnet. Contact shifts as large as 0.7 ppm are easily observed on ^{13}C nuclei in ^{1}H,^{13}C HSQCs of water soluble proteins and protein complexes, after equilibration of the protein at an oxygen partial pressure of 20 Atm. Furthermore, differences in α can be estimated by examining the chemical shift perturbations of the free amino acids, under conditions of constant oxygen concentrations. However, the main obstacle to obtaining A_{solvent} is oxygen preferentially concentrates in areas of local disorder or in hydrophobic pockets, rendering $[\mathrm{O}_2]$ a variable [13,14]. Though it should be possible to independently determine $[\mathrm{O}_2]$ from spin-lattice relaxation enhancements of ^{1}H nuclei, the potential of contact shifts for quantitative measure of solvent accessible surface area has yet to be demonstrated.

Contact shifts have also provided insight into the phenomenon of oxygen permeability in membranes. Using a so-called isotropic bicelle medium, it is possible to obtain well-resolved ^{13}C NMR spectra of the resident lipids in their bilayered state (*vide infra*) such that nearly every ^{13}C nucleus can be resolved and assigned. Contact shifts can then be routinely measured by acquiring spectra equilibrated under oxygen at 30 atm. Much is known of the oxygen solubility–diffusion product in lipid bilayers, from ESR studies [15–18] and computational studies of oxygen in lipid bilayers [19]. NMR clearly offers the advantage of studying such gradients, with near atomic resolution and without the use of a bulky probe.

Immersion Depth

Figure 1 displays both contact shifts and spin–lattice relaxation rates as a function of carbon number for a semi-perfluorinated probe molecule immersed in a lipid bilayer, and equilibrated to an oxygen partial pressure, P_{O_2}, of 100 atm. Figure 2 displays ^{13}C NMR contact shifts associated with resolvable nuclei of the phospholipid, *sn*-2 perdeutero,1-myristelaidoyl,2-myristoyl-*sn*-glycero-3-phosphocholine (MLMPC-d$_{27}$), in a lipid bilayer, at an oxygen partial pressure of 20 atm [20]. The optimal pressure is a function of line broadening, chemical shift dispersion, and natural line widths. In both cases, the

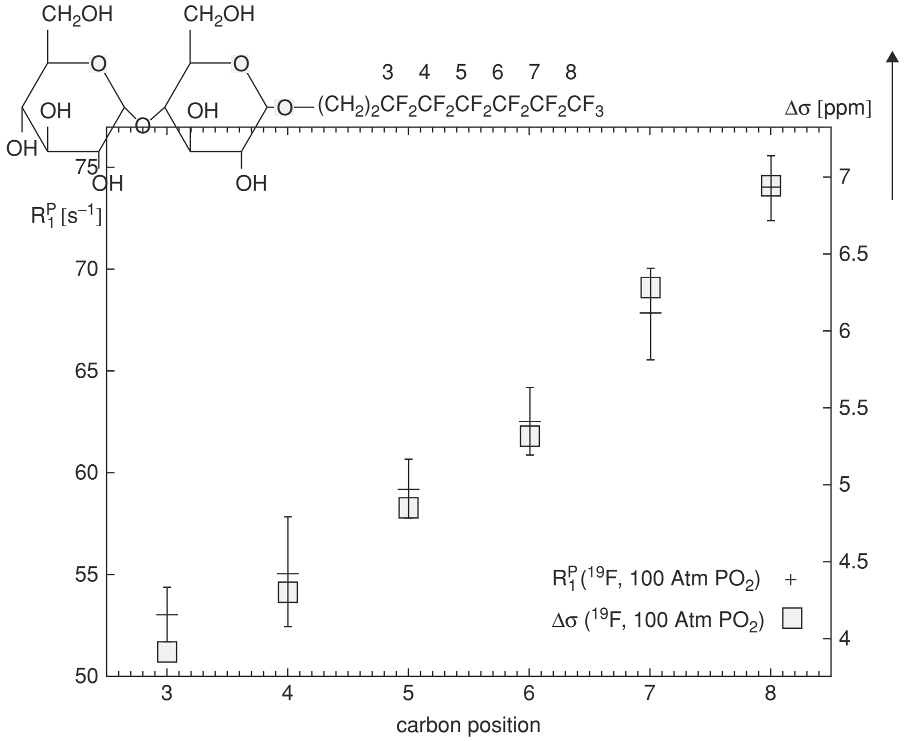

Fig. 1. Paramagnetic spin–lattice relaxation rate profile, R_1^{P} (crosses), and oxygen-induced chemical shift perturbations, $\Delta\sigma$ (open squares), as a function of carbon position for ^{19}F nuclei in TFOM, incorporated in a lipid bilayer membrane model system. Spectra were acquired using a 500 MHz Varian Inova spectrometer and an oxygen partial pressure of 100 atm PO_2. An equimolar mixture of DMPC and DHPC was prepared to provide the TFOM with a bilayer model, appropriate for study by solution NMR [39, 40].

results are dramatic and clearly sensitive to immersion depth, with Angstrom resolution. It should be noted that a significant gradient of chemical shift perturbations is observed despite the fact that the semi-perfluorinated detergent, and in particular the lipid, undergo significant undulations and chain isomerizations. Therefore, the "true" oxygen solubility profile must be significant in lipid bilayers.

The potential of oxygen as a paramagnetic agent for the determination of immersion depth can be further illustrated in Figure 3, which reveals chemical shift changes upon transfer of each of three small drug compounds (imipramine, nicotine, and caffeine) to the lipid bilayer (bicelle) [21]. Chemical shift changes for resolvable nuclei in Figure 3A, are indicated graphically as spheres whose radii are proportional to the magnitude of change. The upfield chemical shifts exhibited by regions of imipramine and nicotine, arise essentially from the transfer of nuclei from water to the non-polar membrane interior. Caffeine, which is essentially water soluble and does not interact with the membrane, exhibits slight downfield shifts, possibly because of a weak interaction with the phospholipid headgroups. Figure 3B reveals the relative paramagnetic spin–lattice relaxation rates obtained after equilibration at an oxygen partial pressure of 20 atm. It is instructive to compare our observations of partitioning to estimations of octanol/water partition coefficients and molecular polar surface areas. Imipramine, nicotine, and caffeine were predicted to have octanol/water partition coefficients (expressed as log P) of 3.43, 0.981, and −0.928, respectively, while molecular polar surface areas are estimated to be 6.476, 24.9, and 94.4, respectively. Based on the partition coefficients, we predict that imipramine is nearly entirely bound to the membrane, while more than 90% of the nicotine partitions into the membrane and is expected to be in fast exchange with the aqueous phase, since we can identify a single (averaged) spectral component of nicotine. In contrast, we expect that 90% of the caffeine partitions into the aqueous phase and is also likely in fast exchange with the surface of the membrane, based

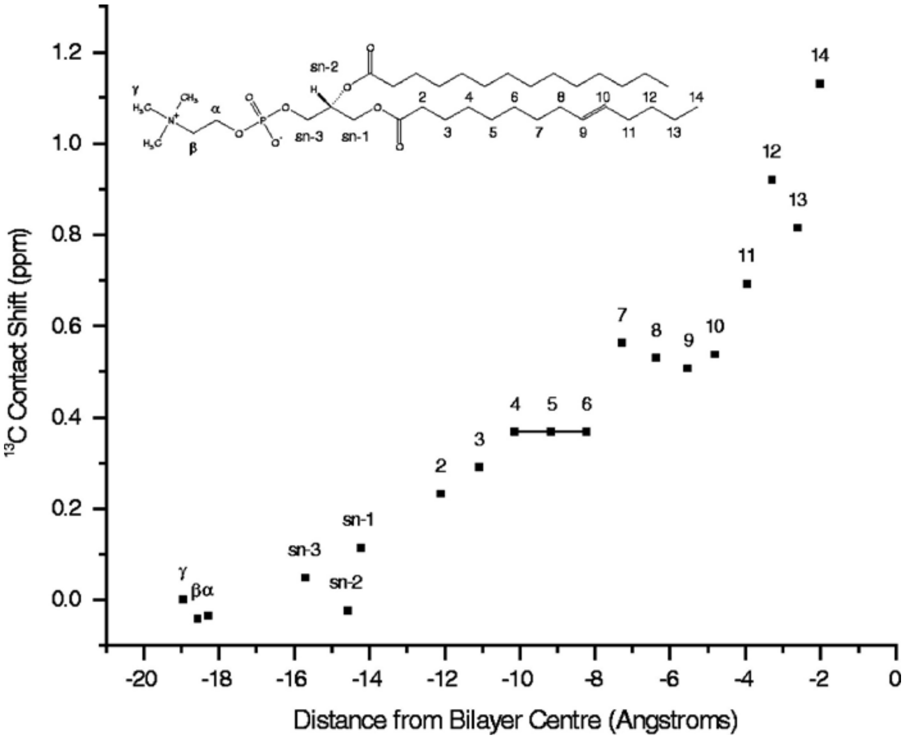

Fig. 2. Oxygen-induced chemical shift perturbations, $\Delta\sigma$, as a function of carbon position for ^{13}C nuclei of the phospholipid, 1-myristelaidoyl,2-perdeutero-myristoyl-*sn*-glycero-3-phosphocholine (MLMPC-d_{27}), in a lipid bilayer. The spectrum was acquired using a 600 MHz Varian Inova and an oxygen partial pressure of 20 atm. The lipid was mixed with DHPC such that the long- to short-chain lipid ratio was either 0.8.

on the absence of two spectral components. The paramagnetic relaxation rate profiles of each of the two membrane bound species, complements the partition coefficient data by giving an indication of the effective immersion depth, with atomic resolution.

Membrane Protein Topology

Paramagnetic reagents have long been recognized as a useful tool in the study of membrane proteins by ESR [22–25] and solution NMR spectroscopy [10, 12, 26]. An appropriate water-soluble paramagnetic reagent, which preferentially partitions into the aqueous phase, will adopt a well-known concentration gradient across the membrane water interface [17] while a hydrophobic paramagnetic species, such as oxygen, will adopt a concentration gradient in which the solubility is a maximum in the hydrophobic interior. Such complementary concentration gradients (and the consequent paramagnetic gradients) are useful for mapping both protein structure and immersion depth positioning of labeled sites. Moreover, paramagnetic spin labels may be attached to a lipid or detergent at a specific location in a membrane or micelle, in which case local paramagnetic effects also facilitate the measure of immersion depth and membrane protein topology [27, 28]. One recent example, which utilized spin labels and oxygen to delineate positioning of a membrane peptide is that of Ellena *et al.* [29]. The use of oxygen as a paramagnetic contrast agent in structure studies of membrane proteins is illustrated in Figures 4 and 5. Figure 4 depicts oxygen-induced chemical shift perturbations as a function of residue for the TM1 domain of the intact homotrimer of the membrane protein, DAGK, reconstituted into dodecylphosphocholine micelles, at 30 °C, and equilibrated to an oxygen partial pressure of 100 atm [30]. The chemical shift perturbations are measured via ^{19}F NMR, using an approach similar to the site directed spin-labeling studies [22]. In this case, single cysteine mutants of DAGK were obtained and labeled with a

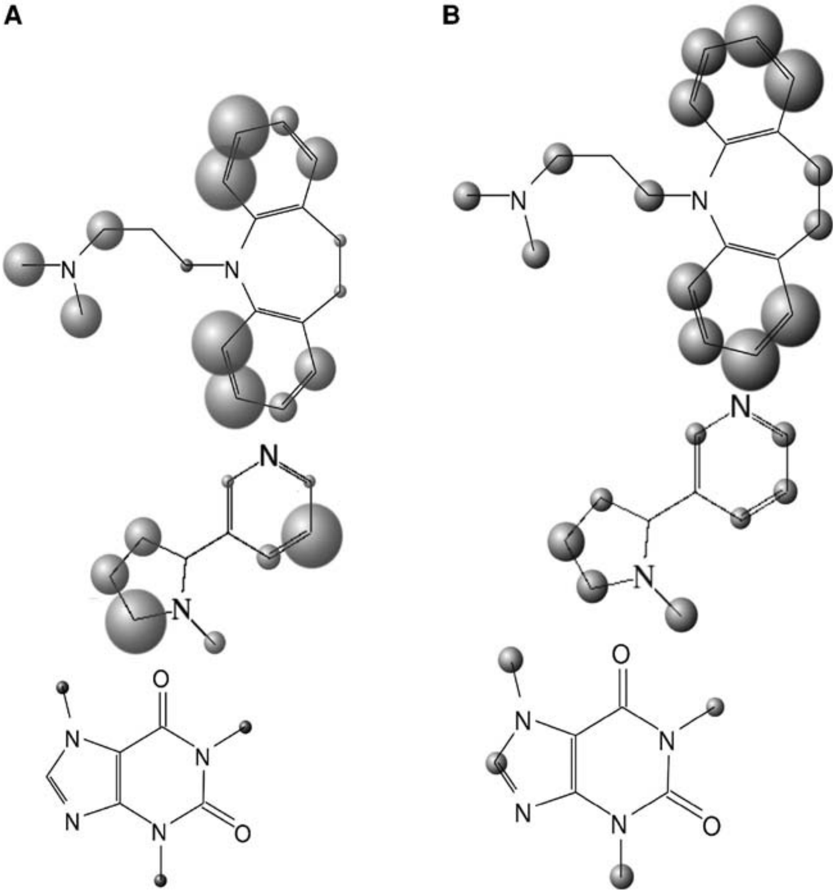

Fig. 3. (A) Changes in chemical shifts upon transfer of each of three small drug compounds (imipramine, nicotine, and caffeine, viewed from top to bottom) to a lipid bilayer model membrane system (bicelle). Spheres, whose radii are proportional to the upfield shifts (light) or downfield shifts (dark), are overlayed on the structure. (B) Paramagnetic spin–lattice relaxation rates of the three drug molecules (imipramine, nicotine, and caffeine) obtained after equilibration at an oxygen partial pressure of 20 atm. Spheres, whose radii are proportional to the paramagnetic rates, are overlayed on the structures. To measure chemical shift perturbations or paramagnetic rates, the three drugs were simultaneously added to a bicelle model membrane system. ^{1}H NMR spectra were obtained at 35 °C at an oxygen partial pressure of 15 atm. The drugs were added such that the lipid to drug ratio was in excess of 25:1. An isotropic bicelle membrane model system consisting of an equimolar mixture of 1,2-dimyristelaidoyl-*sn*-glycero-3-phosphocholine and chain-perdeuterated 1,2-dihexanoyl-*sn*-glycero-3-phosphocholine was used in this experiment. Experiments were performed on a Varian 600 MHz Inova spectrometer.

trifluoropropanone ligand. Upon refolding into DPC micelles, ^{19}F NMR spectra were obtained separately under equivalent partial pressures of oxygen and nitrogen such that the (paramagnetic) chemical shift perturbation could be measured. Note that the resulting shift perturbation profile reveals a prominent oscillation whose periodicity corresponds to 3.6 residues. This oscillation was interpreted to arise from a transmembrane α-helix in which one surface was in contact with one or more transmembrane regions of the DAGK homotrimer, and was therefore excluded from significant oxygen contact. Conversely, the remaining exterior of the TM1 α-helix was determined, based on sizeable chemical shift perturbations, to be in contact with the detergent micelle hydrophobic interior. The envelope of the chemical shift perturbation is used to map the immersion depth; a maximum (near residue 40)

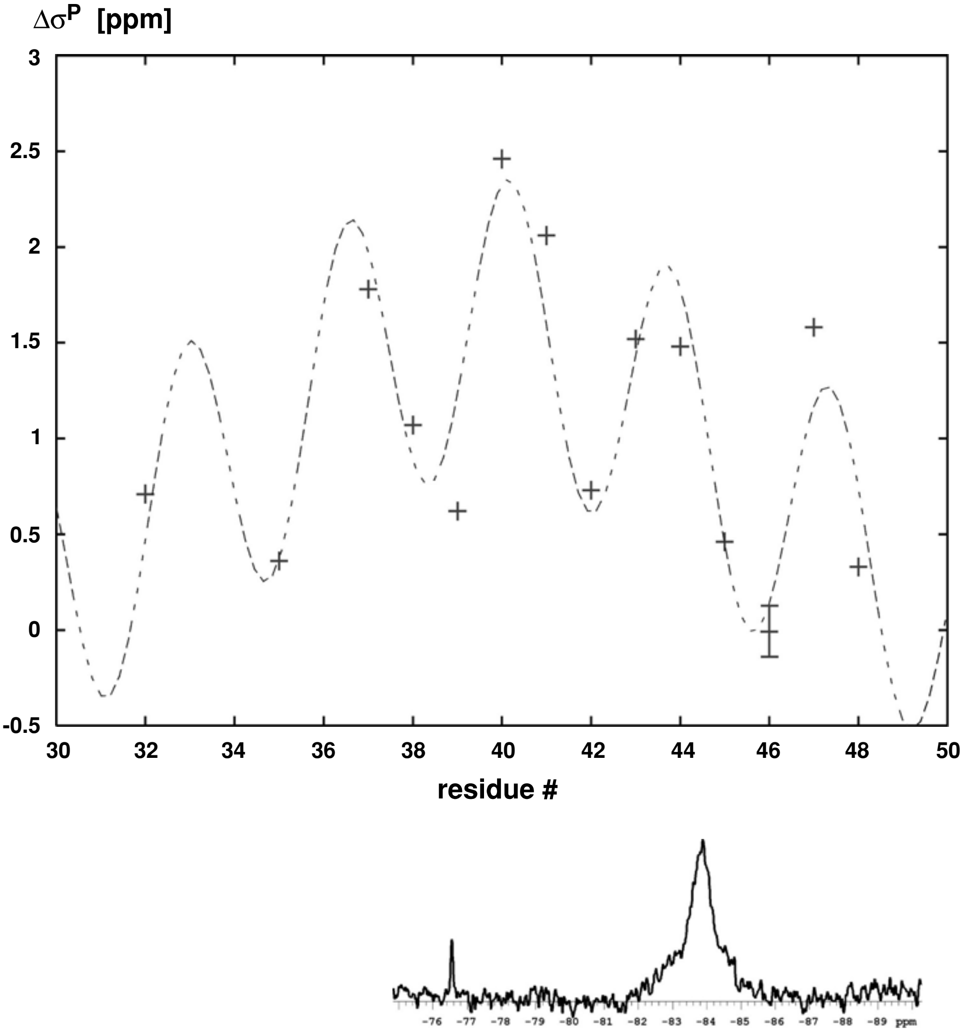

Fig. 4. Oxygen-induced ^{19}F NMR chemical shift perturbations vs. residue for the TM1 domain of the intact homotrimer of the membrane protein, DAGK, reconstituted in dodecylphosphocholine micelles, at 30 °C. ^{19}F chemical shift perturbations were measured by comparing spectra obtained after separately equilibrating at 100 atm nitrogen and oxygen, using single cysteine mutants of DAGK to which was attached a trifluoropropanone label. Typical spectra, as shown in the figure, were acquired on a Varian 500 Inova spectrometer at a Larmor frequency of 470.347 MHz, using between 100 and 200 transients, respectively, with a 2 s repetition time. (See also Plate 48 on page XXXVI in the Color Plate Section.)

in the overall profile, is suggested to arise from maximal solubilities of oxygen in the hydrophobic micelle interior, while residues 32 and 48 are determined to be near the micelle water interface, where the oxygen solubility is lower.

In contrast to the study of DAGK, in which the reporter groups were cysteine specific fluorine labels, it is also possible to combine traditional solution NMR to oxygen scanning experiments such that all resolvable nuclei can be studied at once. In one such study, enhancements of HzNz spin-lattice rates for all resolvable amides, at 20 Atm oxygen partial pressure, were recently measured for the 170 residue ^{2}H,^{15}N-labeled β-barrel, PagP [32]. PagP is a β-barrel membrane protein, whose structure and dynamics has been previously studied by NMR [31] and X-ray diffraction [33]. The paramagnetic rates were

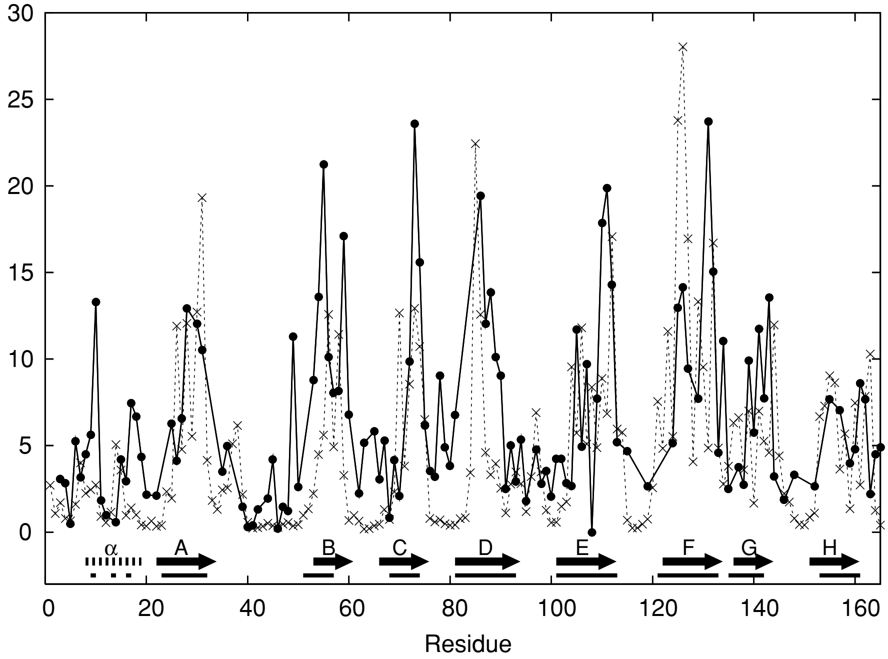

Fig. 5. Paramagnetic contribution to the HzNz spin-lattice relaxation rate, $R_1^P(O_2)$, overlayed with effective local hydrophobicity as a function of residue for the membrane protein, PagP. The effective hydrophobicity at each residue is determined by a weighted average of hydrophobicities within a sphere of radius 6 Å of the source. Note that arrows designate residues which adopt a β-strand secondary structure, while solid bars represent transmembrane residues and the dashed solid bar signifies residues belonging to the N-terminal α-helix.

pronounced for all eight transmembrane β-strands, due presumably to higher hydrophobicities, in the vicinity of the amides in the transmembrane domain. Evidence of the influence of local protein hydrophobicity is presented in Figure 5, where the above paramagnetic rate profile, $R_1^P(O_2)$, is overlayed with local hydrophicities, obtained by a spatially weighted average, using the Kyte-Doolittle scale.

Protein–Protein Interactions

Since oxygen essentially serves as a surface contrast agent, it stands to reason that it might be a useful tool in studies of protein binding interfaces or in studies of ligand protein interactions. Through difference experiments (i.e. experiments performed on a free protein and in the presence of a binding partner) it should be possible to make use of contact shifts or relaxation rates to determine the binding interface. In one study [34], the paramagnetic contribution to the amide ^{1}H spin–lattice relaxation rates, R_1^{P}, was measured for uniformly ^{2}H, ^{15}N-labeled FB protein, a 60-residue 3-helix bundle, constituting the B domain of protein A. Through TROSY versions of inversion–recovery experiments [35], R_1^{P} could also be determined for FB in the presence of a stoichiometric equivalent of an unlabeled Fc fragment of immunoglobulin (Ig) G. To best distinguish the binding interface of FB with Fc, the experimental ratio of paramagnetic rates, $R_1^{\mathrm{P}}(\text{complex})/R_1^{\mathrm{P}}(\text{free})$, was determined and all values of $R_1^P(\text{complex})/R_1^P(\text{free})$ less than unity, were considered to indicate regions protected by binding. The result is shown in Figure 6, where the FB residues exhibiting varying degrees of protection from oxygen, are mapped onto the protein surface. A clear binding interface was revealed, which was shown to be consistent with former cross-saturation studies of the protein [36].

Additional Applications: Family Fold Recognition and O_2 Migration Pathways

Recently, Hernandez *et al.* [37] demonstrated that O_2 penetration depth in water-soluble proteins could be assessed by comparing spin–lattice relaxation rate enhancements of buried amide protons in perdeuterated

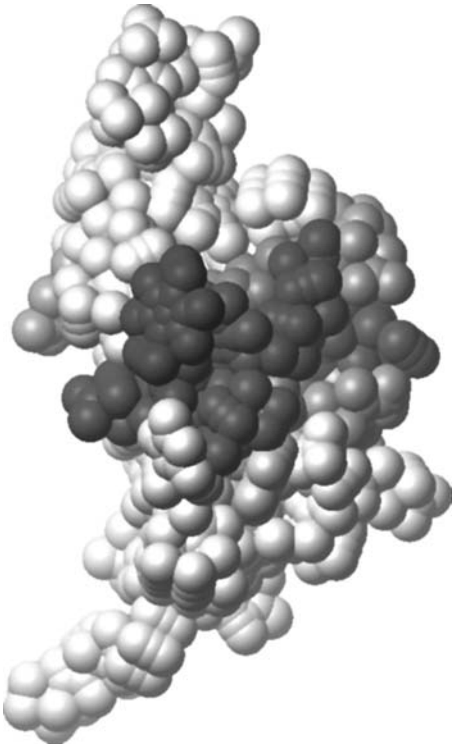

Fig. 6. looseness-1Depiction of $R_1^{\mathrm{P}}(\text{complex})/R_1^{\mathrm{P}}(\text{free})$ mapped onto FB. A gradation of red (strongest binding or greatest change of O_2 accessibility upon binding) to white (no binding) is assigned to residues depending on the magnitude of $R_1^{\mathrm{P}}(\text{complex})/R_1^{\mathrm{P}}(\text{free})$. ^{1}H T_1 TROSY experiments were performed under either 20 atm of nitrogen or oxygen, using a 600 MHz Bruker Avance spectrometer equipped with an HNC cryoprobe. (See also Plate 49 on page XXXVI in the Color Plate Section.)

rubredoxin, from oxygen and a bulky (non-penetrating) water-soluble nitroxide paramagnetic agent. In the absence of stable internal cavities, as is the case in the protein rubredoxin, oxygen solubility was determined to be at most 10% of the bulk value in the protein interior. Furthermore, simulations of paramagnetic rates, based on the assumption that both oxygen and nitroxide spin label remained exterior to the protein, proved to reproduce the observed rates for the majority of residues. The authors proposed that paramagnetic relaxation effects could be used to identify structurally homologous proteins or protein domains, whose sequences are too disparate for sequence-based recognition.

In contrast to rubredoxin, myoglobin possesses four stable hydrophobic cavities, known to accommodate xenon. McNaughton *et al.* [38] have measured the oxygen enhanced amide spin–lattice relaxation rates associated with the zinc-containing diamagnetic analog of sperm whale deoxymyoglobin. Zinc was used in this study to prevent covalent association of oxygen with the porphyrin. An analysis of paramagnetic rates revealed the binding constants of oxygen to all four non-covalent binding sites, thereby furthering ideas on oxygen diffusion pathways to the heme and overall binding to myoglobin.

Final Comments

In this review, we have highlighted current applications of oxygen as a paramagnetic probe in modern solution NMR structure studies of membranous and aqueous systems. Thus far, chemical shift perturbations from oxygen appear to be of practical value in ^{13}C and ^{19}F NMR applications. Furthermore, spin–lattice relaxation rate enhancements are significant in high gamma nuclei such as ^{19}F and ^{1}H. Moreover, the analysis of such rates is made easier due to fast electronic spin–lattice relaxation of oxygen. In general, conditions may be found wherein significant contact shifts or relaxation rate enhancements are observed, without undue line broadening. Though quantitative analysis of paramagnetic effects of oxygen is complicated by the preferential association of oxygen with disordered or hydrophobic surfaces, experiments which involve changes in oxygen accessibility (for example, binding between proteins and ligands or protein unfolding) are anticipated to be useful.

Applications of oxygen to spectroscopic studies of membranous systems abound due to the significant paramagnetic gradient, which exists in both bilayers and micelles. Immersion depth can be assessed for both membrane interacting amphiphiles or large membrane proteins. Given the current limitations of solution NMR to the study of membrane proteins, the use of oxygen paramagnetic effects on ^{19}F, ^{13}C, and ^{1}H nuclei in addition to applications of oxygen with appropriately fluorinated cysteine mutants, should prove helpful in understanding complicated topologies of membrane proteins.

Protein Structure

TROSY NMR for Studies of Large Biological Macromolecules in Solution

César Fernández[1] and Gerhard Wider[2]

Abstract

Transverse relaxation-optimized spectroscopy (TROSY), in combination with isotope labeling techniques and with improvements in NMR instrumentation, have greatly extended applications of NMR spectroscopy to large biological macromolecules that were otherwise not accessible to high-resolution solution state NMR. Important recent applications of TROSY include the structure determinations of integral membrane proteins in detergent micelles, structural and functional studies of large proteins in monomeric form and in macromolecular complexes, and investigations of intermolecular interactions in large complexes. Moreover, TROSY can improve measurements of NMR parameters, such as residual dipolar couplings and scalar couplings across hydrogen bonds, which contribute to a further improvement of the quality and the precision of solution structures of large proteins and oligonucleotides.

Introduction

During the past two decades, liquid-state NMR studies of biological macromolecules have been limited to relatively small structures with molecular weights in the range of 2–25 kDa, with an average around 10 kDa [1]. For biological macromolecules with molecular weights above 25–30 kDa the quality of the NMR data rapidly deteriorates. A major limitation when working with these large molecules arises from the fast relaxation of the NMR signal, causing severe line broadening, which translates into poor spectral resolution and low signal-to-noise ratios. Considerable efforts are devoted to extend applications of solution NMR to larger molecular systems, which would allow, for instance, structure determinations of proteins that cannot be crystallized, including integral membrane proteins, investigations of intermolecular interactions involving large molecules and macromolecular assemblies, and the structure determination of larger oligonucleotides and their complexes with proteins.

Substantial quality improvement of NMR spectra of biological macromolecules with molecular weights above ∼25 kDa can be obtained with deuterium labeling (for reviews, see Refs. [2–5]). With the introduction of transverse relaxation-optimized spectroscopy (TROSY) [6–11], relaxation could be reduced to such an extent that satisfactory NMR spectra can be obtained from particles with molecular weights far above 100 kDa. Along with improved instrumentation, TROSY has greatly extended the size limit for macromolecules that can be studied by solution NMR, opening a wide range of new applications [12–15]. In this chapter, the basis of TROSY and recent applications of TROSY for structural and functional studies of large biological macromolecules will be reviewed.

Technical Background

The NMR Signal

NMR measures the response of nuclear spins in a large, homogenous magnetic field to perturbations caused by the irradiation of electromagnetic fields in the radio-frequency range [16]. In practice, a sequence of radio-frequency pulses is applied, which are separated by interpulse time periods. The response to such a NMR pulse sequence (Figure 1) is a sum of radio-frequencies that have been emitted by the nuclei.

The NMR signal decays exponentially with a characteristic time constant, the transverse relaxation time T_2 (Figure 1A). For the analysis, the signal is Fourier-transformed (FT) into a spectrum containing resonance lines that represent the various emitted radio-frequencies. The width of the resonance lines in the spectrum is inversely proportional to T_2, which depends on the size of the molecule: for increasing molecular masses, T_2 becomes shorter (fast transverse relaxation) and consequently the lines in the spectrum broaden (Figure 1B).

NMR and Molecular Size

When studying large molecules by solution NMR, three major difficulties arise: signal overlap, limited solubility and fast relaxation. In principle, signal overlap can be

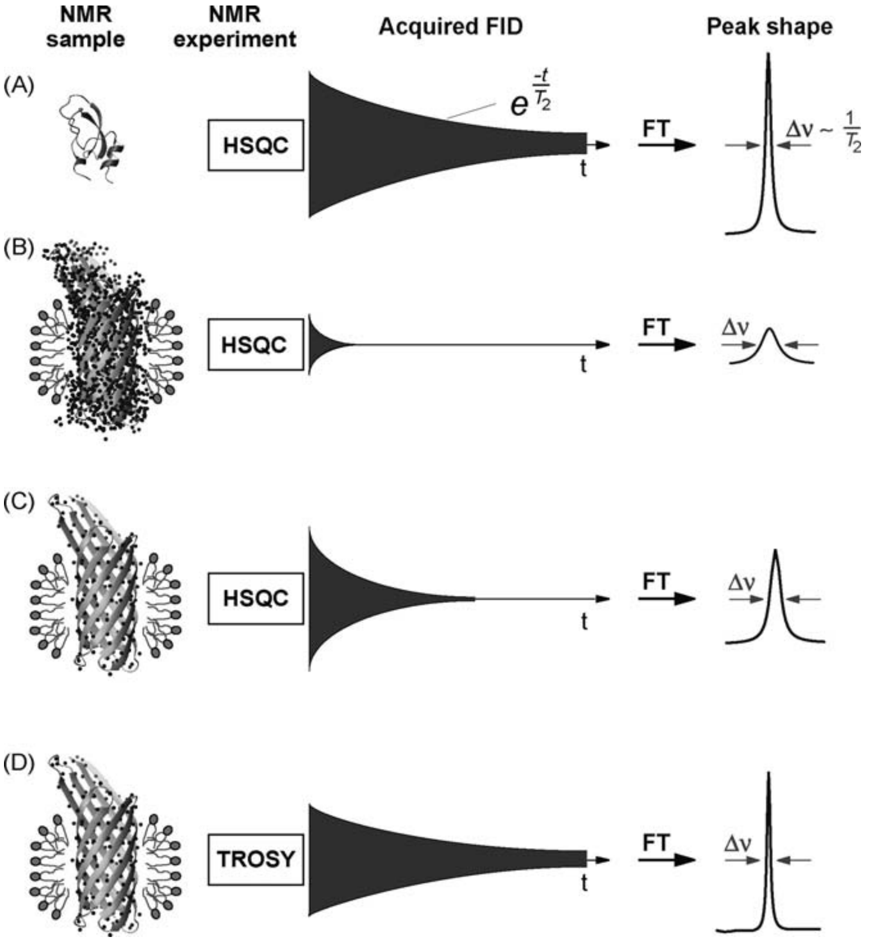

Fig. 1. Solution NMR spectroscopy with small and large molecules. (A) The NMR signal obtained from small molecules in solution relaxes slowly; it has a long transverse relaxation time T_2. Long T_2 values translate into narrow linewidths ($\Delta\nu$) in the NMR spectrum after FT of the NMR signal. HSQC stands for the pulse sequence; the structure on the left hand side represents a small protein. (B) For larger molecules the decay of the NMR signal is faster (T_2 is shorter). This results in a weaker signal after the NMR pulse sequence and broad lines in the spectra. In the schematic structure on the left hand side, the high density of protons is indicated by black dots. (C) By deuteration of the macromolecule (reduced number of protons indicated by less black dots in the schematic structure on the left), the transverse relaxation can be substantially reduced, which yields improved spectral resolution and improved sensitivity for large molecules. (D) Using TROSY pulse sequences with deuterated macromolecular samples the transverse relaxation can be further reduced, thereby increasing considerably the molecular weight amenable to NMR. Adapted from Ref. [14] with permission.

alleviated by proper choice of isotope-labeling schemes, including uniform, segmental, and selective ^{15}N and ^{13}C-labeling techniques [2,17–19]. Limited solubility translates into poor sensitivity, a problem that can be alleviated by new developments in NMR techniques and instrumentation that increase sensitivity, e.g. the development of cryogenic probes and spectrometers with higher magnetic fields.

The limitations caused by nuclear transverse relaxation poses the most severe technical challenge for studies of larger biological macromolecules in solution. Relaxation becomes especially bothering with long and relatively complex pulse sequences that are required for heteronuclear multidimensional NMR experiments. For larger systems, fast transverse relaxation reduces the signal intensities beyond the detection limit before the desired signal can be measured. The combination of deuteration techniques and TROSY alleviate the deleterious effects of transverse relaxation in such systems and increase the molecular size limit (Figure 1C and D).

Isotope Labeling

A major source for transverse relaxation are the protons in the omnipresent hydrogen atoms. Via dipole–dipole (DD) interactions, they efficiently relax any NMR active nuclei, e.g. ^{1}H, ^{13}C or ^{15}N, in macromolecules. The strength of the DD interaction can be greatly reduced by replacing protons by deuterons, because of the much smaller dipole moment of ^{2}H compared to ^{1}H [2]. Deuteration has clear advantages with regard to relaxation [2–4,20], however, protons contribute a major part of the structural information and produce the most sensitive NMR signal. Thus, measuring completely deuterated proteins is not an option and a compromise has to be found. For example, C–H moieties in macromolecules are often deuterated only to a certain extent, e.g. to 70%, or protons are selectively re-introduced into otherwise highly deuterated molecules, e.g. in methyl groups of Val, Leu, and Ile residues [2,5].

For NMR measurements, biological macromolecules are usually dissolved in H_2O, where their exchangeable ^{15}N–^{1}H groups generally become protonated. The strategically important amide groups in the polypeptide backbone of proteins are thus accessible to ^{1}H NMR experiments. Although deuteration of the C–H groups reduces significantly DD interactions between ^{15}N–^{1}H moieties and remote protons, i.e. the protons outside the ^{15}N–^{1}H group (Figure 1C), the ^{15}N–^{1}H DD interactions are omnipresent in ^{15}N-labeled samples. It has been shown that these ^{15}N–^{1}H DD interactions can be reduced by spectroscopic means using TROSY [6] (Figure 1D).

Transverse Relaxation-Optimized Spectroscopy

The Foundations of TROSY

The TROSY technique [6] is based on the interference of different relaxation mechanisms that contribute to the relaxation of a particular nucleus. This interference can be additive or subtractive resulting in increased or reduced relaxation, respectively. In addition to the omnipresent relaxation due to DD coupling, chemical shift anisotropy (CSA) of ^{1}H, ^{15}N, and ^{13}C can be a significant source of transverse relaxation at the high magnetic fields typically used for studies of biological macromolecules. The interference between this two relaxation mechanisms can be nicely illustrated in a correlation spectrum of ^{15}N and ^{1}H nuclei of amide groups in a polypeptide backbone (Figure 2). Each ^{1}H nucleus couples to its directly attached ^{15}N nucleus via scalar coupling. The ^{1}H NMR spectrum of such an amide moiety thus consists of two lines representing the protons attached to ^{15}N nuclei with spin up and spin down, respectively. The corresponding effect is observed for the ^{15}N nucleus. Therefore, in a 2D correlation experiment without decoupling a four-line fine structure is observed (Figure 2B). In conventional NMR experiments, the four multiplet lines are collapsed into one resonance by decoupling. Decoupling averages the relaxation rates (Figure 2A), which for smaller molecules, where all four multiplet components have almost identical linewidths, results in a simplified spectrum with improved sensitivity. However, for large molecules the multiplet components have largely different linewidths (Figure 2B) and decoupling results in a broad line (Figure 2A) which is much broader and less intense than the narrowest multiplet component (Figure 2C). In this situation it would be an advantage to record only the narrowest component.

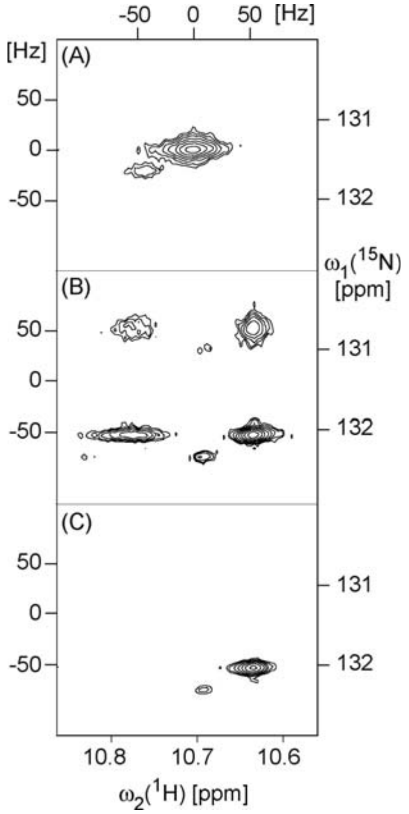

Fig. 2. Contour plots of a backbone amide ^{15}N–^{1}H correlation peak extracted from three different variants of 2D [^{15}N,^{1}H] correlation experiments. (A) Conventional broad-band decoupled [^{15}N,^{1}H]-HSQC. (B) Same as (A) without any decoupling during the experiment. (C) [^{15}N,^{1}H]-TROSY spectrum. Adapted from Ref. [6] with permission.

The TROSY technique selects exclusively the slowest relaxing component of the four line pattern (Figure 2C) eliminating the faster relaxing multiplet components. Thus, TROSY neglects part of the potential signal, which is, however, more than compensated in large molecules by the much slower relaxation during the pulse sequence and the acquisition (Figure 1D).

Field Strength Dependence of TROSY for ^{15}N–^{1}H Groups

The amide proton of a ^{15}N–^{1}H moiety relaxes due to DD interaction with the nitrogen and its own CSA. These two interfering relaxation mechanisms lead to different relaxation rates for the two multiplet components of the proton, with one rate smaller and the other one larger than the average rate. This effect depends on the external magnetic field since only CSA relaxation and not DD relaxation is field dependent. The optimal TROSY effect for one doublet component can thus be obtained by choosing the appropriate field strength, where its relaxation rate will be near zero. For amide protons in polypeptides, this "magic field" is about 23.5 T, corresponding to a proton resonance frequency of approximately 1000 MHz. The ^{15}N nucleus in an amide moiety shows a similar interference between ^{15}N–^{1}H DD interaction and its CSA, which minimizes the ^{15}N relaxation, accidentally, at about the same "magic field."

In practice, small deviations are expected from the "magic field" calculated for an isolated two-spin system, since the CSA varies slightly depending on the exact geometry of the amide moieties. Further, residual DD couplings (especially of amide protons) with remote protons give rise to relaxation that cannot be compensated by the TROSY effect, but that can be minimized by sample deuteration. In general, one approaches the optimal TROSY effect for peptide ^{15}N–^{1}H groups, manifested in optimal resolution and sensitivity, at the highest presently available ^{1}H frequencies of 900 MHz [6] using deuterated samples in aqueous solutions.

Implementation of TROSY: 2D [^{15}N, ^{1}H]-TROSY

The simplest implementation of TROSY into experimental schemes is the 2D [^{15}N,^{1}H]-TROSY [6,21], which does not contain any heteronuclear decoupling, neither during the ^{15}N chemical shift evolution period (t_1), nor during the signal acquisition period (t_2). Without decoupling, the four transitions that correspond to the multiplet components with different relaxation rates (Figure 2) are not mixed. The selection of the slowest relaxing component and the concomitant elimination of the remaining three components are achieved by phase cycling of the rf-pulses. The polarization transfer element ST2-PT [22] retains 50% of the original proton polarization. This residual polarization, however, is slowly relaxing and leads to an overall gain in signal intensity for large biological macromolecules. In general, when working with molecular sizes above 20 kDa at magnetic field strengths corresponding to a proton resonance frequency of at least 700 MHz, a higher signal-to-noise ratio is readily obtained with TROSY when compared with the corresponding conventional experiments.

[^{13}C–^{1}H]-TROSY

The application of the TROSY principle is not limited to ^{15}N–^{1}H groups in biological macromolecules. ^{13}C–^{1}H TROSY can be implemented in experiments with aromatic rings and methyl groups, where cross-correlated relaxation effects are also observed. In aromatic spin systems, the relaxation mechanisms for optimizing ^{1}H and ^{13}C transverse relaxation are ^{13}C–^{1}H–DD coupling and ^{13}C-CSA [8,23]. The large CSA values for ^{13}C can provide efficient compensation of ^{13}C transverse relaxation by dipolar coupling to the attached proton. In contrast, the small CSA of aromatic protons is not suitable for the application of TROSY and protons are decoupled from ^{13}C during acquisition. For aromatic ^{13}C–^{1}H groups the optimal TROSY effect is observed at a ^{1}H frequency of 600 MHz. For ^{13}C-labeled biological macromolecules of any molecular weight, significant sensitivity enhancement in ^{13}C–^{1}H correlation spectra of aromatic spin systems can be obtained with the use of TROSY compared to the conventional HSQC-based experiments.

A ^{13}C–^{1}H TROSY effect can also be observed in methyl groups, where different dipolar interactions compensate each other in large molecules. In methyl groups, the dominant relaxation of a methyl ^{13}C-nucleus originates in the dipolar coupling with the three methyl protons [24]. Interestingly, the standard [^{13}C,^{1}H]-HMQC correlation experiment is an optimized TROSY experiment for methyl carbons, which maintains 50% of the carbon magnetization in slowly relaxing states. For large molecules the 2D [^{13}C,^{1}H]-HMQC experiment yields superior resolution and sensitivity compared to the [^{13}C,^{1}H]-HSQC experiment, which mixes fast and slowly relaxing transitions, deteriorating significantly the spectral quality. It is important to note that the dipolar interaction is field independent and, therefore, the methyl TROSY can be applied at all field strengths for large molecules [25].

TROSY Applications for Studies of Large Biological Macromolecules

Although collection of high-quality data for structure determination of proteins with molecular masses up to ~100 kDa is now technically feasible, the complexity of the NMR spectra generally increases with the size of the molecule studied and the concomitant signal overlap may limit spectral analysis. Therefore, the preferred current use of relaxation-optimized NMR techniques is with large structures that yield relatively simple spectra compared to monomeric globular proteins of the same molecular size, such as homo-oligomeric proteins, individual small or medium-size subunits in large molecular complexes and membrane proteins in detergent micelles [12,14].

2D [^{15}N,^{1}H] TROSY

For large proteins, 2D [^{15}N,^{1}H]-TROSY provides fingerprints with improved resolution and sensitivity compared to conventional experiments (Figure 3A). This extends applications based on 2D [^{15}N,^{1}H] correlation experiments to much larger structures, e.g. for studies of intermolecular interactions, either with low-molecular weight ligands or with other biological macromolecules, which are usually applied in NMR screening to detect binding of compounds that can be optimized to high-affinity ligands by “SAR-by-NMR” [26].

TROSY-based NMR experiments have been applied to a variety of macromolecular complexes. They include the 51-kDa complex formed between the pilus chaperone FimC and the pilus subunit FimH from *Escherichia coli* [27], the P-domain of the lectin chaperone calreticulin and Erp57 in a 66.5-kDa complex [28], the p53 core domain bound in a ~200-kDa complex with Hsp90 [29], a 64-kDa immunoglobulin complex with a domain of protein A [30], and the 91-kDa 11-mer TRAP protein [31]. Recently, application of TROSY to malate synthase G from *E. coli*, an 81-kDa monomeric enzyme, yielded valuable quantitative information on ligand binding based on chemical shift mapping, residual dipolar couplings (RDCs), amide proton exchange rates, and ^{15}N spin relaxation measurements [32].

[^{13}C,^{1}H] Correlation Experiments

The simplest experiment that exploits the ^{13}C–^{1}H TROSY effect in aromatic systems is the 2D constant-time-[^{13}C–^{1}H]-TROSY [23]. With the application of TROSY, 4- to 10-fold signal enhancement has been achieved for resonances of the aromatic rings in an 18 kDa protein [23] and for RNA and DNA molecules [33,34]. Based on the [^{13}C,^{1}H]-TROSY building block, 3D pulse sequences can be developed that allow assignments of aromatic spin systems in proteins and nucleic acids [23].

TROSY can also be very profitably applied to methyl groups [35]. With a 2D [^{13}C,^{1}H]-HMQC experiment, sensitivity gains up to a factor of 3 compared to a [^{13}C,^{1}H]-HSQC have been observed for a perdeuterated, selectively methyl-^{1}H,^{13}C-labeled protein with a rotational correlation time of 400–450 ns (equivalent to a ~800 kDa globular molecule at 37 °C) [24,25]. For very large molecules the methyl ^{13}C–^{1}H TROSY effect can be exploited in 2D and 3D experiments for resonance assignments of methyl groups [36], for stereospecific assignments of prochiral methyls [37], for studies of domain orientation based on RDCs and ligand binding [32] and for studies of dynamic properties [38].

TROSY for Resonance Assignments in Large Molecules

^{15}N–^{1}H TROSY for Assignment of Protein Backbone Resonances

Triple-resonance experiments [39–42], which are usually applied for backbone resonance assignments of ^{13}C,^{15}N-labeled proteins, include the amide moiety. These experiments contain extended time periods with transverse amide nitrogen magnetization and yield dramatic signal enhancement when using TROSY. TROSY versions of the most relevant triple resonance experiments have been implemented [43–48], which in general yield sensitivity gains of more than one order of magnitude with proteins in the molecular weight range from 25 to 150 kDa [43–46,49]. As an example, Figure 3 shows the dramatic improvement in spectral quality that can be obtained with TROSY in a molecular complex of about 60 kDa. Whereas the TROSY version shows clear cross peaks (Figure 3C), the conventional spectrum cannot at all yield the desired correlations (Figure 3D).

Using TROSY techniques, resonance assignments have been obtained for much larger proteins than ever thought possible with conventional NMR techniques. This was first demonstrated with a homo-octameric 110 kDa protein [49], where 20- to 50-fold sensitivity gains in triple resonance experiments were observed. More recently, backbone resonance assignments in the 723-residue monomeric protein malate synthase were obtained, which is the largest single polypeptide chain that has been assigned to date [50].

^{15}N–^{1}H TROSY for Assignment of Protein Side-Chain Resonances

In addition to resonance assignments of nuclei in the polypeptide backbone, ^{15}N–^{1}H TROSY experiments have been developed for assignment of ^{1}H and ^{13}C chemical shifts of methyl groups in selectively methyl-protonated and otherwise deuterated large proteins. In one application, the membrane protein OmpX in 60 kDa DHPC micelles [51] has been selectively protonated at the Val, Leu, and Ile (δ1) methyl groups [52]. With ^{15}N–^{1}H TROSY-based ^{13}C–^{13}C TOCSY experiments, the methyl groups were correlated with the backbone amide groups, yielding complete sequence-specific assignments of the protonated methyl groups [51], which had a significant impact

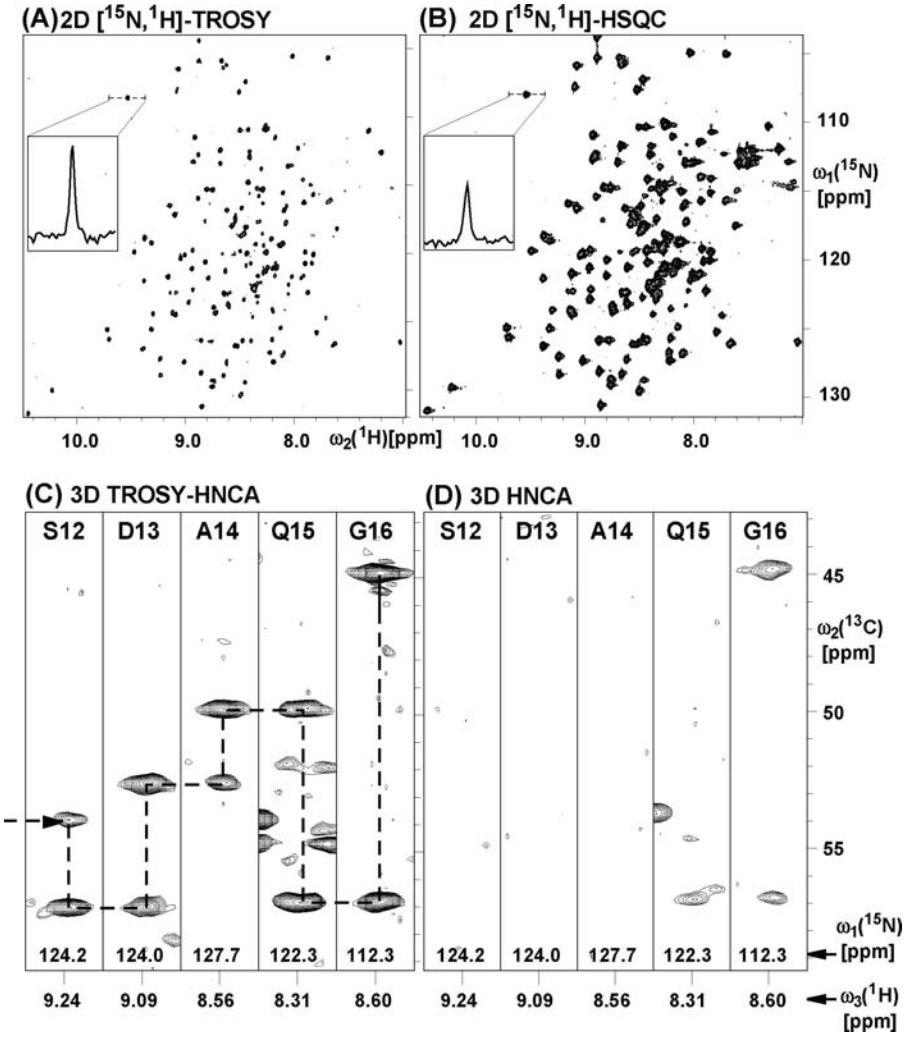

Fig. 3. Impact of TROSY on NMR spectra. The spectra were measured at a ^1H resonance frequency of 750 MHz with a sample of the uniformly ^2H,^{13}C,^{15}N-labeled integral membrane protein OmpX in dihexanoylphosphatidylcholine (DHPC) micelles, a 60-kDa complex. (A) and (B) show ^{15}N–^1H correlation spectra that were identically recorded and processed, except that TROSY was used in (A) only. The inserts show cross sections that were taken parallel to the ω_2 (^1H) axis at the position indicated by the horizontal broken lines. (C) Strips along the ^{13}C-dimension from a 3D [^{15}N,^1H]-TROSY-HNCA spectrum. The strips were taken at the ^{15}N chemical shifts (indicated at the bottom of the strips) of the amino acid residues 12–16, and are centered at the corresponding amide proton chemical shifts, ω_3($^1H^N$). Horizontal and vertical broken lines indicate the connectivities that can be obtained, leading to complete resonance assignments of the polypeptide backbone $^1H^N$, ^{15}N, and $^{13}C^\alpha$ nuclei. (D) Strips from a conventional 3D HNCA spectrum; the strips were taken at the same frequencies as in (C). Adapted from Ref. [14] with permission.

on the precision of the NMR structure [53]. Recently, near complete assignments of Val, Leu, and Ile (δ1) methyl groups have been obtained for the 81 kDa protein malate synthase G using new labeling strategies in concert with new TROSY-type NMR experiments [25,36,37]. The Val and Leu isopropyl groups were labeled with ^1H and ^{13}C in only one of the two methyl groups, and subsequently assigned using TROSY experiments.

TROSY for Observation of Scalar Couplings Across Hydrogen Bonds

Hydrogen bonds are usually indirectly inferred from experimental data, e.g. from nuclear Overhauser enhancement (NOEs) and proton exchange rates, or from analysis of refined 3D structures based on geometrical considerations. Direct detection of hydrogen bonds in proteins and oligonucleotides was enabled by the observation of scalar spin–spin couplings across hydrogen bonds [54–56]. These couplings allow the determination of hydrogen bond partners, which can be used to refine NMR structures, to study intermolecular interactions at atomic level, and to investigate biological mechanisms involving hydrogen bonding interactions.

The sensitivity and spectral resolution in NMR experiments used to detect hydrogen bonds can be substantially improved for large molecules by using TROSY. Applications include: measurements of scalar couplings across hydrogen bonds in a ^{15}N,^{13}C-labeled DNA duplex tetradecamer in a 17 kDa protein–DNA complex [55,57], in 25 kDa RNA oligonucleotides [58], in the 30 kDa ribosome-inactivating protein MAP30 [59], in the 147-residue flavoprotein riboflavin 5′-monophosphate [60], and in the active site of the 44 kDa enzyme chorismate mutase [61].

TROSY for Measurements of RDCs

Residual dipolar couplings (RDCs) provide important structural restraints for obtaining global folds and for refining the 3D structure of proteins and oligonucleotides [62–64]. This is especially important in large, perdeuterated molecules, where only a limited number of constraints can be obtained from NOEs [65,66]. Various TROSY-based experimental schemes have been developed for measuring RDCs (for an overview, see Ref. [63]). Applications to the maltose binding protein in a complex with β-cyclodextrin and to carbonic anhydrase II showed that precise RDCs can be obtained for proteins of 30–40 kDa molecular weight [67]. Furthermore, RDCs in the 723-residue malate synthase G [32], in a 53-kDa homomultimeric trimer from mannose binding protein [68], and in the 41-kDa maltose binding protein [69] were measured using TROSY-based experiments.

TROSY for Studies of Dynamic Processes

In addition to structural data, NMR is able to provide information on dynamic processes at atomic resolution over a wide range of time scales [70,71] which can help in understanding structure and function relationships (see, e.g. [72,73]). Key experiments for dynamic studies measure T_1 and T_2 relaxation times, and heteronuclear ^{15}N{^{1}H}-NOEs of the ^{15}N nuclei in amide groups. For these important experiments, pulse sequences using ^{15}N–^{1}H TROSY were developed [74,75]. Recently, a new experiment based on methyl TROSY has been applied with the 82 kDa enzyme malate synthase G for studies of slow (millisecond) dynamic processes [38].

TROSY in Nuclear Overhauser Enhancement Spectroscopy

Both, the ^{13}C–^{1}H and ^{15}N–^{1}H TROSY effects have been exploited in 3D ^{13}C-resolved and ^{15}N-resolved [^{1}H,^{1}H]-NOESY experiments, respectively [33,76]. In the pulse sequences of these experiments, TROSY-type chemical shift correlation schemes were used instead of the conventional HSQC or HMQC building blocks. A fully relaxation-optimized ^{15}N-resolved [^{1}H,^{1}H]-NOESY, the 3D NOESY-[^{1}H,^{15}N,^{1}H]-zero quantum-TROSY experiment [77], was developed based on TROSY in the ^{15}N–^{1}H zero quantum state. As an advantage, the usually very intense diagonal peaks are almost completely suppressed in this experiment and weak resonances close to the diagonal become amenable for analysis, alleviating a limitation of conventional NOE spectroscopy. The utility of this approach was demonstrated for the 110 kDa protein aldolase [77].

Applications to Nucleic Acids

For NMR structural studies of nucleic acids, TROSY offers considerable benefits (for a review, see Ref. [78]). Direct detection of hydrogen bonds and measurements of RDCs, which were discussed in the previous sections, are of considerable importance for the structure determination of nucleic acids, since in comparison to proteins, inherently fewer protons are available as sources for structural information. In addition, TROSY has been widely applied to increase the sensitivity and the resolution in correlation experiments for nucleic acids, increasing the range of their applicability to much larger oligonucleotides. Examples include the use of TROSY in correlation experiments [33], in NOESY experiments for the bases [79], in experiments for intra-base and sugar-to-base correlations [34,80,81], and in an experiment that provides correlations between all carbon nuclei in the adenine base [82].

Solution NMR Studies of Membrane Proteins

Membrane proteins take part in important physiological functions, and constitute key targets for drug discovery. Structural studies of membrane proteins by X-ray crystallography or by NMR spectroscopy are much more difficult than for soluble proteins. Since real membrane systems are far too large for investigation by solution NMR, membrane proteins are often reconstituted in detergent micelles. From these micellar systems, high-quality spectra can be obtained using TROSY (Figure 3) [83–85].

With the availability of TROSY, the first NMR structures of integral membrane proteins in micelles with molecular weights above 50 kDa have been determined, particularly of *E. coli* outer membrane proteins with β-barrel architecture [53,84–88]. The fold of the outer membrane protein OmpX (148 residues) was obtained in DHPC micelles of about 60 kDa molecular mass [53,84,86], the polypeptide backbone fold of the outer membrane protein OmpA (177 residues) has been determined in dodecylphosphocholine (DPC) micelles of 50 kDa molecular mass [87,89], and the backbone fold of the outer membrane enzyme PagP (164 residues) has been determined both in DPC and *n*-octyl-β-D-glucoside micelles of size 50–60 kDa [88,90].

With regard to future developments, recent results obtained for the 39 kDa homotrimeric protein diacylglycerol kinase in micellar complexes with overall sizes larger than 100 kDa [91–93] suggest that NMR-based structure determination of membrane proteins with α-helical architecture, as large and complex as some members of the G-protein-coupled receptor family, may be feasible. Recently, partial backbone resonance assignments have been reported for native bacteriorhodopsin in dodecylmaltoside micelles [94].

Cross-Correlated Relaxation-Induced Polarization Transfer for Studies of Very Large Structures

In heteronuclear NMR experiments, magnetization between the different nuclei is usually transferred based on their scalar spin–spin couplings using INEPT polarization transfer elements [95,96]. During INEPT transfers, TROSY is not active since the slowly and fast relaxing transitions are mixed. For very large structures with molecular weights above approximately 150 kDa, rapid transverse relaxation during the INEPT periods leads to a complete loss of most signals. This limitation can be alleviated by cross-correlated relaxation-enhanced polarization transfer (CRINEPT) [97,98]. In this technique, INEPT and cross-correlated relaxation-induced polarization transfer (CRIPT) [99] are combined. In contrast to INEPT, the transfer efficiency of CRIPT increases proportional to the size of the molecule, so that it becomes an efficient magnetization transfer mechanism for molecules with sizes above 200 kDa [97,98]. Therefore, when studying very large structures significant gains in sensitivity can be achieved by substituting INEPT by CRINEPT or CRIPT.

Methods that allow resonance assignments of macromolecules with molecular weight above ∼150 kDa are currently not available and therefore CRINEPT/CRIPT spectroscopy is usually applied to obtain ^{15}N–^{1}H fingerprints of very large structures. As with TROSY-based experiments, the preferred current use of CRINEPT is to study relatively short polypeptide chains (up to ∼100–200 amino acid residues) in large supramolecular assemblies, in complexes with large macromolecules, or in large detergent/lipid micelles. The potential of the CRINEPT and CRIPT experiments has recently been demonstrated for 900 kDa complexes formed by GroES with GroEL [98,100].

Conclusion and Outlook

With the development of TROSY, CRINEPT, CRIPT, and isotope labeling techniques, combined with recent advances in NMR instrumentation, solution NMR studies of biological macromolecules with molecular masses well beyond 100 kDa have become a reality. This has been demonstrated in numerous studies dealing with fundamental biological problems, extending from structural investigation of large proteins and the structure determination of the first larger integral membrane proteins in solution, to applications for intermolecular interactions involving relatively large structures [14,15,83,100,101]. The ability to obtain resonance assignments of large biological macromolecules provides the basis for the determination of much larger 3D structures by NMR as thought to be possible just a few years ago. Even if the NMR structure determination is not feasible, the resonance assignment alone can be sufficient to carry out detailed studies of intermolecular interactions and investigations of dynamic processes, which may provide important information on exciting biological systems. However, for very large structures, where CRINEPT and CRIPT are the only means to obtain useful NMR spectra, techniques for resonance assignments are still missing. Nevertheless, NMR fingerprints of proteins with molecular weights up to 900 kDa have been obtained and interesting information could be derived based on the available crystal structure [100].

With the appropriate technical tools available, we expect that many new NMR structures of proteins and nucleic acids with molecular weights above 25 kDa will be elucidated. In this context, techniques that facilitate selective isotope labeling, such as cell-free protein expression [102–105] and segmental isotope labeling [18,19,106,107] may become widely applied to solve larger structures. With the prospect of further advances in NMR techniques and instrumentation, and improved protein expression techniques, larger membrane proteins, as G-protein coupled receptors, may become amenable to solution NMR studies. We are looking forward to future applications of the techniques described in this review and to technical advances that allow studying even more challenging biological systems.

NMR Insight of Structural Stability and Folding of Calcium-Binding Lysozyme

Makoto Demura

Division of Biological Sciences, Graduate School of Science, Hokkaido University, Sapporo 060-0810, Japan

Lysozyme and Calcium Binding of the Homologous Proteins

Lysozymes (LYSs) are antibacterial enzyme, β-*N*-acetylmuramyl-hydrolase, that disrupts a glycosidic bond of the polysaccharide that is found in the cell walls of many bacteria. A number of LYSs are found in nature; in mammalian milk, tears, and egg white. The most common animal LYS is the c type, such as the chicken egg white lysozyme (EWL, 14.3 kDa), found in animal, insects, and plants [1]. LYS and α-lactalbumin (α-LA) have undoubtedly evolved from a common ancestor because of the similarity of their amino acid sequences (Figure 1) [2]. α-LA, which is a major milk component of milk whey, is a calcium-binding metalloprotein [3]. It is the so-called B component of lactose synthase and acts as a specificity modifier of galactosyltransferase to convert it to lactose synthase. The original discovery of its calcium-binding property was made when an effect of ethylenediaminetetracetic acid (EDTA) on the conformational stability of bovine α-LA was demonstrated. Then, a microanalytical method has been developed using high-performance gel-filtration chromatography together with the use of a calcium-specific fluorescent reagent [4]. Binding constants of a calcium ion to calcium-binding LYSs and bovine α-LA are 10^{6-7} M^{-1} [5].

The calcium-binding site of canine milk LYS [6], which contributes to the structural stability, consists of the two backbone carbonyl groups of residues 82 and 87 and the three side-chain carboxyl groups of Asp-85, Asp-90, and Asp-91 in a pseudobridging mode [7], which is distinct from that of the EF-hand where the calcium ion binds in a bidentate mode [8]. Furthermore, it was pointed out that the above three aspartyl residues are all conserved in calcium-binding LYSs from canine, equine, echidna, and pigeon and α-LA (Figure 1A). In the case of chicken EWL, the backbone conformation of the calcium-binding loop is essentially conserved. However, the EWL does not bind calcium because the side chains are radically altered.

Protein Folding Mechanism

The strong interest in partly folded states of proteins, or folding intermediates, resides in the fact that by studying the molecular features of these intermediates, it will be possible to elucidate the mechanism of how proteins fold into their specific biologically active conformations [9,10]. In recent years, the difficulty in detecting and characterizing the transient intermediate species formed during the protein folding process prompted a variety of structural studies on the intermediates that can be generated at equilibrium by dissolving a protein in acid solution or in the presence of moderate concentrations of a protein denaturant, as well as by removing protein-bound metal ions or prosthetic groups [11,12]. These studies led to the development of the concept of the molten globule (MG) state, shown to be equilibrium intermediate between the native and unfolded states of a number of globular proteins. Until recently, the MG state was considered to be a partly folded state having a stable native-like secondary structure but lacking a specific tertiary structure (Figure 1C) [12]. However, in several studies it has been shown that a great variety of MGs do exist, ranging from those having specific tertiary interactions or native-like topology to those resembling the unfolded state of a protein. Evidence has been provided that the MGs of some proteins share conformational features with those transiently observed in kinetic experiments of protein folding [13–15]. Therefore, the detailed characterization of equilibrium intermediates in terms of structure and dynamics appears to be relevant for solving the protein folding problem.

Although the c type LYS and α-LA are homologous to each other, their equilibrium unfolding profiles are quite different, with that of LYS and LA obeying a two-state and three-state model (Figure 1C), respectively [16]. In particular, although LA in acid at pH 2.0 attains a MG state, the chicken EWL remains native under similar acidic conditions. However, the homologous calcium-binding LYS from equine or canine milk or from pigeon egg-white can form the MG state when exposed to acid solution or on

Fig. 1. Sequential homology of various calcium-binding lysozymes and α-LA (A), crystal structure of canine milk lysozyme (CML, 129 aa) (B) and the three-state folding model of proteins (C). Canine, equine, and echidna correspond to source of milk lysozymes. Four-disulfide bonds are linked between squared C. Single and double underlines correspond to calcium-binding sites for backbone carbonyl and side-chain carboxyl groups, respectively (see text). Three-dimensional structure of CML (B) is divided into two domains; helix-rich domain (α-domain) and β-sheet-rich domain (β-domain). The former is composed of four α-helices named A-helix (5–15), B-helix (25–36), C-helix (89–100), and D-helix (110–115), and the latter is composed of three-stranded anti-parallel β-sheet (strand I 43–45, strand II 51–55, and strand III 58–61) [6]. In (B), Ca indicates calcium-binding loop. The substrate can bind at the active cleft. α-Lactalbumin and lysozymes are similar structural super family. (See also Plate 50 on page XXXVII in the Color Plate Section.)

calcium depletion at neutral pH and (moderate) heating [14,16,17]. It is now accepted that proteins exhibit various dynamics covering a wide range of time-scale and amplitude. It was shown that such motions include local movement of loops, or larger movement of secondary structure and structural domains with a time-scale from picosecond to hours.

^{1}H Chemical Shift Calculation of the Calcium-Binding LYS in the Structural Intermediate

Canine milk lysozyme (CML) was studied as a model protein to clarify the folding mechanism, and the relationship between structure, function, and dynamics of protein using NMR [17]. CML was expressed in *E.coli* as inclusion bodies and refolded to form the native structure. Uniformly ^{15}N-labeled CML was obtained by growing the cells in M-9 medium containing $^{15}NH_4Cl$ as the sole nitrogen source. Figure 2 shows the 1D ^{1}H NMR spectra of CML in the native state, the MG at 2 M guanidine hydrochloride (GuHCl) and the unfolded state at 6 M GuHCl concentration. Chemical shifts are widely distributed in the NMR spectrum of CML in the native state (BMRB: 4887). In addition, some methyl signals which are shifted to a lower frequency than 0 ppm. The existence of a rigid hydrophobic core involving aromatic residues has been revealed by the^{1}H chemical shift calculation with the atomic coordinates (PDB: 1EL1) [6] of this protein

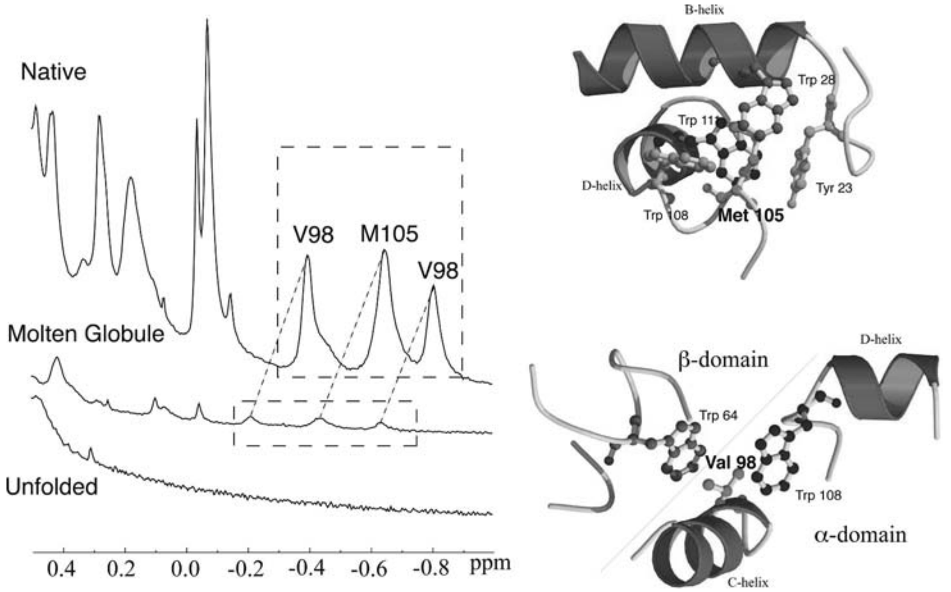

Fig. 2. 1D ^{1}H NMR spectra of canine milk lysozyme (CML) in the native state, the MG at 2 M GuHCl and the unfolded state at 6 M GuHCl concentration (left), and the local structures (right) at Val 98 and Met 105 of CML which were shown on the X-ray crystal structure of CML (PBD: 1EL1 and 1QQY for calcium-binding CLM and calcium-free CML, respectively). ^{1}H NMR spectra were acquired at 400 MHz in a Jeol α-400 spectrometer (Jeol Co., Tokyo, Japan) at 25 °C. The protein sample concentration was 0.5 mM. (See also Plate 51 on page XXXVII in the Color Plate Section.)

based on ring-current shifts, shifts arising from magnetic anisotropies of bonds, and shifts arising from the polarizing effect of polar atoms [17,18]. In the NMR spectrum of CML in the MG state, it appeared that peaks are broadened and poorly resolved when compared with the native state. Spectral broadening and poor chemical shift dispersion are the general characteristics of the NMR spectra of protein in the MG state. In the NMR spectrum of CML in the MG state, several methyl signals are also shifted to a frequency lower than 0 ppm (Figure 2). This indicates that a portion of the side-chain packing around an aromatic cluster is still remained even in the MG of CML. The ring-current-shifted signals of CML in the MG state are arising from γ-methyl protons of Val 98 in C-helix and from the β-methylene proton of Met 105 in D-helix. The side chain of Val 98 is located in the domain interface region, and that of Met 105 is located in the interior of the α-domain. Figure 2 (lower right) shows the 3D-structure in the vicinity of the hydrophobic core around Val 98 of CML in the native state. As shown in this figure, aromatic residues of Trp 64 and Trp 108 are located close to Val 98. Figure 2 (upper right) shows the structure in the vicinity of the hydrophobic core around Met 105 of CML in the native state. In this case, the aromatic residues of Trp 28, Tyr 32, Trp 108, and Trp 111 are located close to Met 105. Based on the chemical shift calculation with the atomic coordinates of CML in the absence of calcium (PDB: 1QQY), the specific side chains, which influence the chemical shift of Val 98 and Met 105, were determined.

H/D Exchange of Calcium-Binding LYS in the Native and the Structural Intermediate

Highly resolved HSQC spectrum of CML is easily observed in the native state. Contrary, the HSQC spectrum of CML in the MG state is significantly different from the native state. It was revealed that the HSQC spectrum of CML in the MG state exhibits broadened and decreased peak dispersion when compared with the native state. Nevertheless, large number of well-resolved and sharp peaks can be observed in the HSQC spectrum of CML in the MG state. Previous study revealed that α-LA in the MG state exhibits poorly resolved, broadened and little dispersed HSQC spectrum. It could be assumed that the MG state of CML exhibits smaller fluctuation and well-defined 3D-structure when compared with α-LA.

In the native state of CML, the Hydrogen/deuterium (H/D) exchange rates were measured at pH 4.5 and 25°C for 81 amide protons distributed throughout the primary structure [17]. The other amide protons were rapidly exchanged to be detectable. To compare the H/D exchange rates of CML with those of α-LA and EML, the protection factors were estimated for individual amide protons as described previously [19]. The protection factor is defined as the ratio of the intrinsic to the experimentally determined H/D exchange rates for each amide proton [20]. There are two important features for the protection factors of CML in the native state: (1) the protection factors of the amide protons in the α-domain are larger than the β-domain and (2) the most protected amides are located in the secondary structure elements. It could be assumed that solvent accessibility of α-domain of CML in the native state is lower than that of β-domain.

The H/D exchange rates of the amide protons of CML in the MG state were measured by the amide hydrogen trapping method [19]. From the H/D exchange rates, the protection factors were estimated for each residue [17]. Figure 3 shows HSQC spectra of the CML as a function of contacting time with D_2O in the MG state. It appeared that 64 amide hydrogens are protected from the H/D exchange reaction in the MG state of CML. It is of note that the number of protected amide hydrogens of CML in the MG state is much larger than EML (17 amide hydrogens)

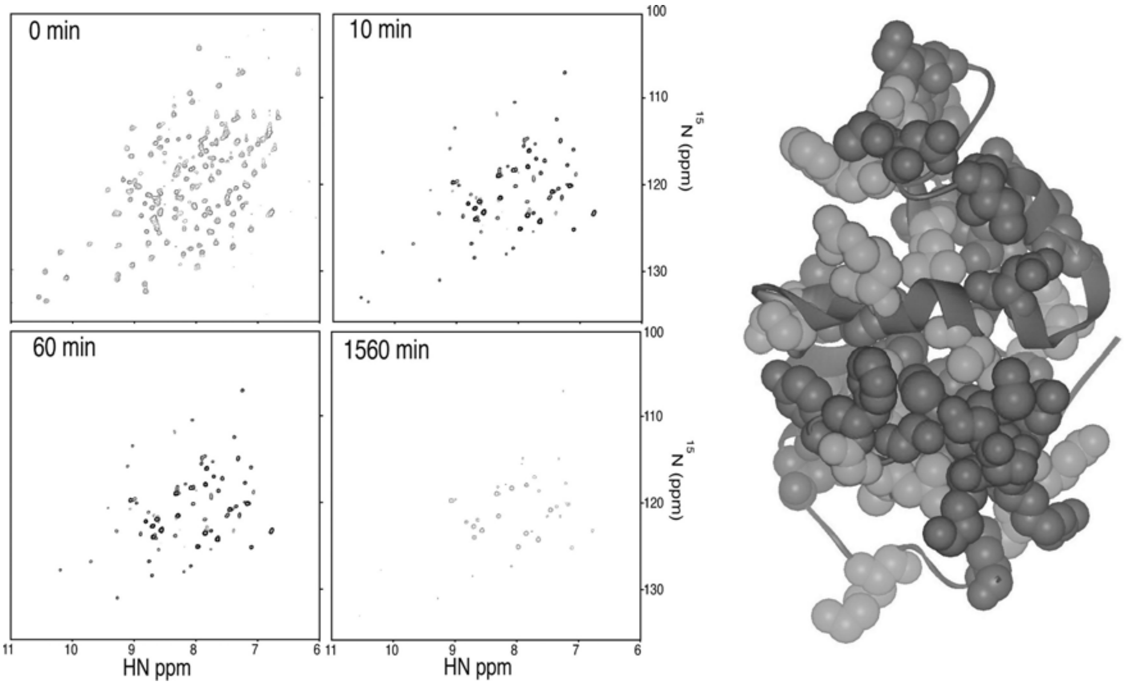

Fig. 3. Hydrogen/deuterium exchange rate measurements based on ^{15}N HSQC spectra of CML as a function of time (left) and mapping of the protection factors of each amino acid residues in the MG state (right). Uniformly ^{15}N-labeled protein with a sample concentration of 0.6 mM was used. The H/D exchange reaction was initiated by dissolving lyophilized protein in 280 μl of D_2O d_4-acetate buffer containing 10 mM $CaCl_2$at a direct pH meter reading of 4.5. A series of HSQC spectra were collected at 500 MHz at 25 °C every 3 hours for 3 days. Data sets of all NMR spectra for the H/D exchange measurements were comprised of 512 (^{1}H) × 128 (^{15}N) of 32 scans, and a sweep width of 8000 Hz for the ^{1}H and of 1800 Hz for the ^{15}N dimensions. The H/D exchange rates were determined by the decay of the peak volume as described previously [21]. The H/D exchange rate of the MG was measured by the amide hydrogen trapping method as described previously [19]. The H/D exchange reaction of CML in the MG state was initiated by dissolving the lyophilized protein in 3 ml of D_2O at pH 2.0. After various period of time ranging from a minute to 10 days, the H/D exchange reaction was quenched by freezing the sample in liquid N_2 and then lyophilized. The samples were redissolved in D_2O d_4-acetate buffer containing 10 mM $CaCl_2$ to a final pH of 4.5 and HSQC spectra were collected. Immediately before the measurements of HSQC spectra, 1D ^{1}H NMR spectra were collected and peak volumes were normalized by using non-exchangeable resonance arising from methyl group. Red and green circles on the left mapping correspond to the protection factor more than 50 and more than 20, respectively. (See also Plate 52 on page XXXVIII in the Color Plate Section.)

[19]. The protection factors of CML in the MG state are large in residues which form secondary structure in the native state. The protected amides are mapped on the 3D-structure of CML (Figure 3 right). The protected amides (protection factor >20) are colored green and the most protected amides (protection factor >50) are colored red. The most protected amides exist mainly in the hydrophobic core region of the native state. They originate from Arg 10 to Met 15 in the A-helix, from Met 17 and Phe 20 in the loop region between the A- and B-helices, from Val 29 to Glu 33 in the B-helix, from Trp 108 and Val 109 in the D-helix, and from His 114, Cys 115, Lys 118, and Cys 127 in the C-terminal region. It should be noted that the most protected residues of the A- and D-helices are located in the region that forms the interface with the B-helix. It could be assumed that arrange of the A-, B-, and D-helices of CML in the MG state is similar to the native state. It was revealed that A-helix is the most protected among four α-helices, followed by B-, D-, and C-helices in the MG state of CML. On the other hand, B-helix was most protected in the MG state of EML [19], followed by the A-, D-, and C-helix. The MG state of CML exhibits two orders of magnitude larger protection factor than those of EML. This indicates that α-helices are more stable in the MG state of CML when compared with EML. It should be noted that several amides in the β-sheet region are protected from the H/D exchange reaction in the MG state of CML. A series of studies revealed that α-domain adopts a native-like backbone topology, whereas the β-domain remains largely unstructured in the MG state of EML and α-LA. It could be assumed that the MG state of CML has significantly ordered structure when compared with α-LA and EML. More recently, instability, unfolding, and aggregation of human LYS variants underlying amyloid fibrillogenesis are compared with homologous proteins, CML, and α-LA.

NMR Investigation of Calmodulin

Tapas K. Mal and Mitsuhiko Ikura
Department of Medical Biophysics, University of Toronto and Division of Signalling Biology, Ontario Cancer Institute, Toronto, ON, Canada M5G 2M9

Abstract

Calmodulin (CaM) is a 16.7-kDa heat-stable protein that functions as Ca^{2+} sensor in eukaryotes. Because of its physicochemical properties and its remarkable well-resolved NMR spectra for a helical protein, CaM has been extensively studied by a number of researchers for NMR methodology development as well as its biological applications. This chapter describes the past and current NMR studies of CaM to serve as an example of structure and dynamic characterization of a protein.

Calmodulin (CaM) was discovered in 1970 as an activator for cyclic nucleotide phosphodiesterase [1, 2]. Soon it has become obvious that CaM is a ubiquitous intracellular calcium sensor protein expressed in most, if not all, eukaryotes from humans to yeast. Concentration of CaM is tissue-, organ- and cell-specific, with high expression in the brain and reproductive organs [3]. The amino acid and gene sequences of CaM have been determined from various species and are highly conserved through evolution [4–7]. CaM is a small 16.7-kDa and heat-stable protein. It contains a number of well-conserved hydrophobic residues and a relatively high number of acidic residues ($pI = 4.3$). It also contains an unusually high number of methionine residues, which are believed to confer promiscuous binding ability owing to the flexible nature of side-chains [8]. CaM possesses a number of post-translational modifications, including acetylation of the N-terminal Ala-1, trimethylation of Lys-115 in mammalian CaM, dimethylation of Lys-13 in *Paramecium* CaM, and phosphorylation at various threonine, serine, and tyrosine residues [9]. However, the significance of these modifications *in vivo* is still unclear. *In vitro* studies have shown that phosphocalmodulin binds some targets with different binding affinities and even affects subsequent target kinase activities [10].

The crystal structure of Ca^{2+}-bound CaM (Ca^{2+}-CaM) was solved in mid 1980s [11, 12] followed by a number of refined structures [13–15]. The structure has an unusual dumbbell shape (Figure 1) in which the N- and C-terminal globular domains are connected by a long α-helix. Each domain possesses a hydrophobic patch, which is considered to be responsible for target binding. A higher resolution structure (1.0 Å) solved 12 years later [16] showed that considerable disorder was found "at every accessible length-scale," particularly in residues within the interdomain linker and those comprising the hydrophobic binding pockets. CaM binds four Ca^{2+} ions, with each domain containing two Ca^{2+} binding helix-loop-helix motifs of EF-hand type, first discovered in parvalbumin by Kretsinger and co-workers [17]. The C-terminal domain of CaM binds to Ca^{2+} at higher affinity ($K_d = 10^{-6}$ M) than the N-terminal domain ($K_d = 10^{-5}$ M).

Biological Functions

As a ubiquitous Ca^{2+} "sensor" in eukaryotes, CaM functions as a regulator of a large array of different target proteins and enzymes, including protein kinases, protein phosphatases, ion channels and pumps, nitric oxides synthases, adenylyl cyclases, and phisphodiesterases. Among these diverse CaM targets, CaM-regulated serine/threonine kinases (CaM Kinases) are the best characterized structurally and functionally. The CaM kinase family includes CaM kinase I (CaMKI), CaM kinase II (CAMKII), CaM kinase IV (CaMKIV), CaM kinase kinase (CaMKK), myosin light chain kinase (MLCK), and several other CaM kinases whose functions and structures are not well characterized [18]. As one of the major Ca^{2+} "sensor" proteins in the cell, it responds to an increase in the concentration of intracellular calcium from the resting state by undergoing a large conformational change upon binding Ca^{2+} ions, enabling it to interact with and, as a result, activate its target. CaM-binding regions in many target enzymes and proteins have been mapped. In many cases, the CaM binding domain on the target overlaps or is proximate to an autoinhibitory domain (AID) that maintains enzyme inactivity at resting levels of Ca^{2+}. CaM binding to the target displaces the AID to render the enzyme active. In most cases, CaM binding regions are generally 14–27 amino acid peptides and rich in basic and hydrophobic residues. These peptides are typically unstructured in absence of CaM and form α-helical structure when bound to CaM. A number of naturally occurring peptides are also known to bind CaM in a Ca^{2+}-dependent manner [19]. These peptides include insect venom peptides such as mastoparans and melittin, and certain hormones and opiods such as ACTH, VIP, glucagons, and

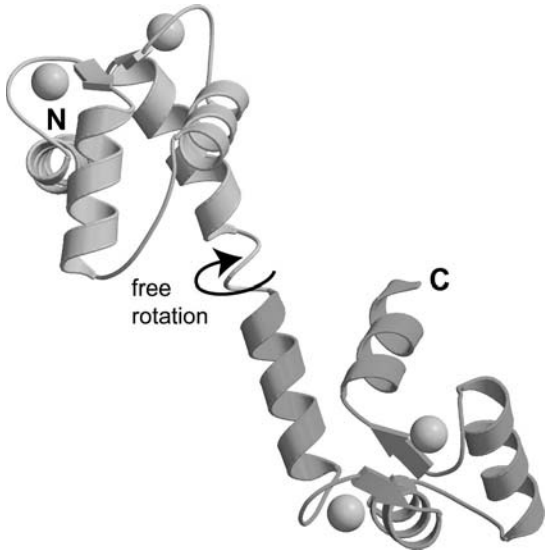

Fig. 1. Schematic representation of the **2.2-Å crystalstructure of Ca^{2+}-CaM, PDB code 3CLN. The N- and C-terminal domains are shown in yellow and green, respectively. Ca^{2+} ions are illustrated in grey spheres. The middle portion of the central linker (D78–S81) possesses a high degree of mobility as evidenced by (^1H)-^{15}N backbone relaxation measurements [50]. (See also Plate 53 on page XXXVIII in the Color Plate Section.)

substance P. However, biological functions of these CaM–peptide interactions are not well understood. In addition, phenothiazines and other hydrophobic drugs including trifluroperazine (TFP), chlorpromazine, and W-7, bind CaM and inhibit the CaM-mediated activation of enzymes [20]. Proteolytic fragments and synthetic peptides comprising the CaM-binding regions of target proteins, as well as the insect and hormone peptides and the hydrophobic drugs, have been extensively used to study the structural and biochemical properties of the interaction of CaM with targets. Numerous studies have been done on CaM and its complexes with target peptides to understand the detailed mechanism by which CaM regulates the activity of its vast targets involved in wide range of cellular functions. NMR studies have contributed tremendously to our understanding on the structure–function relationship of CaM. At the same time, CaM has also been extensively used for NMR methodological development since 1990. NMR studies on CaM and its complex with targets, and contribution of CaM to NMR from early studies to date will be focused in the following discussion.

Early NMR Studies on CaM

The ^1H spectra of bovine brain CaM were first recorded on 250 and 360 MHz NMR instruments in 1979 and 1980 [21,22]. These studies demonstrated that the dramatic ^1H chemical shift changes associated with Ca^{2+} binding could be monitored by ^1H NMR. Subsequently, Klevit *et al*. [23], and Krebs and Carafoli [24] studied the interaction of bovine brain CaM with TFP using ^1H NMR while Shimizu *et al*. [25,26] used ^{19}F NMR to study the interaction of porcine brain and *Tetraphymena pyriformis* CaM with TFP.

The detailed assignments for aromatic ring and methyl protons, and Ca^{2+}-induced conformational changes of scallop testis CaM were reported by Ikura *et al*. [27, 28] in 1983. Several resonances of C-terminal domain (Phe-99, His-107, trimethyl Lys-115, and Tyr-138) are shifted in an early stage of Ca^{2+} titration (0–2 mol Ca^{2+} per mol of CaM), indicating that the C-terminal domain has higher affinity toward Ca^{2+} than the N-terminal domain. In 1984, ^1H NMR studies on the two tryptic fragments of CaM (TR_1C, residues 1–75; and TR_2C, residues 78–148) were reported by three groups [29–32] almost at the same time. All these studies provided further evidence for the order of Ca^{2+} binding to four sites in CaM and also confirmed that the two tryptic half-fragments retained the same conformations as they would in intact CaM.

Two-Dimensional ^1H NMR

In 1984, the first 2D ^1H NMR recorded on 600 MHz for fragment TR_2C were reported in the absence of Ca^{2+} and provided assignments for side chain proton resonances of many residues [33]. Then in 1985, Ikura *et al*. [34] provided about 30% backbone and side-chain proton assignment both in presence and absence of Ca^{2+} using 2D ^1H NMR techniques to the TR_2C fragment. Extremely high field shifted amide proton resonances (10.0–11.0 ppm) were assigned to the glycine residues at the fifth position of the Ca^{2+}-binding loops. These uniquely shifted glycine amide proton were further characterized using both TR_1C and TR_2C fragments [35]. Such large shifts of amide protons of this conserved glycine were also found in troponin C [36], calbindin [37], recoverin [38], and many other EF-hand proteins demonstrating that this feature is universal among the members of the EF-hand superfamily, thus serving a marker for functional EF-hand structures. Hoffman and Klevit [39] reported using 2D ^1H NMR on Ca^{2+}-free TR_1C fragment that the hydrophobic contacts between Phe-16 and Val-35 were absent in the crystal structure of Ca^{2+}-bound CaM [11,12]. The complete backbone assignments of Ca^{2+}-free TRC fragment were reported by Finn *et al.* [40], indicating that the Ca^{2+}-free form retains helix-loop-helix secondary structure similar to that observed in the Ca^{2+}-bound state. In 1990 Starovasnik *et al.* [41] showed that CaM from yeast *Saccharomyces cerevisiae* binds only three Ca^{2+} ions unlike four in case of vertebrate CaM.

Multidimensional and Heteronuclear NMR of CaM

The characterization of CaM and its biophysical properties using ^{1}H 1D and 2D NMR has so far been discussed. Being a highly soluble and heat-stable protein, during the late 1980s and early 1990s, CaM was extensively used for multidimensional heteronuclear NMR method development by Bax's group at NIH. For these heteronuclear NMR experiments, the protein was isotopically enrichment with ^{15}N and ^{13}C. In 1981, a partial CaM cDNA clone was isolated from the electric eel [42] and later many other ortholog cDNA clones have also been isolated. An Efficient purification of CaM by phenyl-sepharose affinity chromatography was soon reported [43] and then mammalian CaM gene was cloned and overespressed in *E. coli* [44,45]. Uniformly ^{15}N- and/or ^{13}C-labeled CaM from *Drosophila malanogaster* [46] and *Xenopus laevis* [47] were soon expressed as a recombinant protein in *E. coli* expression system for NMR studies. Figure 2 shows the ^{1}H–^{15}N heteronuclear single quantum coherence (HSQC) spectrum of Ca^{2+}-free (apo-CaM) and -bound form of recombinant uniformly labeled CaM. Ikura *et al.* [48,49] reported complete backbone and side-chain ^{1}H, ^{13}C, and ^{15}N assignments of Ca^{2+}-bound *Drosophila* CaM using a series of triple resonance 3D and 4D experiments. The secondary structure in solution determined using Nuclear Overhauser Effect (NOE), $^3J_{NH\alpha}$ coupling constants, and ^{13}C chemical shift data [48] compliments the crystal structure [11,12] very well. However, the NMR data clearly indicated that the long central helix (residues 65–92), found in the crystal structure, possesses a flexible region at residues D78–S81 in solution [50], which was suggested earlier by small-angle X-ray scattering [51, 52] and chemical cross linking studies [53]. This finding has been supported later by the recent 1 Å crystal structure of Ca^{2+}-CaM [16]. The ^{15}N relaxation studies provided additional insights into the structure and dynamics of Ca^{2+} -CaM [50]. The rotational correlation time for the N- and C- domains (7.1 and 6.3 ns, respectively) reflect that the two domains move independently in solution [50].

Vogel and coworkers [54, 55] have characterized side chain of seven lysine residues in CaM in apo, Ca^{2+}-bound and complex with target peptide derived from smMLCK (smMLCKp) and measured pK_a values of individual lysine residues in ε-dimethylated form using ^{1}H–^{13}C correlation NMR to understand the importance of these residues as Lys-13 and −115 residues are post-translationally methylated in *Paramecium* and mammalian CaM respectively. The dynamic properties of ε-trimethylated Lys-115 was studied by ^{14}N NMR relaxation measurements [56] and it was possible due to the unique symmetrical tetrahedral methyl substitution to its side chain that give rise to sharp ^{14}N signal. Chemical and thermal stability of intact CaM and its two isolated C- and N- domains has been extensively studied using selective ^{15}N Ile labeled and mutated protein by Bayley's group [57,58] employing 2D ^{1}H-^{15}N HSQC NMR experiment.

Solution Structure of CaM

There was no solution structure of Ca^{2+}-bound CaM till 2001 when Bax and coworkers [59] solved a high resolution solution structure of Ca^{2+}–CaM with the use of recently developed residual dipolar couplings (RDCs) in NMR and the high resolution X-ray structure as an initial template. The results showed that the two domains remain flexible despite conformational change upon Ca^{2+} binding. The tertiary structure of the C-terminal domain is similar to that found in the crystalline state, but the interhelical angles of the N-terminal domain EF-hands are smaller and approximate the "semi-open" conformation observed for the EF-hands of the myosin light chains [60].

In 1995, three groups independently solved the solution structure of apo-CaM, a compact molecule with two globular domains connected by a highly flexible linker [61–63] (Figure 3). The NMR structure of apo-CaM from *S. cerevisiae* is similarly flexible [64,65]. Due to the flexible linker, ensemble of calculated structures can only be superimposed over one of the domains, with the second domain occupying a "mushroom cap"-like space. Considerable backbone flexibility is also observed in the loop regions within the EF-hands. The structure clearly illustrates the Ca^{2+}-induced conformational change undergone by CaM, particularly the EF-hand helix orientation (Figure 4). The Ca^{2+}-binding to apo-CaM changes the interheloical angle of the two helices of each EF-hand by approximately 40° and such that CaM undergoes a transition from the "closed" conformation to the "open" conformation [61,63]. This conformational change results in the creation of a large hydrophobic pocket on each domain, which is essential for target binding for CaM [66–68] (Figure 4).

Metal and CaM Interactions

Various metal NMR were employed to explore biophysical and functional properties of CaM. Vogel and coworkers [69,70] studied ^{43}Ca and ^{113}Cd NMR by using two tryptic fragments of CaM to monitor preferential Ca^{2+} binding to each site of the two domains of CaM. These experiments also support the earlier finding by Ikura *et al.* [28]. ^{1}H saturation transfer and spectral simulation methods were employed to obtain the exchange rate constants and activation parameters between Ca^{2+}-free and -bound states for two fragments [71]. Two distinct rate constants of 3–10 s$^-$ [1] and 300–500 s$^-$ [1] were found at 22 °C for the C- and N-terminal fragments, respectively. ^{77}Se NMR was studied to examine the functional importance of nine Met residues in apo, Ca^{2+}- and target-bound CaM, and all

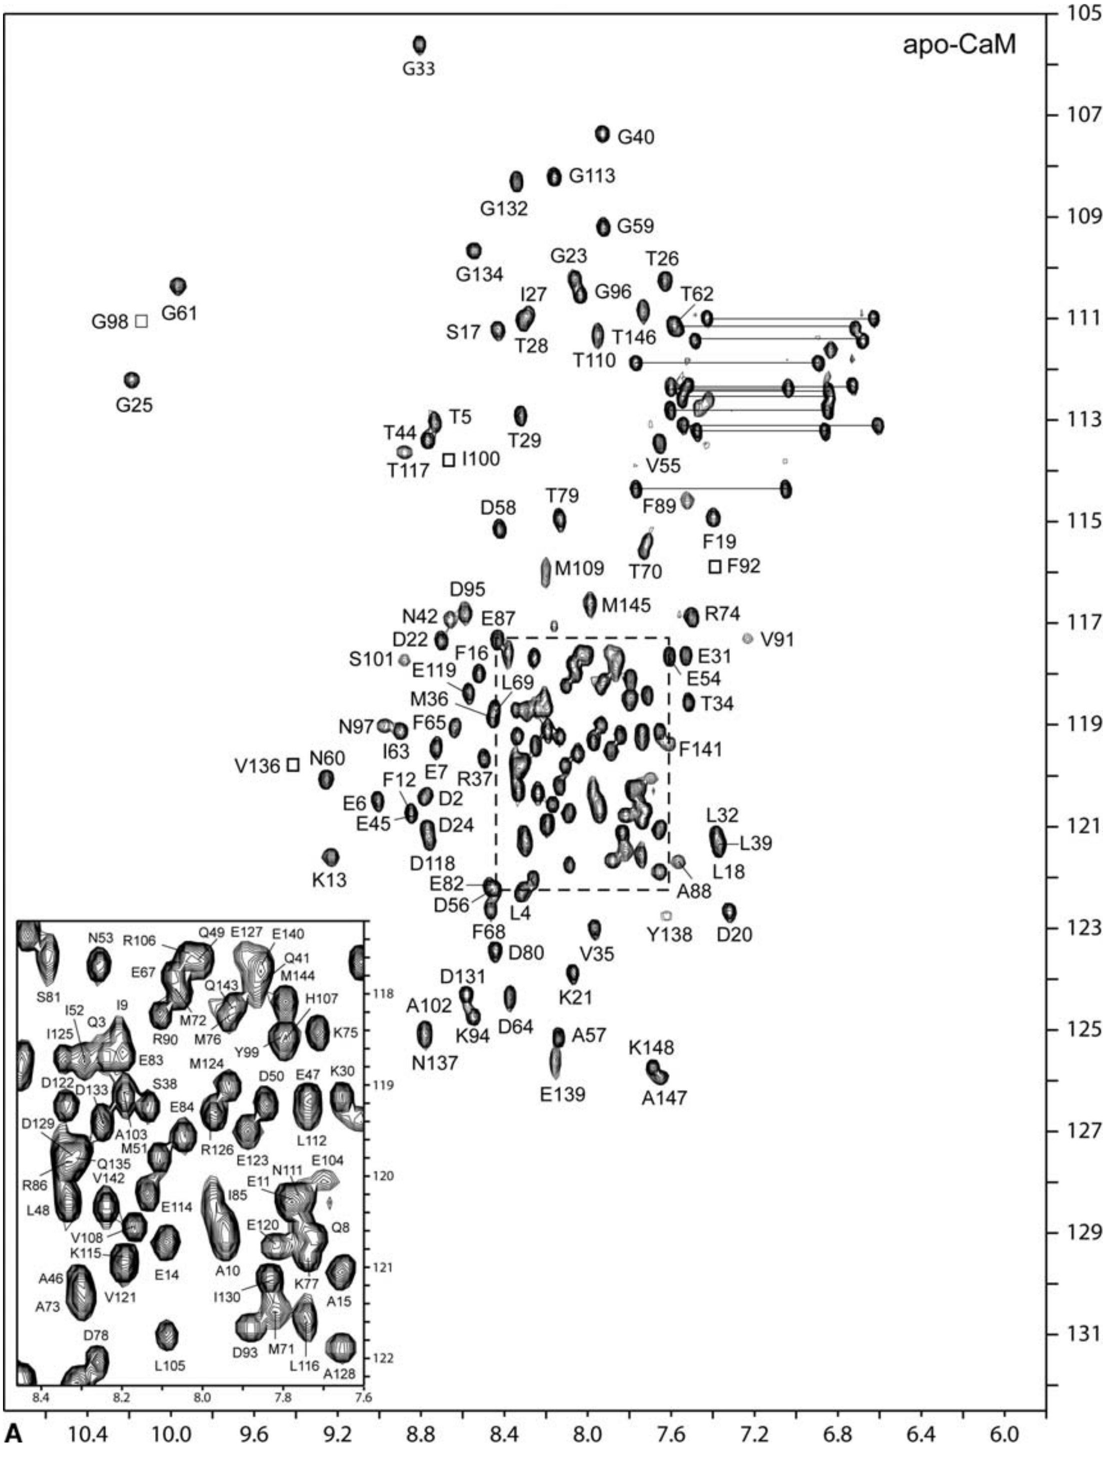

Fig. 2. ^{1}H-^{15}N HSQC spectra of uniformly ^{15}N-labeled (A) apo-CaM (Ca^{2+}-free) and (B) Ca^{2+}-CaM recorded on 600 MHz NMR spectrometer equipped with a triple resonance pulse field gradient probe. Both data were recorded with 1 mM CaM at 32 °C in identical buffer (15 mM Bis–Tris, 100 mM KCl, pH 6.72) except with 5 mM CaCl$_2$ for Ca^{2+}-bound and 2 mM EGTA for **apo-CaM samples, respectively. Resonances are labeled using one letter amino acid code and sequence position of the corresponding residue represents missing resonances in apo-CaM due to line broadening under the NMR sample condition.

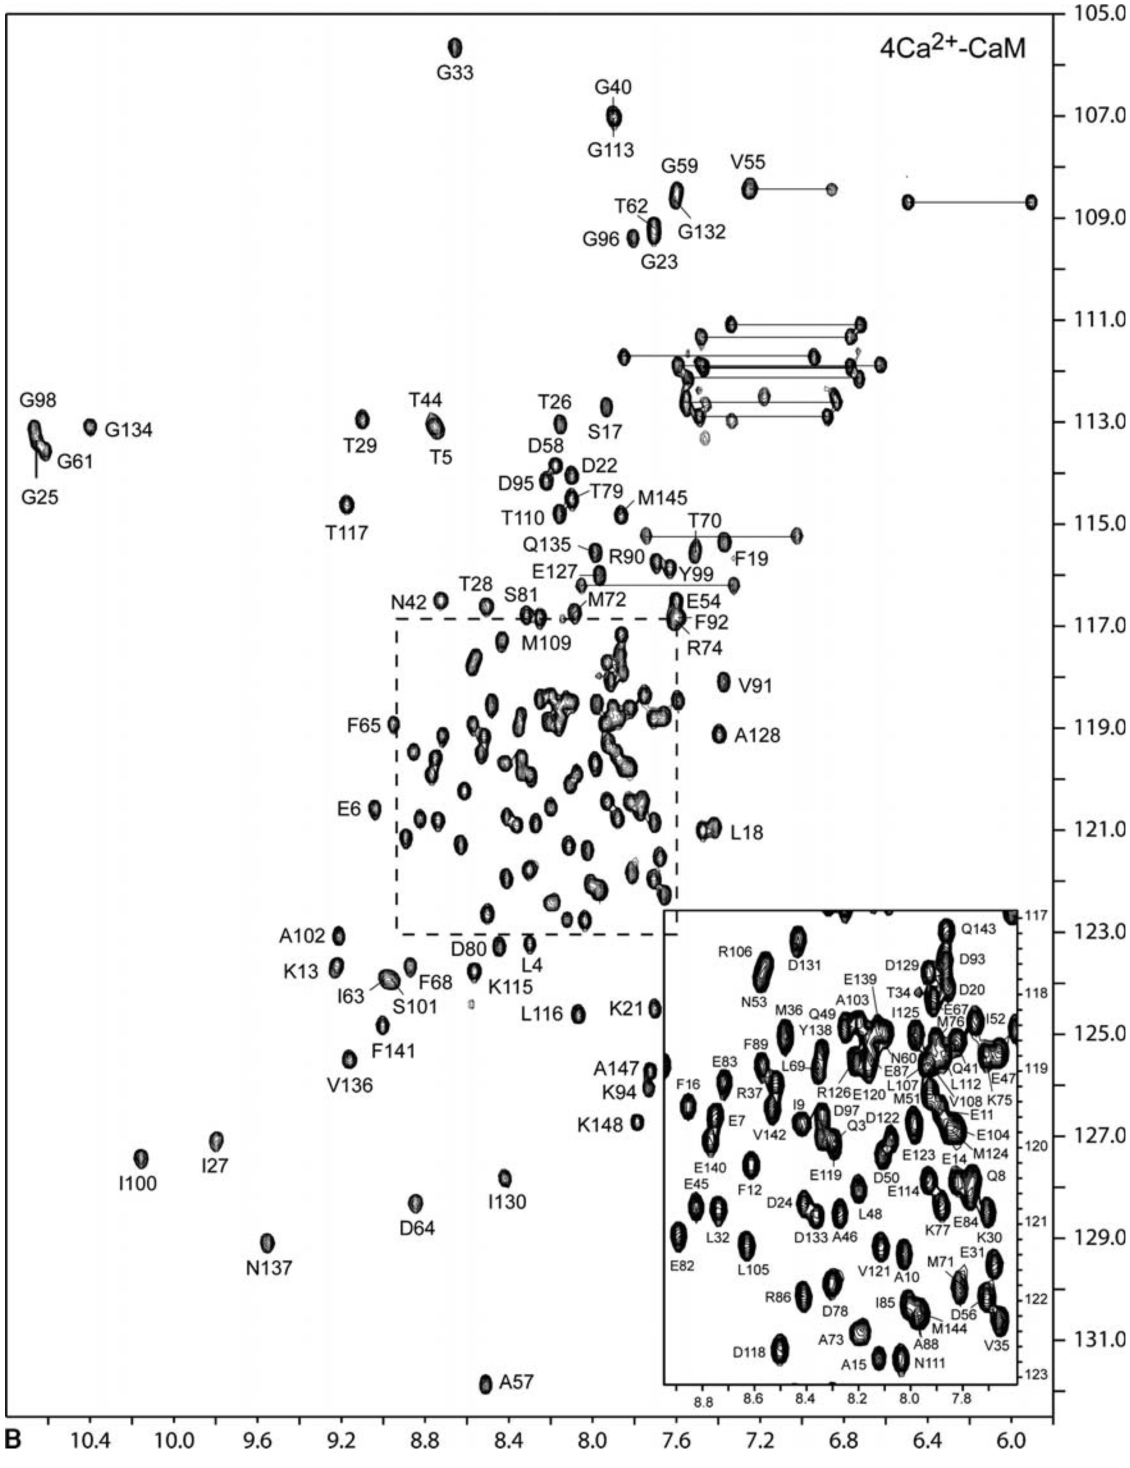

Fig. 2. (*Continued*)

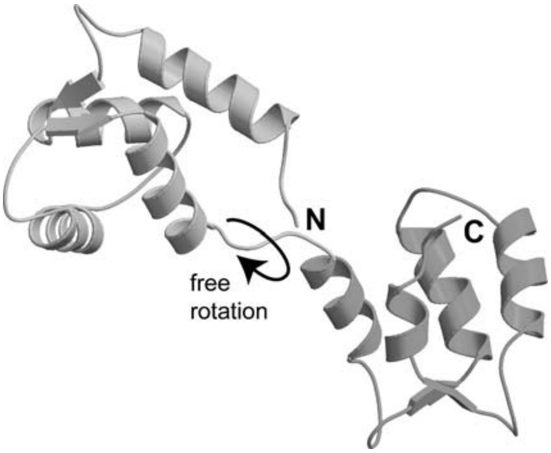

Fig. 3. Schematic representation of the NMR structure of apo-CaM, PDB code 1DMO model 11. The N- and C-terminal domains are shown in yellow and green, respectively, and the central flexible linker region in grey. The middle portion of the central linker is highly flexible similar to Ca^{2+}-CaM state. (See also Plate 54 on page XXXVIII in the Color Plate Section.)

of these Met residues were biosynthetically substituted by selemethionine [72]. The binding kinetics and stability of different metal ions to CaM has also been explored using heteronuclear NMR [73,74].

In recent years the interaction studies of paramagnetic lanthanide ions (Ln^{3+}) to CaM have become more popular due to their unique NMR properties. Bertini's group [75,76] has studied binding interactions of CaM with two Ln^{3+} metal ions including Yb^{3+} and Ce^{3+}. The solution structure of the $(Ce^{3+})_2$ complex of the N-terminal domain of CaM has been solved employing new NMR parameters, paramagnetic T_1 relaxation enhancements and pseudocontact shifts introduced by Ce^{3+} ions, to supplement conventional NOE-based distance constraints [76]. Recently, Bayley's group [77,78] has exploited further on the lanthanide interaction of CaM with Tb^{3+} ions. The partial replacement of diamagnetic Ca^{2+} by Tb^{3+} in Ca^{2+}–CaM allows the measurement of interdomain pseudocontact shifts as well as RDCs due to partial magnetic alignment of the molecule in presence of paramagnetic ion. These studies have become extremely useful for the determination of relative orientation of multidomain proteins.

Calcium-Calmodulin-Peptide Complexes

In early 1980s a number of ^{1}H and ^{113}Cd NMR studies [79–83] were done to examine the interaction with short peptides from either CaM binding domain of targets including skeletal muscle myosin light chain kinase (skMLCK), melittin or mastoparans. All these studies established that the peptides assume α-helical conformation upon binding CaM, and CaM also undergoes conformational change in presence of peptides. In 1991, the complete backbone assignment of ^{1}H, ^{15}N and ^{13}C for Ca^{2+}–CaM in complex with M13 (peptide derived from skMLCK) were reported [84] by using multidimensional heteronuclear NMR methods. ^{1}H assignments of M13 were also obtained using $^{15}N/^{13}C$-filtered experiment [85] and subsequently, the 3D NMR structure of Ca^{2+}-CaM–M13 complex was reported by Ikura *et al.* [66]. In the structure, the conformation of N- and C-terminal domains of CaM remains essentially unchanged even in complex with M13. However, the long central helix is disrupted into two helices connected by a long flexible loop (residues 74–82) as well as the orientation of several hydrophobic side chains are changed in the binding interface, thereby enabling the two domains to clamp around the helical peptide. The key anchoring hydrophobic residues of the peptide are responsible for anchoring the two domains of CaM are Trp-4 and Phe-17. A crystal structure of Ca^{2+}–CaM in complex with smMLCKp was reported [67] later in the same year, showing the same characteristic feature as observed for the solution structure of Ca^{2+}-CaM-M13. Subsequently, the structures of Ca^{2+}-CaM in complex with a number of peptides derived from CaMKI (CaMKIp) [86] and CaMKII (CaMKIIp) [68], and CaMKK (CaMKKp) [87,88] have been determined by crystallography and NMR. The structures of CaM in all these complexes are quite similar, with the two domains of CaM wrapping around the helical peptides. The CaM-CaMKK peptide complex differs from others in that the orientation of the peptide is in the opposite direction to that of CaMKIp, CaMKIIp, and M13 peptides with respect to the two CaM domains, and there is additional interaction with the unstructured tail following the helix (Figure 5). The recent dynamic studies of methyl side chains of CaM have explored the thermodynamic nature of CaM and target binding interface in details. Wand's group [89,90] has employed ^{2}H relaxation to probe methyl side chain dynamics of Ca^{2+}-CaM in presence and absence of smMLCKp. The dynamics of side chains are significantly perturbed and suggest extensive enthalpy and entropy exchange during the formation of CaM and target interface.

The target peptides are characterized by two bulky hydrophobic residues spaced 8, 12, and 14 residues apart, known as hydrophobic anchors and each anchor interacts with the hydrophobic pocket of one CaM domain. Based on the positions of anchoring residues, three different CaM binding motifs [91] (1–10, 1–14, and $1–16^{-}$) have been classified (1–10, CaM-CaMKIIp; 1–14, CaM-MLCKp; $1–16^{-}$, CaM-CaMKKp). The recognition modes of CaM with kinases differ from each other in the orientation of the two globular domains of CaM with respect to the helical binding region of the kinases (Figure 5). The flexible "inter-domain linker" between the two CaM domains is primarily responsible for rearrangement

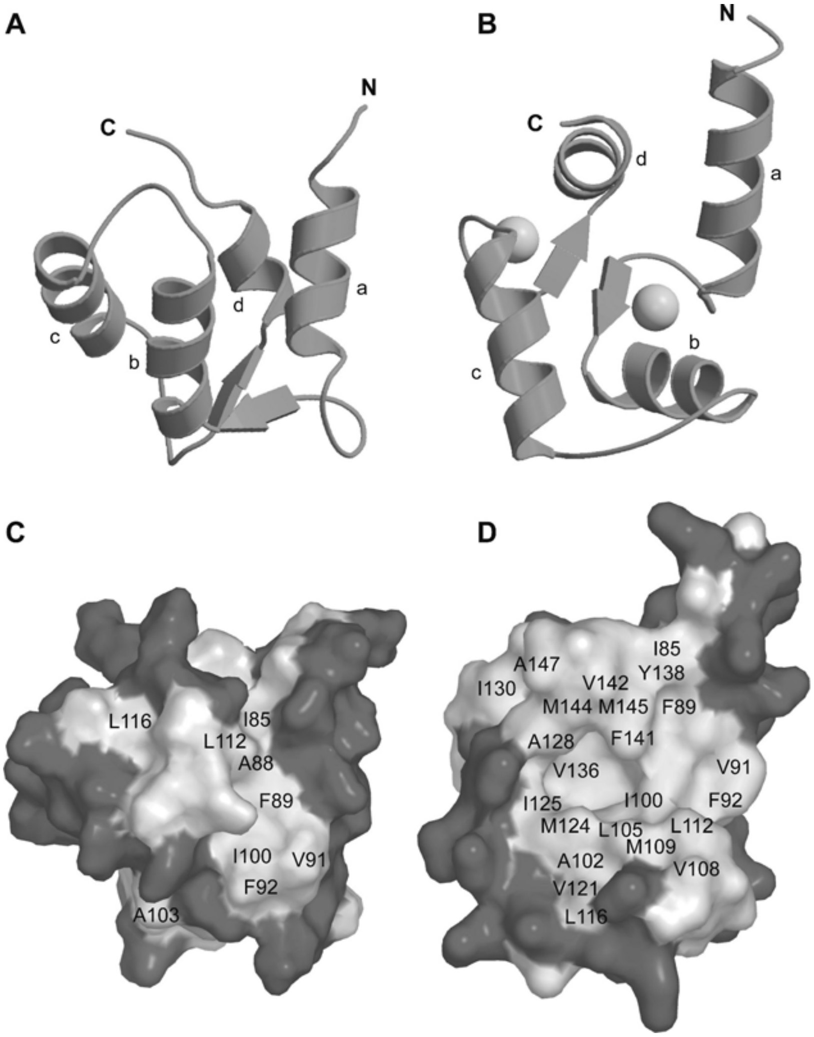

Fig. 4. Schematic representation of the C-terminal domain of CaM in the (A) "closed" Ca^{2+}-free and (B) "open" Ca^{2+}-bound states show Ca^{2+} induced conformation change in the EF-hand helix orientation. Helices are labeled with a, b, c, and d for easy visualization of helix orientation from "closed" to "open" state. Exposure of hydrophobic surface on binding of Ca^{2+} to CaM is shown in surface representation of both states of the C-terminal domain of CaM in (C) Ca^{2+}-free and (D) Ca^{2+}-bound. Hydrophobic residues (Ala, Ile, Leu, Met, Pro, Phe, Tyr, and Val) are shown yellow, negatively charged residues (Asp and Glu) in red, positively charged residues (Arg, His, and Lys) in magenta, and polar residues (Asn, Gln, Gly, Ser, and Thr) in white. Surface figures were generated using PyMol [111]. (See also Plate 55 on page XXXIX in the Color Plate Section.)

of the two domains in promoting an energetically favorable interaction with the target.

In 2002, Yap *et al.* [92] reported that more than 350 CaM target proteins had been identified thus far and that the binding domains of which had been classified in a database (http://calcium.uhnres.utoronto.ca/ctdb/) into several motif families based on sequence comparison. These sequence-based analyses, however, fail to predict CaM binding modes when no significant similarity is found between query and known sequences or when query sequences have several possible anchoring residues. Recently, Mal *et al.* [93] described a RDC-based NMR approach that can characterize the molecular recognition of CaM with target derived from protein kinases. RDCs

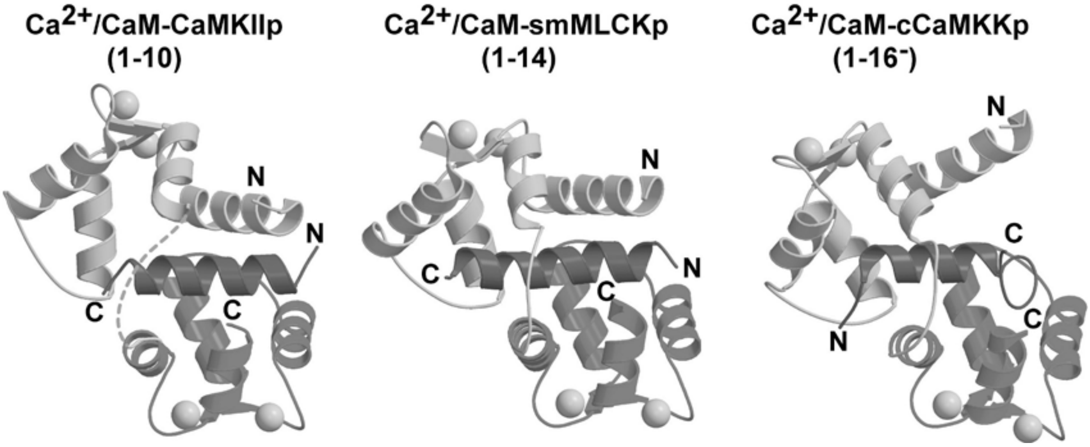

Fig. 5. (A) Ca^{2+}/CaM binding sequences from CaMKII, skMLCK, rCaMKK, CaMKI, and CaMKIV. The possible anchoring residues binding to the hydrophobic pocket of Ca^{2+}/CaM are highlighted in red. (B) Ribbon representation of three crystal structures of Ca^{2+}-CaM in complex with cCaMKKp (PDB code 1IQ5), smMLCKp (PDB code 1CDL), and CaMKIIp (PDB code 1CDM). Kinase-derived peptides are drawn in magenta, the N-and C-terminal domains are shown in yellow and green, respectively, and the central linker region and Ca^{2+} are in grey. (See also Plate 56 on page XL in the Color Plate Section.)

[94] contain information about the orientation of atomic bond vectors in a protein. In recent years, RDCs have been successfully used to characterize molecular binding [95–97], assist in homology modeling [98], and determine relative domain orientations [99,100] in multidomain proteins. Uniformly ^{15}N-labeled CaM was partially aligned in the negatively charged phage Pf1 phage (Asla Labs.). ^{1}H-^{15}N RDCs of CaM in complex with each target peptides derived from CaMKK, CaMKII, and MLCK, were experimentally measured and then analyzed in conjunction with the crystal structures of CaM-CaMKKp, CaM-CaMKIIp, and CaM-smMLCKp complexes using a best-fit molecular alignment tensor obtained by the singular value decomposition methods [100,101]. The best correlation was obtained when the experimental RDC data of a CaM-target peptide complex was compared with the corresponding crystal structure. For example, RDC data of CaM in complex with CaMKKp will have the best fit only with the CaM-CaMKKp crystal structure, not with the CaM-smMLCKp or CaM-CaMKIIp structure (Figure 6). Using this RDC-based NMR approach, the CaM binding motif (1–14 type) was determined in the complex of CaM–CaMKIp, for which no crystal and NMR structure was available at that time (Figure 7). This result was later

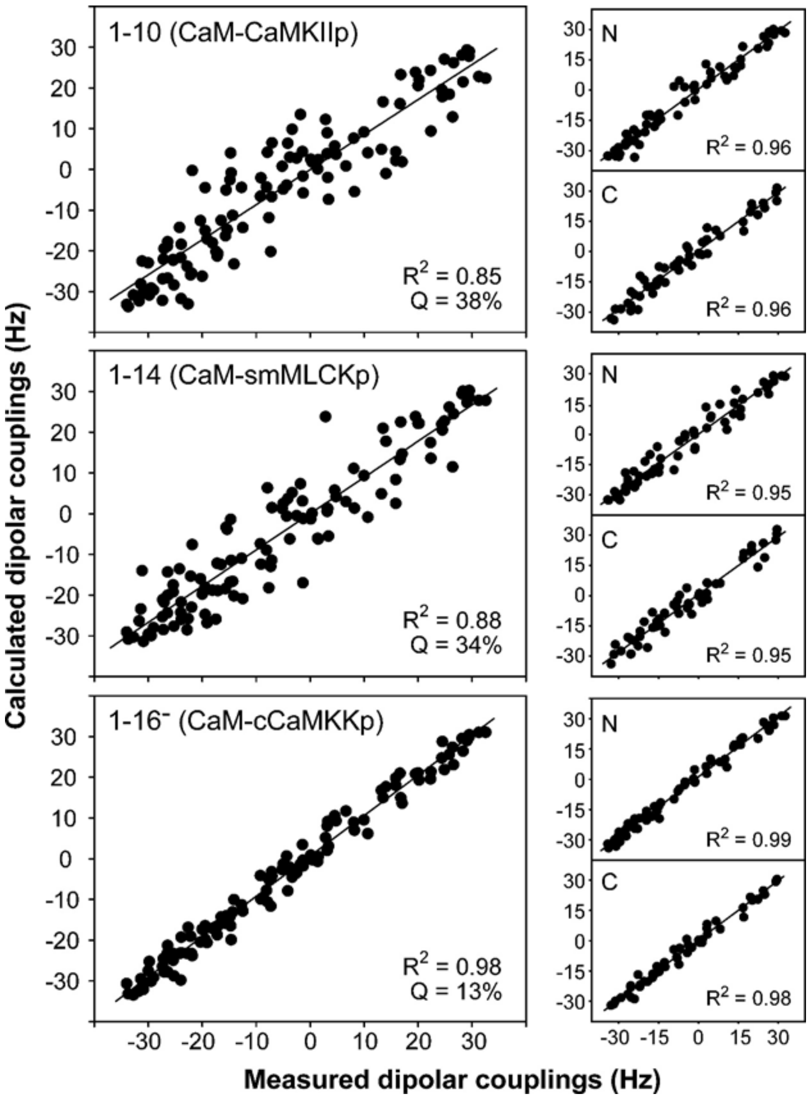

Fig. 6. Correlations between experimentally measured ^{1}H-^{15}N RDCs of the **CaM–rCaMKKp complex and the best fit RDC values calculated with the **CaM-CaMKIIp, CaM-smMLCKp, and CaM-cCaMKKp crystal structures. The correlation coefficient R^2 and quality factor Q for each complex are given in the plots. The correlations derived for individual domains (N and C) of CaM are shown in the small panels to the right. (Adopted by permission of the American Chemical Society from Mal *et al.* [93])

confirmed by the crystal structure of CaM–CaMKIp complex [86].

However, the orientation of the target helix remained undefined in this approach. Recently, Mal *et al.* [102] determined the orientation from a pair of ^{1}H-^{15}N correlation spectra of CaM in complex with a peptide construct containing an ATCUN (amino terminal Cu^{2+}(Ni^{2+})-binding) motif recorded with and without Cu^{2+}. They have taken the advantage of paramagnetic property of Cu^{2+} that specifically binds the ATCUN motif part of the peptide. By mapping the residues that were broaden due to the influence of paramagnetic relaxation of Cu^{2+} on CaM, the orientation of target peptide in a complex was quickly determined.

Two recent crystal structures of CaM-peptide complex demonstrates that other targets interact in a similar manner

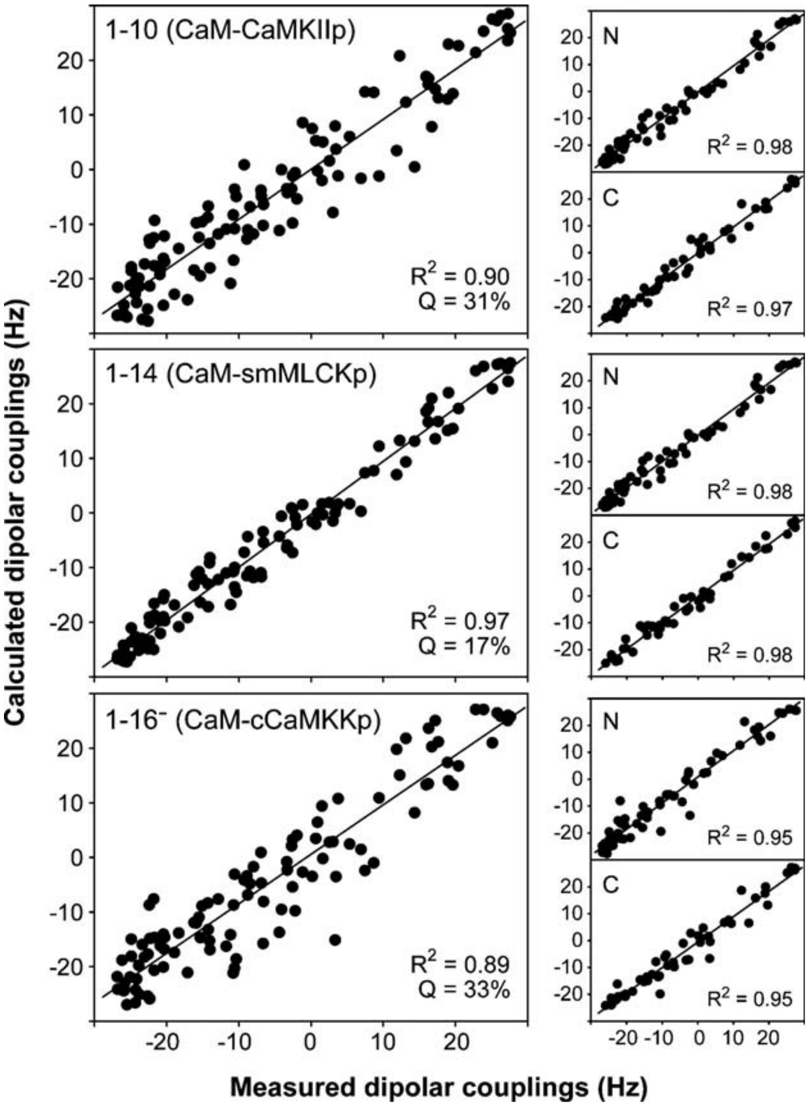

Fig. 7. Correlations between experimentally measured ^{1}H-^{15}N RDCs from the **CaM–CaMKIp complex and the best fit RDC values obtained with the crystal structures of CaMKIIp, CaM–smMLCKp, and CaM–cCaMKKp complexes. The correlations derived on the basis of individual domains (N and C) of CaM are shown in the small panels to the right. (Adopted by permission of the American Chemical Society from Mal *et al.* [93])

to the CaM-dependent kinase: CaM in complex with a peptide derived from endothelial nitic oxide synthase [103] illustrates an interaction similar to that of the CaM–MLCKp complex, while the interaction between CaM and a peptide from myristoylated alanine-rich C kinase substrate (MARCKS) [104] results in a similar CaM conformation, despite an elongated peptide structure containing only a single-turn helix. Therefore, the RDC-based NMR approach can also be applied to other complexes to define CaM binding mode beyond the complex with peptides from kinase family. The model of CaM-target interaction as two domains wrapped around a single, amphipathic

α-helix remaind until the crystal structure of CaM bound to the gating domain of the Ca^{2+}-activated K^+ channel (SK2) [105] and anthrax adenylyl cyclase (aAC) [106] were solved. These two complexes added diversity in to the CaM binding modes. The solution structure of CaM in complex with a dimeric peptide from plant glutamate decarboxylase has illustrated another unusual binding stoichiometry [107]. More recently, the study [108] between CaM and the target sequence from phosphofructokinase reveals that the complex is pH dependent and the affinity of complex formation increases 1000-fold from pH 9.0 to 4.8, adding another complexity into the CaM and target recognition.

In addition to these Ca^{2+}-dependent CaM-target peptide studies, there are a number of target proteins that interact with apo-CaM. Often these CaM binding domain contains a consensus sequence (IQXXGRXXXR), known as IQ motif [109] such as those found in myosin and neuromodulin. There are not many NMR studies available on the interaction of apo-CaM with IQ motif sequence. An early NMR study [110] was done on the complex of apo-CaM and a peptide derived from neurocalmodulin. This complex is sensitive to salt concentration suggesting that electrostatic interactions dominate to the complex formation. No structure of apo-CaM bound to a target or target peptide has been determined. It is very likely that CaM residues mediating the apo-CaM and target interaction are not entirely the same as those involved in Ca^{2+}-dependent interactions [110].

Despite the unique stoichiometry and secondary and tertiary structures of the targets bound to CaM in recently determined structures, CaM in all complexes display a remarkable conserved tertiary backbone (excluding the complex with SK2 and aAC), with the primary difference being the orientation of the N- and C-domains with respect to each other. This multiple-target binding ability of CaM should be attributed to the side chains comprising the hydrophobic patch exposed upon Ca^{2+} binding. NMR studies of CaM and its complex with various targets have contributed greatly to our understanding of its structure-function relationship. Despite a significant number of structural studies, there remains much to learn about the details of the mechanism of activation, in addition characterization of the other hundreds of CaM target proteins that have been identified over the two decades [92].

Acknowledgment

We thank Dr. Mingjie Zhang, The Hong Kong University of Science and Technology for providing apo-CaM assignments. This work is supported by the Canadian Institutes of Health Research. M. I. holds the Canadian Research Chair in Cancer Structural Biology.

Analytical Framework for Protein Structure Determination by Solid-State NMR of Aligned Samples

Alexander A. Nevzorov and Stanley J. Opella

Department of Chemistry and Biochemistry, University of California, San Diego La Jolla, California 92093-0307 USA

Abstract

A compact formulation of the experimental solid-state NMR observables in terms of the irreducible basis of rotations is presented. Quadratic-form representations are derived for the ^{15}N and ^{1}H chemical shift anisotropy, as well as ^{1}H–^{15}N and ^{1}H$_{\alpha}$–^{13}C$_{\alpha}$ dipolar interactions. Peptide plane geometries together with the torsion angles Φ and Ψ are incorporated into the corresponding Wigner rotation matrices, which allow one to establish the mapping of the protein structure onto its multidimensional solid-state NMR spectra in analytically semi-closed form. The structural fitting of experimental two-dimensional NMR spectra of Pf1 bacteriophage is presented. Examples of protein structure calculations from simulated three-dimensional solid-state NMR spectra for protein G, two-helical hairpin fragment of bacteriorhodopsin, and a loop region from KcsA are also presented. Moreover, analytical expression is obtained for the periodicity of secondary structures as an explicit function of Φ and Ψ.

Introduction

Solid-state NMR of aligned samples is emerging as a method for determining the atomic-resolution structures of proteins in biological supramolecular assemblies. Already, the structures of nine proteins determined with this approach have been deposited in the protein data bank. These include coat proteins in virus particles and membrane proteins in lipid bilayers. With the recognition that 20–30% of the proteins encoded in a genome are helical membrane proteins, and the difficulty in determining the structures of these proteins by conventional X-ray diffraction and solution NMR approaches, solid-state NMR of aligned samples has the potential to play an important role in structural biology.

There are three principal aspects to protein structure determination by solid-state NMR of aligned samples. First is the preparation of highly aligned samples of proteins that are immobilized by their associations with other biopolymers, for example the other coat protein subunits in virus particles or the phospholipids in membrane bilayers. Recent advances have made it possible to prepare magnetically aligned samples of proteins obtained by expression in bacteria with mosaic spreads less than or equal to those observed in single crystals of peptides. Second, multidimensional solid-state NMR experiments are needed to narrow the resonances and to measure several angular-dependent NMR frequencies for each residue in the polypeptide as input for structure determination. This follows in a long tradition of high-resolution solid-state NMR multiple-pulse and double- and triple-resonance experiments being applied to molecules of increasing complexity including proteins. Third, an analytical framework is needed that can effectively translate the orientation constraints into protein structures, and this is the subject of this chapter. We focus on determining the backbone structures of proteins labeled with ^{15}N and ^{13}C.

Heteronuclear dipolar couplings and the chemical shift anisotropy (CSA) associated with labeled ^{15}N and ^{13}C sites are the most common sources of angular constraints used to determine the orientations of peptide planes relative to the direction of the applied magnetic field. The detection of the orientation-dependent frequencies associated with these interactions is usually accomplished through a labeled dilute spin site such as ^{15}N and ^{13}C in peptide bonds. The ^{15}N CSA can be correlated with its corresponding ^{1}H–^{15}N dipolar interaction through separated local field experiments. Since the advent of this technique for aligned polymers was nearly 30 years ago [1], significant progress has been made with regard to narrowing spectral lines in the dipolar dimension using experiments such as MREV8 [2], TMREV [3], PISEMA [4], and SAMMY [5], which allows one to detect heteronuclear couplings (e.g. ^{1}H–^{15}N) under conditions of homonuclear (^{1}H–^{1}H) decoupling. Additional experimental measurements can be added including ^{1}H and ^{13}C CSA and ^{1}H–^{13}C dipolar couplings. This involves more sophisticated experiments and isotopic labeling. Examples of such experiments include the heteronuclear correlation experiment (HETCOR) and ^{1}H–^{15}N–^{13}C triple-resonance experiments with doubly labeled peptides [6]. Additional frequency dimensions not only enhance spectral resolution but also serve as sources of orientation restraints as input for structure determination.

The anisotropy of nuclear spin interactions results in a unique mapping of structure onto the resonance frequencies observed in NMR spectra of aligned samples. Therefore, it is straightforward to calculate solid-state NMR spectra from the structures of proteins [7–10]. This mapping is clearly demonstrated in the spectra of helices and sheets. For example, "wheel-like" patterns of resonances are observed in two-dimensional PISEMA spectra of helical membrane proteins. We refer to these patterns as polarity index slant angle (PISA) wheels [11,12]. They correspond to helical wheel projections and, hence, provide direct indices of secondary structure and topology; the 3.6 residues per turn periodicity of a α-helix results in an arc of 100° between adjacent residues in a helical wheel and between their resonances in a PISA wheel. The wheel-like pattern reflects the slant angle (tilt) of the helix, and the assignment of the resonances reflects the polarity (rotation) of the helix. When the helix axis is parallel to the direction of the applied magnetic field, all amide sites have the same orientation and all of the resonances overlap. Tilting the helix breaks the symmetry and introduces variations in the orientations of the amide NH bond vectors relative to the field. This is manifested as dispersions in the chemical shift and dipolar coupling frequencies. Since nearly all transmembrane helices are tilted with respect to the bilayer normal, the combination of the tilt and the 17° difference between the principal element of the ^{15}N amide chemical shift tensor and the NH bond vector makes it possible to resolve many resonances in two-dimensional separated local field spectra of polytopic membrane proteins. Dipolar waves are complementary and represent the periodic wave-like variations of the magnitudes of the dipolar couplings as a function of residue number, in the absence of chemical shift effects [13–15].

The PISA wheels for two different helix rotations (polarities) are identical because the dipolar and chemical shift frequencies reflect only the tilt of the helix axis. However, the spectra differ in their resonance assignments, whose patterns mirror exactly the polarity of the corresponding helical wheel. As a result, the PISA wheel patterns in experimental spectra can be used to assist the assignment process [16]. NMR spectra of selectively labeled samples are routinely used to assign resonances to types of amino acids; however, in this application they provide additional information. Using only ^{15}N labels and two-dimensional spectra, we have been able to assign the spectra of coat proteins in filamentous bacteriophages that have 40–45 residues in aligned helices [17–19], which is equivalent to three transmembrane helices. Further, the method can be readily extended to three-dimensional spectra if additional resolution is needed. The full application of "shotgun" NMR (named for the "spread" of labeled sites in the sequence and on the PISA wheel target) where the assignment and structure determination processes are performed in parallel, rather than sequentially, yields both complete resonance assignments and unique protein structures from the NMR data [16–20]. Inevitably, there will be some resonances that cannot be assigned with the shotgun approach. However, some elements of the mapping of structure onto the spectra assist in establishing unambiguous assignments in regions of non-periodic structures. For example, we found in the case of Pf1 coat protein that the N-terminal "double hook" structure has resonances that fall in a regular but not helical wheel pattern; they could be assigned with the assistance of a few selectively labeled samples and by eliminating possibilities established for other sites [18,19].

In the most general approach to structure determination of aligned samples, all types of secondary and tertiary structure can be handled with equal facility [21]. It is necessary to measure two or more frequencies for each residue of a protein in order to determine the orientation of a peptide plane. Once the orientations of all of the individual peptide planes are determined experimentally, then the planes are assembled into a complete protein structure because they are all related to the common axis defined by the direction of the applied magnetic field [7]. Side-chain orientations can be determined in a similar manner [22]. A key feature of this approach is that experimental determinations are made relative to an external non-molecular axis; therefore, the effects of errors and uncertainties in tensors and bond-lengths do not accumulate. Previous determinations of protein structures by solid-state NMR relied on orientation constraints derived from the frequencies of independently assigned resonances [16–20, 22–25].

In practice, we apply four complementary methods of interpretation to the solid-state NMR data: PISA wheels [11,12], Dipolar waves [13], Structural Fitting [26], and Direct Structural Calculation [16,21]. With partial or complete assignment information derived from the applications of PISA wheel and Dipolar waves to the helical residues and spin-exchange and triple-resonance experiments to linker and terminal segments, it is possible to perform "structural fitting" to the resonances in experimental PISEMA spectra [26]. Structural fitting is an alternative to structure calculations directly from the frequencies of individual resonances [7,21] and the related strategies being developed independently by Cross and co-workers [27,28], and Nielsen and co-workers [8,9]. With assignments, the structural fitting algorithm is able to identify minor structural variations such as kinks and bends in helices [15,17,20] and is equally capable of determining irregular structures in linker and terminal regions of membrane proteins.

A Spherical-Basis Treatment of Experimental Angular Constraints for Protein Structure Determination

A formulation for the backbone conformations in terms of the Cartesian basis, widely used in solution NMR for structure determination, is not very efficient for the structure calculations in NMR of aligned samples where the angular information is directly contained in the experimental observables. Therefore, there is a need for an alternative framework, which would treat these constraints in an angular basis without involving the Cartesian basis. Since the ultimate goal is to be able to calculate the protein structure directly from its solid-state NMR spectrum in an *ab initio* fashion, it is, therefore, important to determine the minimum number of experimental angular constraints that are necessary to determine the complete structure of a protein with atomic resolution.

We choose the irreducible spherical basis of rank 1 to relate the protein structure to its multidimensional solid-state NMR spectrum. Rank-1 irreducible basis can be easily converted back to the Cartesian *xyz* space, and its mapping onto the second-rank NMR observables can be implemented by constructing the relevant quadratic forms in this basis. Such a formulation utilizes much faster vector-matrix multiplications and, therefore, greatly reduces the time required to explicitly calculate the trigonometric functions involved in the analytical expressions for these observables.

Formulation of NMR Observables as Quadratic Forms

The molecular frame (MF) associated with an individual peptide plane is depicted in Figure 1. Here the x-axis is chosen along the NH bond, and the z-axis is perpendicular to the plane running through the N–H and C′N bonds (which would coincide with the ideal peptide plane). In terms of the orientation of the magnetic field relative to the MF given by the angles α and β, the solid-state NMR observables such as ^{15}N CSA and ^{1}H–^{15}N dipolar coupling can be written as:

$$\nu(^{15}N) = \sigma_{11}\sin^2\beta\sin^2(\alpha-\gamma) + \sigma_{22}\cos^2\beta + \sigma_{33}\sin^2\beta\cos^2(\alpha-\gamma) \tag{1a}$$

$$\nu(^{1}\mathrm{H} - {}^{15}\mathrm{N}) = \pm\chi\,\frac{3\sin^2\beta\cos^2\alpha - 1}{2} \tag{1b}$$

Here $\gamma = 17$–20° is the angle between the NH bond and the σ_{33} axis of ^{15}N CSA, and the dipolar coupling constant is given by: $\chi \equiv \dfrac{\gamma_N\gamma_H\hbar}{r^3_{N-H}}$.

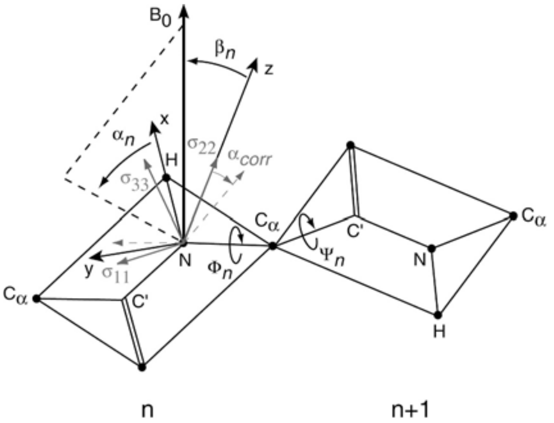

Fig. 1. Choice for the MF and the orientation of the CSA tensor relative to the peptide plane. Dashed arrows show the small tilt of the CSA frame away from the peptide plane given by the angle α_{corr}.

In the present formulation, instead of calculating the sine and cosine functions explicitly we invoke the irreducible spherical basis of rank 1. In the spherical basis, the above expressions for the frequencies can be rewritten in a unified manner as a more compact quadratic form.

$$\nu = \mathbf{Y}(\beta,\alpha)\left[\mathbf{D}(\Omega_{\mathrm{MP}})\,\mathbf{M}\,\mathbf{D}^{+}(\Omega_{\mathrm{MP}})\right]\mathbf{Y}^{+}(\beta,\alpha) \tag{2}$$

Here the Wigner matrix $\mathbf{D}(\Omega_{\mathrm{MP}})$ describes the transformation from the MF to the principal axis system of each tensor, $\mathbf{M}$ is the corresponding interaction matrix, and the superscript "+" denotes the Hermitian conjugate. The row vector of unnormalized spherical harmonics $\mathbf{Y}(\beta,\alpha)$ is given by the following combination of the trigonometric functions:

$$\mathbf{Y}(\beta,\alpha) = \left(-\frac{\sin\beta}{\sqrt{2}}e^{i\alpha}\ \ \cos\beta\ \ \frac{\sin\beta}{\sqrt{2}}e^{-i\alpha}\right) \tag{3}$$

and the rank-1 Wigner matrix is given by [29]:

$$\mathbf{D}(\Omega) \equiv \mathbf{D}(\alpha,\beta,\gamma) = \begin{pmatrix} e^{-i\alpha}\dfrac{1+\cos\beta}{2}e^{-i\gamma} & -e^{-i\alpha}\dfrac{\sin\beta}{\sqrt{2}} & e^{-i\alpha}\dfrac{1-\cos\beta}{2}e^{i\gamma} \\ \dfrac{\sin\beta}{\sqrt{2}}e^{-i\gamma} & \cos\beta & -\dfrac{\sin\beta}{\sqrt{2}}e^{i\gamma} \\ e^{i\alpha}\dfrac{1-\cos\beta}{2}e^{-i\gamma} & e^{i\alpha}\dfrac{\sin\beta}{\sqrt{2}} & e^{i\alpha}\dfrac{1+\cos\beta}{2}e^{i\gamma} \end{pmatrix} \tag{4}$$

For any CSA, the interaction matrix **M** is expressed via the principal components σ_{11}, σ_{22}, and σ_{33} as ($\sigma_{33} > \sigma_{22} > \sigma_{11}$):

$$\mathbf{M} = \begin{pmatrix} \dfrac{\sigma_{11} + \sigma_{22}}{2} & 0 & \dfrac{\sigma_{22} - \sigma_{11}}{2} \\ 0 & \sigma_{33} & 0 \\ \dfrac{\sigma_{22} - \sigma_{11}}{2} & 0 & \dfrac{\sigma_{11} + \sigma_{22}}{2} \end{pmatrix} \tag{5}$$

For ^{15}N CSA the Euler angles for the transformation are given by: $\Omega_{\mathrm{MP}}^{(15\mathrm{N})} = (\gamma, \pi/2, \pi/2 + \alpha_{\mathrm{corr}})$. If the σ_{11} and σ_{33} principal axes lie in the peptide plane, $\alpha_{\mathrm{corr}} = 0$, and Equation (1a) holds rigorously. However, there is evidence that the ^{15}N CSA tensor is slightly tilted off the peptide plane, for which $\alpha_{\mathrm{corr}} = 10 - 25°$ [30–34]. For the orientation of the ^{1}H CSA frame [35], one has: $\Omega_{\mathrm{MP}}^{(1\mathrm{H})} = (-\pi/2, -\pi/2, \pi/2)$.

For the dipolar interactions, the interaction matrix assumes a simple diagonal form:

$$\mathbf{M} = \chi \begin{pmatrix} -1/2 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & -1/2 \end{pmatrix} \tag{6}$$

For the ^{1}H–^{15}N dipolar coupling the Euler angles for the corresponding transformation are given by: $\Omega_{\mathrm{MP}}^{(1\mathrm{H}-15\mathrm{N})} = (0, \pi/2, 0)$.

The overall matrix in the square brackets in Equation (2) needs to be calculated only once, and the protein chain geometry is contained in the spherical harmonics, $\mathbf{Y}(\beta,\alpha)$. The latter vary throughout the backbone via the recurrence relation:

$$\mathbf{Y}(\beta_{n+1}, \alpha_{n+1}) = \mathbf{Y}(\beta_n, \alpha_n)\mathbf{P}(\Phi_n, \Psi_n) \tag{7}$$

The propagator matrix $\mathbf{P}(\Phi_n,\Psi_n)$ is given in terms of the product of two Wigner rotation matrices as [26]:

$$\begin{aligned} \mathbf{P}(\Phi_n, \Psi_n) = {} & \mathbf{D}(\alpha_{\mathrm{NC}_\alpha}, \Phi_n, \gamma_{\mathrm{tetra}}) \\ & \times \mathbf{D}(0, -\Psi_n - \pi, \gamma_{\mathrm{C}_\alpha \mathrm{C}}) \end{aligned} \tag{8}$$

In geometric terms, $\mathbf{P}(\Phi_n, \Psi_n)$ brings the MF associated with the n'th peptide plane into coincidence with the MF of the following residue, $(n + 1)$, as illustrated in Figure 1. The first Euler angle in the first Wigner matrix of Equation (8) is the angle between the y-axis of the MF and the N–C$_\alpha$ bond of the n'th plane, $\alpha_{\mathrm{NC}\alpha} = 151.8°$; the third Euler angle γ_{tetra} in the first Wigner matrix is the tetrahedral angle (typically 110–112° in real proteins instead of $\gamma_{\mathrm{ideal}} = 109.47°$); finally, the third Euler angle in the second Wigner matrix is the angle between the C$_\alpha$–C bond and the y-axis of the MF of the $(n + 1)$'th plane, $\gamma_{\mathrm{C}\alpha\mathrm{C}} = 34.9°$. The numerical values for the bond angles reflect the geometry of a standard peptide plane [36] and are assumed to be constant, regardless of the residue type or position in the sequence.

The situation for ^{1}H$_\alpha$–^{13}C$_\alpha$ dipolar couplings is slightly more complicated since the transformation from the MF associated with the preceding peptide plane involves an additional rotation about one torsion angle, Φ. This yields:

$$\mathbf{D}(\Omega_{\mathrm{MP}}^{(\mathrm{CH})}) = \mathbf{D}(\alpha_{\mathrm{NC}_\alpha}, \Phi - \rho, \pi/2 - \gamma_{\mathrm{ideal}})\mathbf{D}(0, -\pi/2, 0) \tag{9}$$

The angle ρ describes the Fischer projection angle for the C$_\alpha$–H$_\alpha$ bond. For the ideal sp^3 geometry it is equal to $\rho = 60°$. If γ_{tetra} is different from its ideal value, but the NC$_\alpha$H$_\alpha$ angle is still ideal, ρ is given by:

$$\rho = \arccos\left[-\frac{\tan(\gamma_{\mathrm{tetra}}/2)}{\tan \gamma_{\mathrm{ideal}}}\right] \tag{10}$$

Formal Geometric Properties of Polypeptide Chains

Using the matrix for the chain propagator, a useful closed-form expression can be obtained that gives the periodicity of various secondary structures directly as a function of the torsion angles. By explicitly finding the eigenvalues of matrix $\mathbf{P}(\Phi, \Psi)$, Equation (8), we obtain:

$$\begin{aligned} p &= \frac{2\pi}{\arccos[(1 - \cos \gamma_{\mathrm{tetra}})(1 - \cos(\Phi + \Psi))/2 - 1]} \\ &= \frac{2\pi}{\arccos[-(1 + 2\cos(\Phi + \Psi))/3]} \end{aligned} \tag{11}$$

The above equality is exact in the case of ideal $sp2$ hybridization of the bonds in a peptide plane, for which $\alpha_{\mathrm{NC}\alpha} = 150°$ and $\gamma_{\mathrm{C}\alpha\mathrm{C}} = 30°$. Two notable examples include the α-helix and β sheet. Substituting $\Phi = -65°$, $\Psi = -40°$ we get $p = 3.63$ for the α-helix. For the antiparallel β-sheet one has: $\Phi = -139°$, $\Psi = 135°$, and $p = 2.05$. Equation (11) shows that the periodicity is in fact a function of the sum of torsion angles Φ and Ψ. This demonstrates the potential of working in the irreducible basis of rotations. More closed-form expressions can be obtained for the β-turns, NH-bond tilt angles with respect to the helix axis, etc.

To calculate the three-dimensional protein structure, we obtain the position of any given bond relative to the laboratory frame of the N-th peptide plane, given by x, y and z, using the orientation of this bond relative to the MF given by x_{MOL}, y_{MOL}, and z_{MOL}. This is accomplished by summing over a series of rotational transformations from the laboratory to the MF given by the Euler angles Ω_{LM}:

$$\vec{v}^{\,+} = \left[\sum_{n=1}^{N} \mathbf{D}(\Omega_{\mathrm{LM}}^{(n)})\right] \vec{u}_{\mathrm{MOL}}^{\,+} \tag{12}$$

The coordinates relative to the molecular and laboratory frames, respectively, are given in the spherical basis as:

$$\vec{v} = \left(-\frac{x+iy}{\sqrt{2}}, z, \frac{x-iy}{\sqrt{2}}\right) \tag{13a}$$

$$\vec{u}_{\mathrm{MOL}} = \left(-\frac{x_{\mathrm{MOL}}+iy_{\mathrm{MOL}}}{\sqrt{2}}, z_{\mathrm{MOL}}, \frac{x_{\mathrm{MOL}}-iy_{\mathrm{MOL}}}{\sqrt{2}}\right) \tag{13b}$$

The transformations $\mathbf{D}(\Omega_{\mathrm{LM}})$ are decomposed in terms of the product of operators $\mathbf{P}(\Phi_j,\Psi_j)$ as:

$$\vec{v}^{\,+} = \mathbf{D}(\Omega_{\mathrm{LM}}^{(1)})\left[\mathbf{1} + \sum_{n=1}^{N-1}\prod_{j=1}^{n}\mathbf{P}(\Phi_j\Psi_j)\right]\vec{u}_{\mathrm{MOL}}^{\,+} \tag{14}$$

where $\Omega_{\mathrm{LM}}{}^{(1)}$ gives the orientation of the first peptide plane relative to the laboratory frame. Finally, the transformation back to the Cartesian basis can be readily accomplished using Equation (13a).

The Structural Fitting Algorithm

The structural fitting algorithm uses Equations (2)–(9) to determine the torsion angles Φ and Ψ between the NMR frequencies corresponding to two adjacent residues. Only absolute values for the dipolar couplings are used. Since the $^{1}\mathrm{H}_{\alpha}$–$^{13}\mathrm{C}_{\alpha}$ coupling for the preceding residue already contains one torsion angle, Equation (9), it can be used as an additional constraint to find the orientation of the peptide plane containing the following residue. The direction of the H_{α}–C_{α} bond is chiral, which greatly reduces the number of possible solutions for the peptide plane orientations (hence for the torsion angles Φ and Ψ) from considering just the ^{15}N CSA and ^{1}H–^{15}N dipolar couplings. The torsion angles are determined by minimizing the difference between the quadratic forms and the experimental data points which could be accomplished using a simplex algorithm. To be able to pick up different solutions, the starting values for Φ and Ψ are randomized. The simplex search also allows one to treat the experimental uncertainty of the data in a straightforward way, i.e. the search stops if the deviation from the data falls within a pre-defined error in Hz. Once a pair of Φ and Ψ angles satisfying the experimental restraints is found, the search continues onto the next residue pair. If no solution is found, the algorithm can go backwards and try to search for another solution for the previous residue(s). Additional restraints could be easily included in the search such as the Ramachandran angle restraints and specific residue-type information (CSA tensor values, bond angles, etc). The structural fitting algorithm was coded in MATLAB, which provides a fast and convenient tool for matrix calculations.

Examples of Structural Fitting

Structural Fitting to Two-Dimensional Spectra

In the case of relatively simple helical domains of proteins, a converged set of solutions can be found using only two spectral dimensions, e.g. ^{15}N CSA and ^{1}H–^{15}N dipolar couplings, by imposing Ramachandran angle restraints for the torsion angles. The angles are allowed to vary within a certain limited range relative to their ideal values, i.e. $\Phi = -65^{\circ}$, $\Psi = -40^{\circ}$. The fitting of the experimental two-dimensional spectra of Pf1 bacteriophage [18,19] is shown in Figure 2. The data in Figure 2(A–B) correspond to two temperatures, 30 °C and 0 °C, respectively, and it is known that the protein changes structure between these temperatures. As can be seen, the solid-state NMR spectra show significant differences at 30 °C and 0 °C, and the fitting of the spectra can provide the structural basis for this temperature transition. The fit of each spectrum was performed by assuming an experimental uncertainty of about 1 ppm or 76 Hz in each dimension, and the Φ and Ψ angles were allowed to vary within 20°. Slight variations in the CSA tensor values were also allowed to satisfy the Ramachandran restraints and the experimental data. The calculated protein structures are shown in Figure 2(C). The RMSD of the structural fit in each case is less than 2 Å. Only the average structures are shown.

Structural Fitting to Three-Dimensional Spectra

For proteins with more complex tertiary structures, additional frequency dimensions are needed. Figure 3A shows a simulated two-dimensional PISEMA spectrum of a membrane-associated version of protein G, using the torsion angles generated from its structure (pdb ID 2GB1, shown in blue) and assuming a fixed peptide plane geometry. This immunoglobulin-binding peptide is immobilized and aligned with the lipid bilayer when it is modified by N-terminal myristoylation [10]. The two-dimensional PISEMA spectrum has been back calculated, but does not yield a converged set of structures when subject to the procedures described above. By contrast, after including a third-frequency dimension, namely $^{1}\mathrm{H}_{\alpha}$–$^{13}\mathrm{C}_{\alpha}$ dipolar couplings, to form the simulated three-dimensional spectrum shown in Figure 3B, the RMSD of the calculated structures is reduced to about 3 Å (100 structural solutions are shown). This demonstrates that the $^{1}\mathrm{H}_{\alpha}$–$^{13}\mathrm{C}_{\alpha}$ dipolar

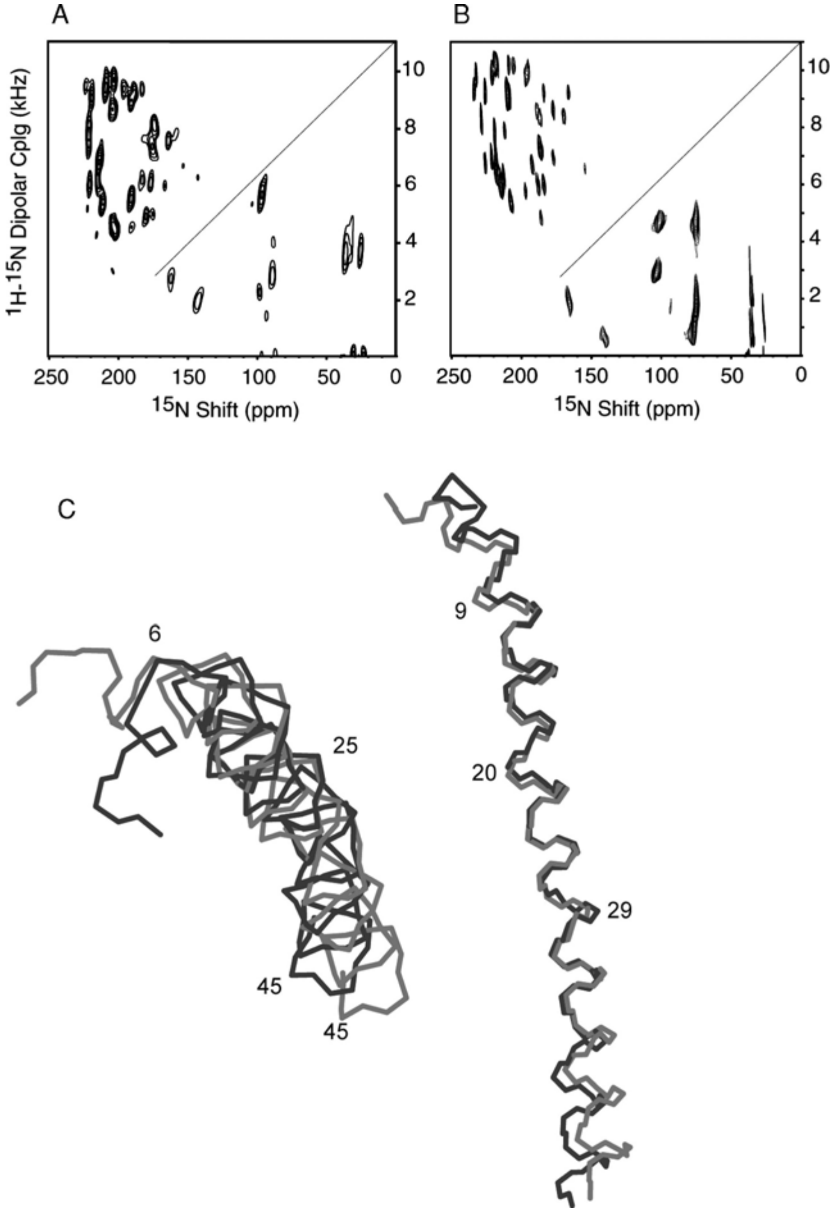

Fig. 2. Structural fitting of the experimental solid-state NMR spectra of magnetically oriented Pf1 bacteriophage. (A) Spectrum at 30 °C. (B) Spectrum at 0 °C. (C) High- (red line) and low- (blue line) temperature structures obtained from the fitting of the spectra. (See also Plate 57 on page XLI in the Color Plate Section.)

interaction is a powerful orientation constraint. Moreover, as shown in Figure 3C, mathematically unique solutions can be obtained if one assumes that the CSA frame is slightly tilted away from the peptide plane ($\alpha_{\text{corr}} = 25°$). In geometrical terms, this tilt introduces an additional chirality, and thus entirely eliminates the local orientational ambiguities associated with the even parity of the CSA and dipolar interactions.

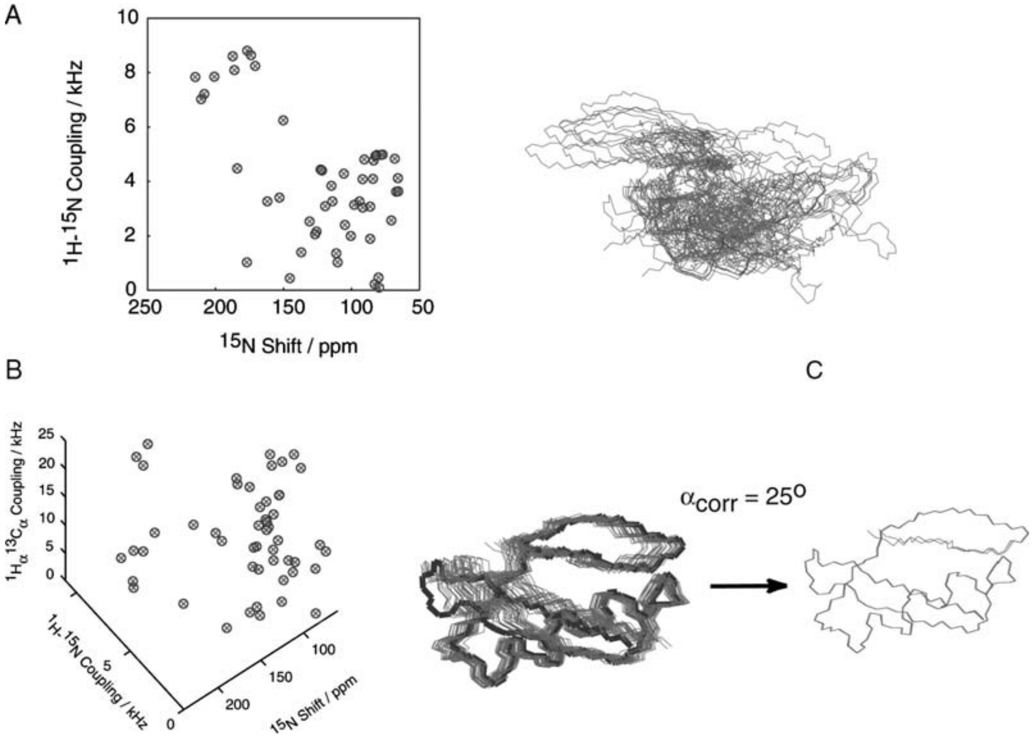

Fig. 3. Structural fitting of calculated solid-state NMR spectra of protein G simulated using the torsion angles generated from its pdb file and assuming constant peptide plane geometry. (A) Fitting of simulated spectra in two dimensions. No converged set of solutions. (B) Fitting of simulated spectra in three dimensions including $^1H_\alpha$–$^{13}C_\alpha$ dipolar interactions. Converged set of solutions (3 Å RMSD). (C) Fitting of simulated spectra in three dimensions assuming an additional tilt of the ^{15}N CSA frame, $\alpha_{corr} = 25°$. Unique solution is obtained in this case. (See also Plate 58 on page XLII in the Color Plate Section.)

Figure 4 shows the simulated three-dimensional spectrum for a two-helix hairpin extracted from the X-ray structure of bacteriorhodopsin (pdb ID 1C3W). Unlike in Figure 3, the spectrum was simulated entirely from the pdb coordinates, which include slight variations in the peptide plane geometry. The spectrum was back calculated using the structural fitting with the standard (fixed) peptide plane geometry. The RMSD of the structural fit shown in Figure 4 is about 3 Å. If one invokes the tilt ($\alpha_{corr} = 25°$) of the tensor relative to the peptide plane, then the RMSD is reduced to 1.5 Å. The success of such a structural fit can be regarded as a demonstration of feasibility for extending solid-state NMR to polytopic membrane proteins, for example GPCRs with seven transmembrane helices.

KcsA is well suited for its role as a principal test system for developing experimental and calculation methods to deal with the non-helical regions of membrane proteins. About 30% of its residues are in linker regions. It is relatively small and readily expressed and purified. Its crystal structure has been determined with atomic resolution [37,38]; therefore, it presents an excellent opportunity to compare the structure of a membrane protein in a crystal to that of the same protein in its native environment of fully hydrated lipid bilayers as in bicelles samples [39,40]. With the addition of the $^1H_\alpha$–$^{13}C_\alpha$ dipolar coupling frequencies, it is possible to determine the structure of all regions of the protein. This is illustrated in Figure 5 for the 12-residue loop encompassing residues 75–86 of KcsA. For clarity, the simulated data in "unflipped" bicelles are shown in two-dimensional spectra for the complete structure (Figure 5A) and for the loop region (Figure 5B). The structure of these residues in the crystal structure 1BL8 is shown in black in two views (Figure 5 C–D). The structure determined by structural fitting to the simulated NMR data is shown in gray, overlapped with the crystal structure. The RMSD between these two structures is 2.3 Å, which was accomplished with no constraints on the dihedral angles in the computer program.

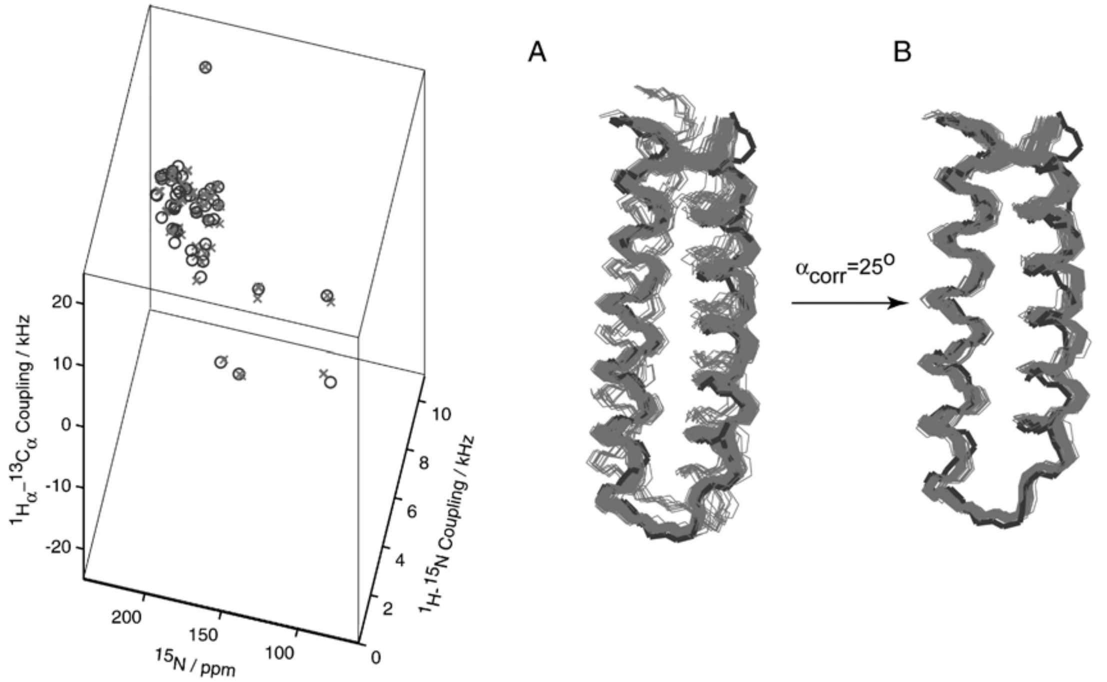

Fig. 4. Structural fitting of calculated three-dimensional solid-state NMR spectra for a two-helical fragment of bacteriorhodopsin simulated using its pdb coordinates. (A) Converged set of solutions with an RMSD of 3 Å. (B) Improved convergence using an additional tilt of the ^{15}N CSA frame ($\alpha_{\text{corr}} = 25°$), RMSD = 1.5Å. (See also Plate 59 on page XLII in the Color Plate Section.)

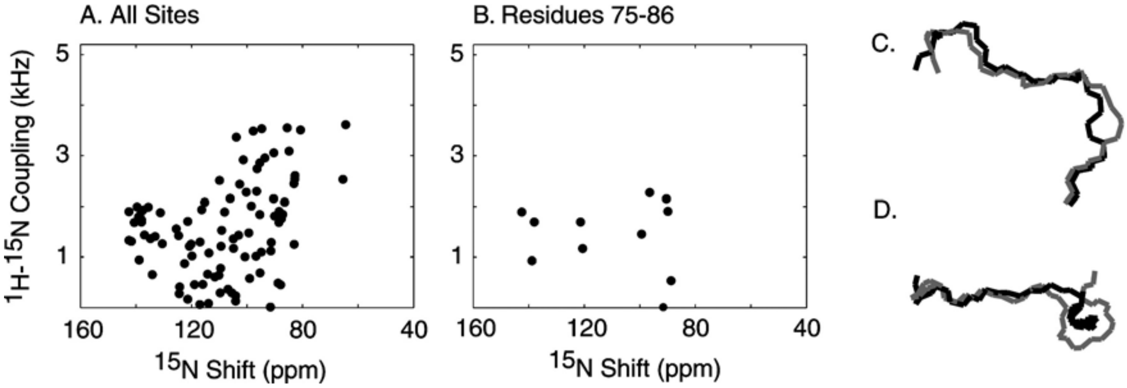

Fig. 5. (A) Simulated 2D PISEMA spectrum of uniformly ^{15}N labeled KcsA in “unflipped” bicelles. (B) Subset of resonances from residues 75–86. (C) and (D) Two views of the structure of residues 75–86. Black is from the crystal structure (1BL8) and gray is from structural fitting of the simulated three-dimensional NMR data including ^{1}H$_\alpha$–^{13}C$_\alpha$ dipolar interactions.

Conclusions

It is possible to calculate the three-dimensional backbone structure of a protein directly from its multidimensional solid-state NMR spectrum. A compact formulation for the solid-state NMR observables in an angular basis is described in this chapter. Analytical expressions for backbone conformations are obtained. The fitting method allows one to include the uncertainties in the experimental data as well as variations in the CSA components. The structural fitting program is fully automated and directly gives three-dimensional protein backbones as the final output. Unlike with earlier programs, there is no need to deal with degenerate solutions for the α and β angles, nor with complicated analytic expressions since the sines and cosines need not be calculated explicitly when the spherical basis is used.

The most important aspect of the structural fitting is the ability to calculate the structure of a protein from its NMR spectrum and to obtain a convergent set of solutions. For single-helix proteins and peptides, two-dimensional experiments can be sufficient since the Ramachandran angles Φ and Ψ occupy a relatively narrow window. To be able to obtain structures of proteins having arbitrary topology, additional frequency dimensions are necessary. The development of the relevant experiments is under way. Simulations can provide useful insights into the possibilities for the complete structure determination of membrane proteins from the angular-dependent solid-state NMR measurements. Since the solid-state NMR spectrum of an aligned protein can be readily simulated from its known structure, basic concepts of the structural fitting can be tested. It has been shown that without using any restrictions on the torsion angles, the combination of ^{15}N CSA, ^{1}H–^{15}N dipolar couplings, and ^{1}H$_\alpha$–^{13}C$_\alpha$ interactions yields a convergent set of structural solutions. An additional tilt of the ^{15}N CSA tensor frame may dramatically improve the convergence of the structural fit. More accurate measurements of the ^{15}N CSA tensor are needed to verify the presence of this tilt before it can be used with confidence in the actual structure calculations. To be able to account for the deviations from ideal peptide geometry, additional measurements may be necessary including C–N couplings and ^{1}H and ^{13}C CSA. It is also possible to further extend this method to the fitting of side-chain conformations, which could be done similarly to the treatment of ^{1}H$_\alpha$–^{13}C$_\alpha$ interactions.

The torsion angles are considered here to be the only degrees of freedom and the spectrum is fit in a sequential manner. Simulated annealing [41] of the solid-state NMR spectrum is also possible, and is perhaps more advantageous than the sequential fitting. Work is currently in progress with regard to implementing simulated annealing protocols in the structural fitting of solid-state NMR spectra of membrane proteins. The spherical-basis formulation presented herein has the potential to be used in torsion-dynamics simulations. With multiple ways of calculating protein structures from the orientation dependent frequencies measured on aligned samples, solid-state NMR has the potential to contribute to the structural biology of proteins in supramolecular assemblies.

Determining Protein 3D Structure by Magic Angle Spinning NMR

Ovidiu C. Andronesi, Henrike Heise, and Marc Baldus
Department for NMR-Based Structural Biology, Max Planck Institute for Biophysical Chemistry, 37077 Göttingen, Germany

Introduction

Solid-state NMR has long been utilized to study biomolecular structure and dynamics ranging from applications to protein complexes [1] and nucleotides [2] to membrane proteins [3–5] and protein fibrils [6]. In the case of macroscopically oriented membrane peptides, solid-state NMR furthermore has provided structural constraints to assemble three-dimensional (3D) membrane protein structures (see Ref. [7] for a recent review). Under magic angle spinning (MAS) [8], structural investigations were focused for a long time on the determination of local structural parameters. Recently, substantial progress has been made in NMR methodology, instrumentation, and sample preparation that now permits 3D molecular structure determination under MAS from one or a limited set of NMR samples. These approaches will be discussed in the context of this chapter. The interested reader is also referred to a series of recent review articles [9–11].

Sample Preparation and Methodology

Unless molecular size or mobility allow for the direct use of ^{1}H evolution and detection periods, a high degree of ^{13}C and ^{15}N isotope labeling is mandatory if molecular structure is to be investigated under MAS conditions. Depending on the application of interest, chemical synthesis, cell free, or bacterial expression systems are employed. In the case of protein expression in cell cultures, uniform isotope labeling is easily achieved using uniformly labeled starting media such as uniformly ^{13}C-labeled glucose and $^{15}NH_4Cl$. More advanced labeling patterns can be generated if specifically labeled precursors, amino acids, or growth media are supplied. In the case of membrane proteins, the uniformly labeled protein of interest is subsequently reconstituted into model membranes which can be studied in liposomes, possibly macroscopically oriented on solid glass [12] or polymer supports [13].

In a first stage, sequential resonance assignments must be obtained which are usually generated using a combination of (^{13}C,^{15}N) [14] and (^{13}C,^{13}C) [15] correlation methods. Since backbone chemical shifts provide a sensitive means of local dihedral angle constraints, these resonance assignments provide an easy and powerful instrument to assess polypeptide secondary structure. In addition to the conformation-dependent chemical shift ($\Delta\delta$, Figure 1), distances (encoded as dipolar couplings d) can be used to refine the local polypeptide conformation in the solid state. For example, the backbone (H_α, H_N) distance between sequential residues strongly correlates with the backbone dihedral angle ψ and can easily be detected during an NHHC correlation experiment [16]. Likewise, the sequential ^{15}N–^{15}N distance can be used to refine the backbone topology [17]. Information about the backbone conformation in the solid state can also be obtained by correlating two anisotropic interactions such as the chemical shift anisotropy (CSA) or the dipolar coupling in a two-dimensional (2D) experiment. Here, one exploits the defined orientation of dipolar tensors along the internuclear vector and empirical knowledge regarding the orientation of CSA tensors. These anisotropic interactions can be recoupled during the evolution and/or detection period of a homonuclear or heteronuclear 2D correlation experiment by appropriate radio frequency schemes. The resulting cross-peak pattern is characteristic for the relative orientation of the two anisotropic interactions [18]. In uniformly labeled peptides, correlations between NH/NH [19] and NH/CH [20] dipolar tensors have been used for backbone dihedral angle determinations. Alternatively, relative tensor orientation may be encoded in the evolution of a double-quantum (2Q) two-spin state under the effect of two anisotropic interactions. Applications correlating CH/NH [21] and CN/CN [22,23] dipolar couplings or sequential carbonyl CSAs [24] have been demonstrated. In a 2Q correlation experiment under CN dipolar dephasing, the signal amplitude can directly report on the backbone torsion angle and can hence conveniently be applied in multiply labeled polypeptides [14]. In the case of severe spectral overlap, extensions to three spectral dimensions are possible [25,26]. All these experiments can help to establish local distance or torsion angle constraints that can be supplemented in a conventional structure calculation.

The 3D structure is finally determined if medium- and long-range distance constraints can be derived from MAS

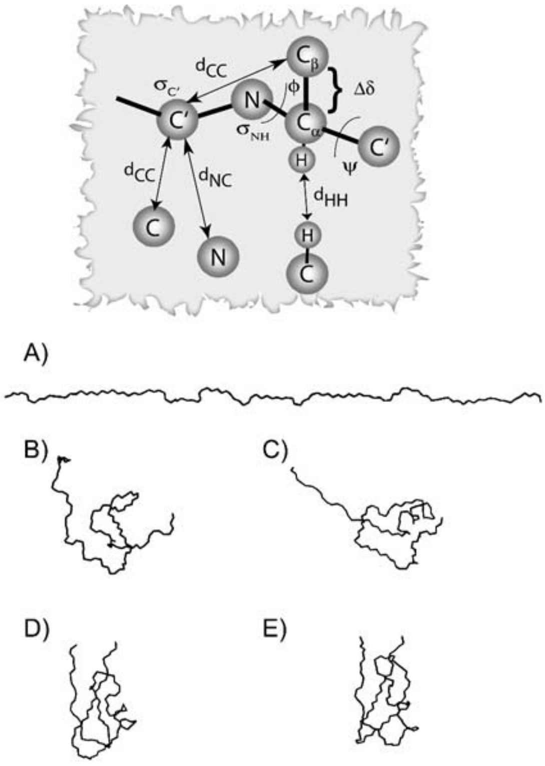

Fig. 1. Structural parameters to be detected in the context of MAS NMR: In addition to the isotropic chemical shift (which can be used to define conformation-dependent chemical shifts $\Delta\delta$) CSA interactions (such as σ_{C}, σ_{NH}) can be used to establish dihedral or orientational constraints. In addition, distances (d) determine local and overall molecular 3D structure and can be measured by a variety of experimental methods. The combination of these parameters can be used to construct a 3D molecular structure from a single, or a small set of isotope-labeled molecules under MAS conditions. In (A)–(E), different stages of structure calculation routine based on MAS NMR data are exemplified for the case of KTX (see Ref. [30] and text for further details).

NMR data. In the case of uniformly labeled molecules, the spin systems dynamics are dominated by one-bond (^{13}C,^{13}C) and (^{13}C,^{15}N) interactions. If spectral dispersion is favorable, selective (^{13}C,^{15}N) or (^{13}C,^{13}C) distance measurements can be performed in uniformly labeled peptides [27] and proteins [28]. Moreover, isotope labeling schemes can be applied that lead to a partial dilution of the coupled (^{13}C,^{15}N) spin network. As a result, the influence of one-bond interactions is reduced and local (^{13}C,^{13}C) dipolar couplings can become comparable to medium- and long-range interactions [29]. In addition, proton–proton distance restraints that provide the most abundant source of inter-residue interactions in the range up to 4 Å can be probed. For this purpose, indirect detection schemes are available that encode proton–proton polarization transfer in high-resolution ^{15}N and ^{13}C evolution and detection periods [16]. Finally, orientational constraints can be established if anisotropic interactions such as NH CSA or dipolar tensor components are measured in macroscopically oriented systems. Under fast MAS, tailored RF schemes that [13] recouple anisotropic interactions can be used.

The details of a subsequent structure calculation are exemplified for the 38 amino acid polypeptide kaliotoxin (KTX): First, an extended conformer is created (Figure 1A) and subjected to simulated annealing protocol consisting of several stages. While in Figure 1B, three disulfide bonds are used as sole structural constraints, we have incorporated in (Figure 1C) 65 dihedral angle restraints. As a result, secondary structure is formed but the overall 3D fold remains undefined. For this reason, proton–proton distance restraints are supplemented which relate to unequivocal spectral assignments in the first (Figure 1D) or second round (Figure 1E) of structure calculations. An ensemble of conformers with the lowest energy is finally reported. Further details of the structure calculation in the case of KTX are given in Ref. [30].

Applications

Probably, the first molecular structure determined purely by MAS-based NMR was reported by Terao and coworkers [27] and relates to the dipeptide glycyl isoleucine (Figure 2A). In this case, chemical shift selective transfer methods were applied to determine (^{13}C,^{13}C) distance constraints. Three years later, the molecular structure of the tripeptide *N*-formyl-L-Met-L-Leu-L-Phe-OH (Figure 2B) was published [31]. Here, NMR experiments were conducted on a uniformly (^{13}C,^{15}N)-labeled sample. Three differently (^{13}C,^{15}N)-labeled protein samples were employed to determine the 3D fold of a microcrystalline sample of the α-spectrin SH3 domain (1M8M, [29,32]) and of the 11-amino acid stretch of transthyretin (TTR(105–115), [33]). The corresponding structures are shown in Figure 2C and D.

Using indirectly detected proton–proton interactions, our group has recently [30] determined the 3D structure of a uniformly (^{13}C,^{15}N)-labeled version of KTX that strongly inhibits potassium ion channels. No attempts were made to obtain microcrystalline material. Proton–proton distance restraints and dihedral angle constraints derived from conformation-dependent chemical shifts resulted in 3D structure with an average backbone RMSD of 0.81 Å. The 10 conformers with the lowest energy are shown in Figure 2E (PDB entry: 1XSW). Structures

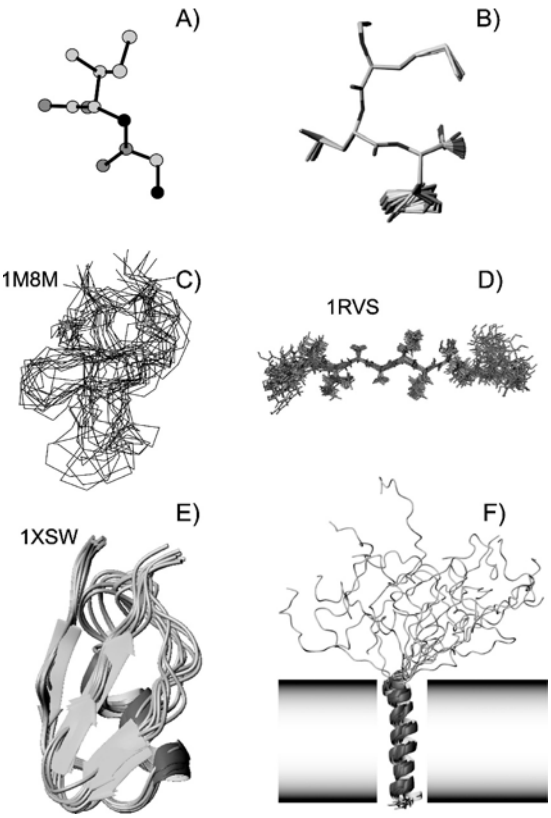

Fig. 2. Structures of polypeptides determined thus far by MAS solid-state NMR. The PDB file numbers are given when available. (A) The dipeptide glycyl isoleucine. (D) An 11-amino acid stretch of transthyretin (TTR(105–115)), (E) Kaliotoxin (KTX) and (F) phospholamban in lipid bilayers. (See also Plate 60 on page XLIII in the Color Plate Section.)

with a different fold display significantly higher overall energies. Refinement of these structures using software routines originally developed for the solution state is ongoing.

In the case of phospholamban (PLN, Figure 2F), the topology in lipid membranes was determined using a combination of dipolar and scalar polarization schemes [34]. The latter techniques permit one to also probe dynamic disorder in cytoplasmic segments of the protein. In principle, the supramolecular arrangement of partially immobilized macromolecules can be probed by similar experiments, provided that the monomer conformation is known [35,36] or if isotope labeling schemes are used that permit discriminating between intra- and intermolecular transfer [37].

Conclusions

MAS-based solid-state NMR has recently made considerable progress in the structural study of polypeptides and proteins. In many of these investigations, spectral assignments provide the basis for further investigations of 3D structure or dynamics. Recent applications include protein aggregates and fibrils, membrane-interacting peptides and proteins and the analysis of protein–protein interactions. Advances regarding sample preparation (e.g. including modular labeling, *in vitro* expression, and intein technology [38]) and improvements in NMR hardware instrumentation could open up new areas of solid-state NMR research such as the investigation of large protein–protein complexes or the complete 3D characterization of larger membrane proteins.

Clearly, additional efforts to streamline 3D protein structure determination by MAS NMR are necessary. Novel concepts may make extensive use of the rapidly increasing power of bioinformatics and computational chemistry. Already, general approaches have appeared to predict 3D structure from a limited set of solution-state NMR data. In parallel, the ability to relate molecular structure to NMR detectable parameters by *ab initio* quantum chemistry calculations and DFT approaches is improving. These techniques already have empowered novel material science applications of solid-state NMR and will greatly expand the use of MAS solid-state NMR for the study of polypeptides and proteins. Complementary to crystallographic methods and solution-state NMR techniques, MAS solid-state NMR methods hence provide a powerful tool to study protein structure, folding, and function under biologically relevant conditions.

Introduction

Because of their ubiquitousness and abundance as well as their many unique physicochemical properties arising primarily from the presence of a haem group, usually an iron–protoporphyrin IX complex (protohaem; structure shown in Fig. 1A), haemoproteins are the most studied group of proteins. Haem is the prosthetic group of a number of proteins possessing remarkably different functions, *i.e.* oxygen storage or transport proteins (myoglobin (Mb) or haemoglobin), electron transfer proteins (cytochromes, etc.), oxidase enzymes (peroxidase, catalase, etc.), and gas sensor proteins (Fix L [1], Haem AT [2], etc.). Since these proteins contain the same prosthetic group at their active sites, their functional differences are thought to arise from differences in the way that they interact with the haem.

Myoglobin, a typical haemoprotein, is a monomeric protein with a molecular weight of about 17 kDa, and a single haem is embedded in its protein moiety, which consists of eight helices (A–H) (Fig. 1B). The haem iron is bound to the protein matrix through the proximal His residue (His F8), the 8th residue in the F helix (Fig. 1C). In general, the haem iron in Mb is either in the ferrous or ferric state. The numbers of electrons in the 3d orbitals of ferrous and ferric iron are six and five, respectively. Hence, the total spin quantum number S is an integer and half-integer for ferrous and ferric irons, respectively. Depending upon the degree of spin pairing of electrons in the 3d orbitals, ferrous haem iron can have 4, 2, or 0 unpaired electrons, corresponding to $S = 2$, 1, or 0, respectively, and for ferric haem iron $S = 5/2$, $3/2$, or $1/2$ with 5, 3, or 1 unpaired electron, respectively. Based on an octahedral ligand field, the energy levels of the five 3d orbitals of the iron atom are split into two groups in such a way that the levels of the d_{z^2} and $d_{x^2-y^2}$ orbitals are higher than those of the other three orbitals, d_{xy}, d_{yz}, and d_{xz} (Fig. 2). The spin state of a haemoprotein depends on the chemical nature of the ligand. For ferrous haem iron, the deoxy (no ligand) form is penta-coordinated with a high-spin configuration, $S = 2$, and the oxy (O_2) or carbonmonoxy (CO) form possesses a low-spin configuration, $S = 0$. On the other hand, the binding of ligands of relatively weak field strength such as H_2O to ferric haem iron gives high-spin state $S = 5/2$ (met-aquo form), and low-spin state $S = 1/2$ is achieved with a strong ligand such as CN^- (met-cyano form). There are some ferric haemoproteins, such as the met-hydroxyl (OH^-), -azido (N_3^-), and -imidazole forms, that exhibit values of magnetic susceptibility between those of the high- and low-spin states. Each of these proteins was found to be a mixture of the high- and low-spin states [3].

Taking advantage of unpaired electron(s), resonances arising from nuclei located in close proximity to the paramagnetic center exhibit hyperfine shifts and hence are observed outside of the diamagnetic envelope in which signals due to the protein overlap severely. Hyperfine shifted signals are extremely sensitive to structural properties of molecules, as has been fully described elsewhere [4–17], and NMR studies on paramagnetic haemoproteins have provided a wealth of information about the detailed haem–protein interaction, which could provide valuable insights into the structure–function relationships of these proteins [9,10,12,15]. Although ^{1}H NMR is a powerful tool for characterizing the haem–protein interaction at the active sites of proteins, characterization of physiologically relevant forms of a protein, *e.g.* in the cases of Mb, oxy Mb, and deoxy Mb, is often hampered by the resolution of the signals. In order to overcome the problem of signal overlapping, the use of ^{19}F NMR for the study of the structure–function relationships of haemoproteins has been proposed [18–25]. Owing to the absence of interfering background signals, the introduction of fluorine atom(s) into the side-chain(s) of haem facilitates the observation of their signals in various oxidation, spin, and ligation states of haemoproteins, which are expected to serve as potential spectroscopic probes for characterizing the haem–protein interaction [20,21,23–25]. The van der Waals radius of a fluorine atom is only slightly larger than that of a hydrogen atom, *i.e.* 0.135 and 0.11 nm for fluorine and hydrogen, respectively, and hence the introduction of fluorine atom(s) into a molecule of interest is expected to

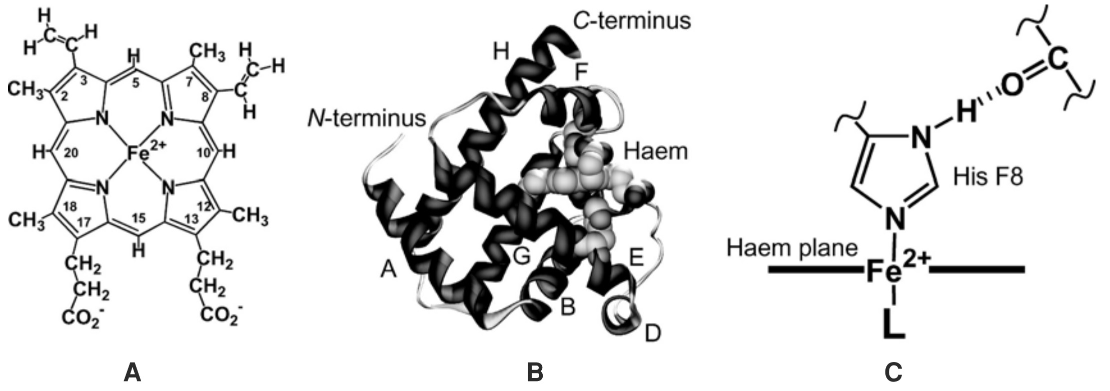

Fig. 1. (A) Structure and numbering system for the iron–protoporphyrin IX complex (protohaem) and (B) the X-ray structure of Mb from skeletal muscle of sperm whale, *Physter catodon* [55] (The haem and protein are illustrated as space-filling and ribbon models, respectively. The eight helices are labeled A–H.), and (C) the structure of the ligand-binding site in Mb. The iron is coordinated to proximal His (His F8) and an exogenous ligand (L).

perturb its structure only slightly. On the other hand, care should be taken regarding large perturbations in the electronic structure of the molecule, which may be caused by ^{19}F labeling due to its high electronegativity. ^{19}F is a 100% abundant nucleus with nuclear spin $I = 1/2$ and, because of a relatively high gyromagnetic ratio, ^{19}F NMR is about 83% as sensitive as ^{1}H NMR. Furthermore, a high gyromagnetic ratio of ^{19}F facilitates the observation of dipolar connectivity between ^{19}F nuclei or between ^{19}F and ^{1}H nuclei, which provides valuable information about molecular structure. In addition, because of the wider spectral range for ^{19}F NMR than ^{1}H NMR, the former is considerably more sensitive to the local magnetic environment than the latter. Therefore, it is more likely that individual signals will be resolved on ^{19}F NMR and the signals will in turn be a sensitive probe for detailed characterization of proteins at the atomic level.

^{19}F Labeling of *b*-Type Haemoproteins Using Reconstitution

A technique called reconstitution, combined with the use of fluorinated haems [20,26–31], can be used to introduce fluorine atom(s) selectively and specifically into the active sites of *b*-type haemoproteins. Hence, this ^{19}F labeling is completely different from that utilized for the ordinary proteins [32–36]. As schematically illustrated in Fig. 3, haem (protohaem; structure shown in Fig. 1A) was extracted from a native protein according to the method previously described [37]. Since there is no covalent bond between the haem and the protein moiety in a *b*-type haemoprotein, partial unfolding of the protein at pH < 2.7 promotes haem release. The released haem is extracted from the apo-protein solution using 2-butanone. Then the apo-protein solution is exhaustively dialyzed against water to remove 2-butanone distributed. The apo-protein solution is adjusted to neutral pH and then a stoichiometric amount of the haem of interest is mixed in to reconstitute the holo-protein. Using the reconstitution technique, desired haems and even non-haem compounds can be incorporated into *b*-type haemoproteins.

Aiming at incorporation into Mb, several fluorinated haems have been synthesized (Fig. 4) [18,21,26–31]. The initial attempts to incorporate fluorine atom(s) into haem were focused on the substitution of a perfluoromethyl group, CF_3, for the haem methyl group [26–30]. The introduction of a strongly electron-withdrawing

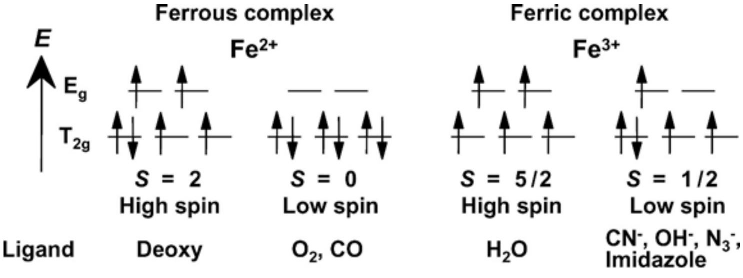

Fig. 2. Haem iron oxidation/spin states of Mb.

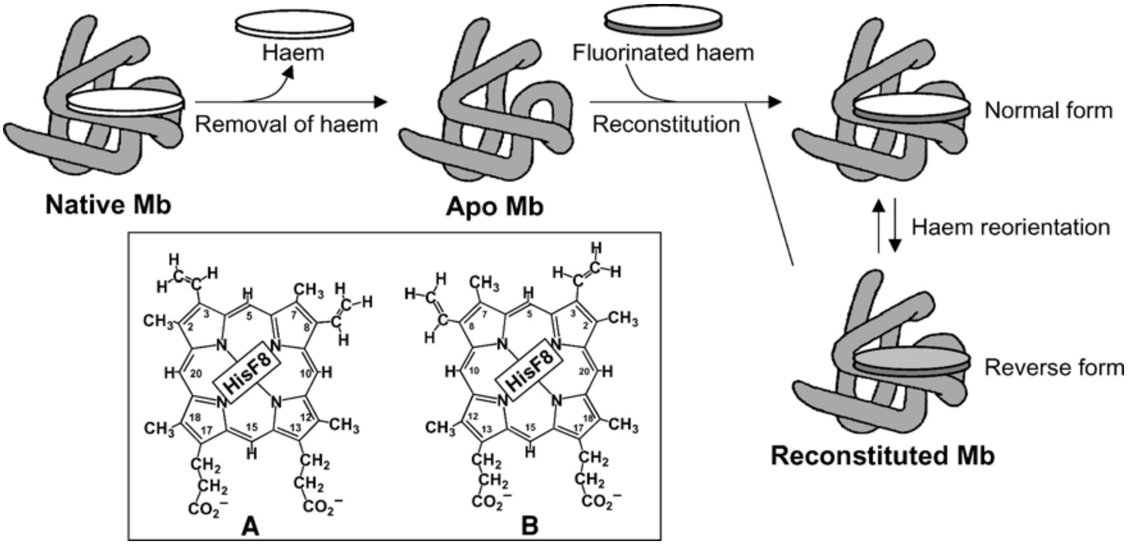

Fig. 3. Schematic representation of the ^{19}F labeling of haem peripheral side-chain(s) in a *b*-type haemoprotein using the reconstitution technique. Two possible orientations of haem relative to His F8 are shown in the inset; (A) that found in the crystal structure of sperm whale Mb [55] and (B) that with the haem rotated by 180° about the 5,15-H meso axis from that of (A).

perfluoromethyl group into the porphyrin ring, however, greatly affects the π-system of the haem and has marked effects on the physicochemical properties of haems as well as Mb reconstituted with such fluorinated haems [30,31,38–40]. On the other hand, ring-fluorination of porphyrin is expected to induce relatively small perturbation of the haem electronic structure due to a strong repulsive interaction between electrons in the π orbitals of the fluorine atom and the π-system of the porphyrin ring, and therefore provides a suitable ^{19}F NMR probe for characterization of the haem–protein interactions in proteins [18,20,21,24].

^{19}F NMR *vs.* ^{1}H NMR

^{19}F and ^{1}H NMR spectra of the *bis*-cyano form of 13,17-*bis*(2-carboxyethyl)-3,7-difluoro-2, 8, 12,18-tetramethyl-porphyrinatoiron(III) (3,7-DF; structure shown in Fig. 4C) and Mb reconstituted with 3,7-DF [Mb(3,7-DF)] in

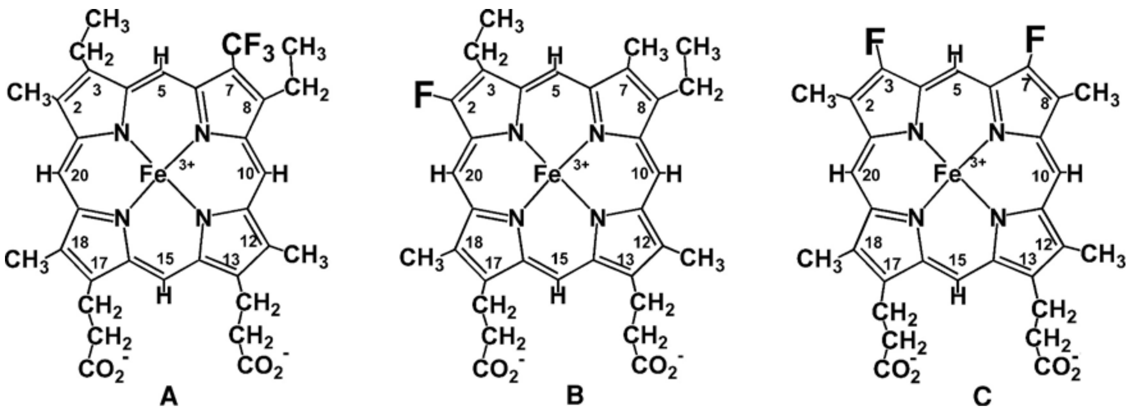

Fig. 4. Structures of (A) 7-PF: 13,17-*bis*(2-carboxylatoethyl)-3,8-diethyl-2,12,18-trimethyl-7-trifluoro-methylporphyrinatoiron(III) [29], (B) 2-MF: 13,17-*bis*(2-carboxylatoethyl)-3,8-diethyl-2-fluoro-7,12,18-trimethylporphyrinatoiron(III) [18], and (C) 3,7-DF:13,17-*bis*(2-carboxylatoethyl)-3,7-difluoro-2,8,12,18-tetramethyl-porphyrinatoiron(III) [20].

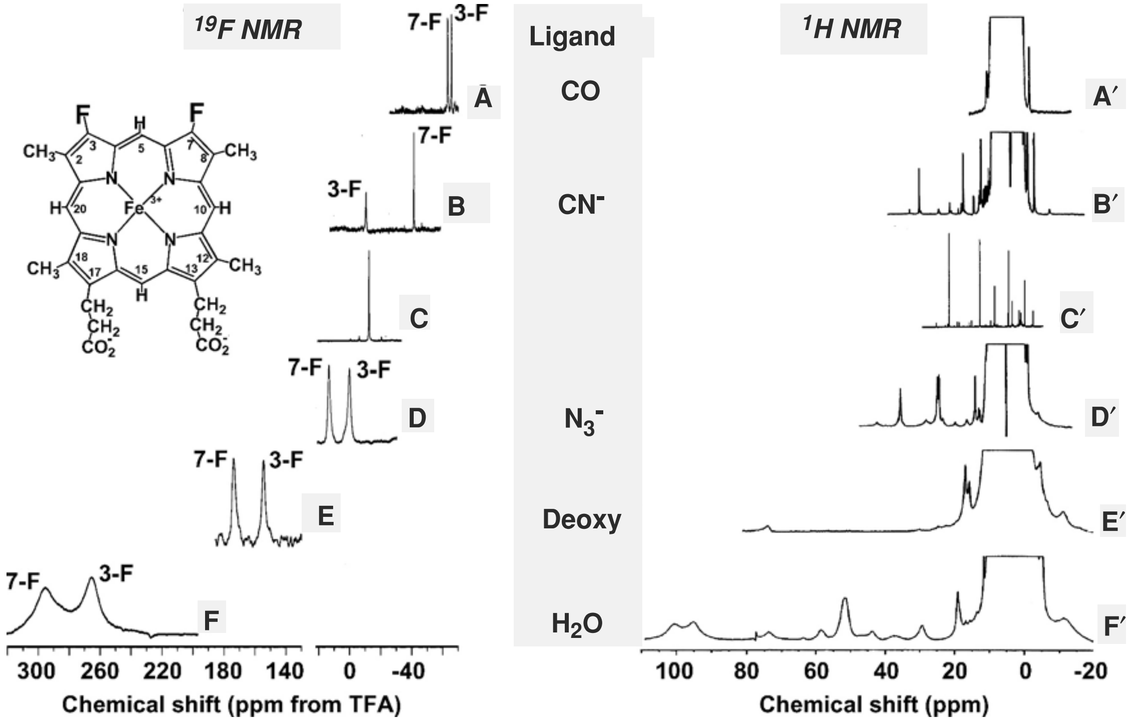

Fig. 5. (A–F) 376 MHz ^{19}FNMR spectra of Mb(3,7-DF) in various oxidation/spin/ligation states and *bis*-cyano 3,7-DF, and (A′–F′) ^{1}H NMR spectra of the corresponding proteins and haem complex. (A, A′) CO Mb, pH 6.15, (B, B′) met-cyano Mb, pH 8.03, (C, C′) *bis*-cyano 3,7-DF, (D, D′) met-azido Mb, pH 7.48, (E, E′) deoxy Mb, pH 7.08, and (F, F′) met-aquo Mb, pH 7.02, at 25 °C. The peak indicated by an asterisk arose from an impurity. The molecular structure of and numbering system for 3,7-DF are indicated in the inset.

various oxidation, spin, and ligation states are compared in Fig. 5.

Bis-cyano 3,7-DF ($S = 1/2$)

As expected from the C_2-symmetric nature of the electronic structure of 3,7-DF, a single ^{19}F NMR signal is observed at -18.04 ppm relative to trifluoroacetic acid (Fig. 5C). The ^{1}H NMR spectrum of *bis*-cyano 3,7-DF is compared with that of *bis*-cyano protohaem in Fig. 6. The C_2-symmetry of the haem electronic structure of 3,7-DF about the 5,15-H meso-proton axis is supported by the observation of only seven ^{1}H NMR signals in the spectrum. The spread of haem methyl proton signals for *bis*-cyano 3,7-DF is larger than that for *bis*-cyano protohaem, indicating that the introduction of fluorine atoms into the porphyrin ring at the 3- and 7-positions increases the differences in unpaired electron density between pyrroles I, II and pyrroles III, IV. The upfield-shifted meso H-5 proton signal of *bis*-cyano 3,7-DF, relative to the corresponding signal of *bis*-cyano protohaem, could also be attributed to the effect of fluorine substitution. Despite these differences, the similarity in the ^{1}H NMR spectral pattern between the two *bis*-cyano haems indicates that the influence of the fluorine substitution on the haem electronic structure is rather small.

Carbonmonoxy Mb ($S = 0$)

The observation of two signals in the ^{19}F NMR spectrum of CO Mb (Fig. 5A) is not due to the presence of haem orientation isomers [41] (see below), because 3,7-DF possesses a twofold rotation axis along the 5,15-H meso-proton axis, but results from the removal of the degeneracy of the magnetic environments of the two fluorine atoms of the haem through the haem–protein interaction. In the ^{1}H NMR spectrum of diamagnetic CO Mb, a methyl proton signal is present in the furthest upfield-shifted region due to the ring-current effect of haem, and this signal has been assigned to the γ-CH_3 proton of Val E11 [42]. The Val

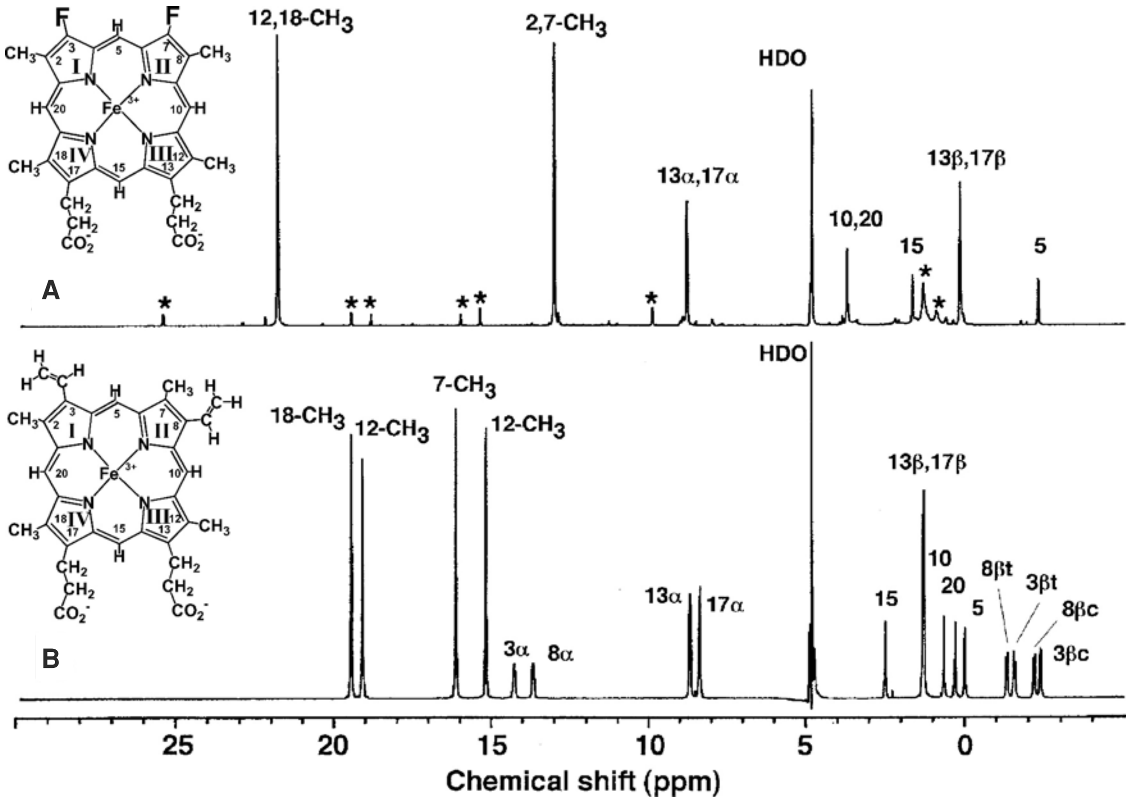

Fig. 6. 400 MHz ^{1}H NMR spectra of (A) *bis*-cyano protohaem and (B) *bis*-cyano 3,7-DF in $^{2}H_2O$ at 25 °C. The signal assignments are indicated in the spectra. The concentration of the haems was about 3 mM and the signals exhibit concentration-dependent shifts. The peak indicated by an asterisk arose from an impurity. The structures of and numbering systems for haems are indicated in the insets.

E11 γ-CH_3 proton signals of the CO forms of Mb(3,7-DF) and native Mb are observed at -2.27 (Fig. 5A′) and -2.31 ppm [42], respectively. The similarity in the Val E11 γ-CH_3 proton shift between the two CO Mbs suggests that their active site structures are highly similar, and hence that the incorporation of 3,7-DF into Mb does not alter the haem–protein interaction in Mb.

Met-cyano Mb ($S = 1/2$)

The separation of the two ^{19}F NMR signals is dramatically increased in the spectrum of met-cyano Mb (Fig. 5B). The assignments of the signals were based on the measurement of ^{1}H–^{19}F Nuclear Overhauser effect (NOE) connectivity (Fig. 7). In the ^{1}H NMR spectrum of met-cyano Mb(3,7-DF) (Fig. 7A), the Ile FG5 δ-CH_3 proton signal is at -3.32 ppm. The corresponding signal of native met-cyano Mb is at -3.46 ppm [43]. The similarity in the shift between the two Mbs also supports the view that the haem–protein interaction is not significantly altered by the introduction of 3,7-DF into Mb. On the other hand, a relatively large shift difference, ~2 ppm, was observed for the γ-CH proton signal of the Ile FG5 residue (the shifts were -7.61 and -9.60 ppm [43] for met-cyano Mb(3,7-DF) and native met-cyano Mb, respectively, under similar experimental conditions). However, a small displacement of the proton relative to the unpaired electron leads to a significant change in the paramagnetic shift, *e.g.* displacement by ~0.01 nm results in a shift change of >4 ppm [44]. Therefore, the shift difference of ~2 ppm could be explained by a small change in the conformation of the Ile FG5 side-chain between the two Mbs. Assuming that the haem–protein interaction in Mb(3,7-DF) is similar to that in native Mb, 3- and 7-F are expected to be located at ~1.11 and ~0.57 nm, respectively, from the Ile FG5 δ-CH_3 proton [45]. Irradiation of the Ile FG5 δ-CH_3 proton signal gave a negative NOE only to

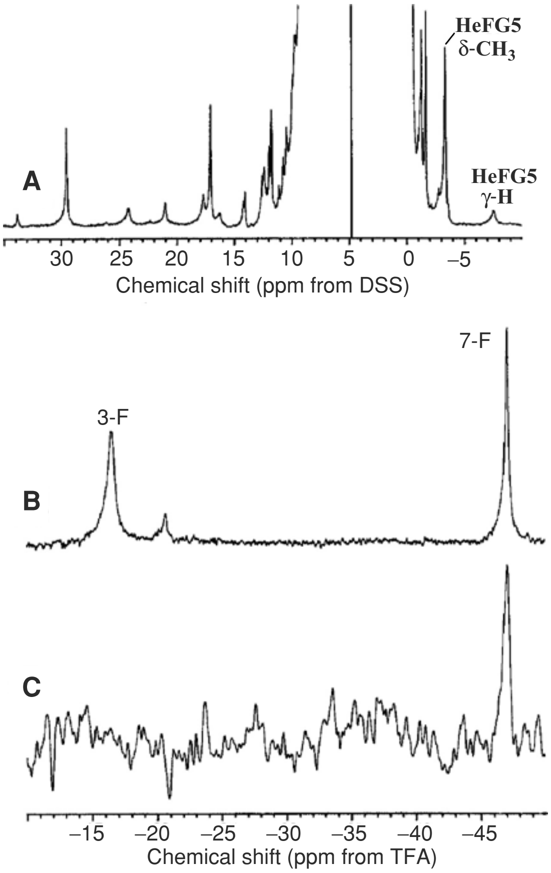

Fig. 7. (A) 400 MHz ^{1}H NMR and (B) 376 MHz ^{19}F NMR spectra of met-cyano Mb(3,7-DF) in ^2H_2O, pH 8.03, at 25 °C, and (C) the NOE difference spectrum resulting from saturation of the Ile FG5 δ-CH_3 proton signal for 100 ms. The assignments of the Ile FG5 γ-CH_3 and δ-CH_3 proton signals are indicated in trace A. The observation of an NOE only for the ^{19}F signal at −47.10 ppm led to the signal assignments shown in trace B (see the text).

the signal resonating at a lower (Fig. 7C). The observed NOE connectivity allowed the unambiguous signal assignments indicated in the spectra. Curie plots, *i.e.* observed shift *vs.* reciprocal of absolute temperature, for the ^{19}F NMR signals of met-cyano Mb(3,7-DF) exhibit straight lines with positive slopes in the temperature range between 5 and 35 °C, with the intercepts of −95.7 and −53.4 ppm for the 3- and 7-F signals, respectively. Although, in principle, the intercepts at $T^{-1} \rightarrow 0$ of the Curie plots reflect the shifts for the corresponding diamagnetic complexes, the measurement in a limited temperature range as well as non-linearity of Curie plots, which is caused by the temperature-dependence of the molecular/electronic structure, often impede determination of diamagnetic shifts from Curie plots [15]. But comparison between the intercepts of the signals for paramagnetic met-cyano Mb and the shifts of the signals in the spectrum of diamagnetic CO Mb (Fig. 5A) allows tentative signal assignments for CO Mb(3,7-DF), as indicated in the spectrum.

Met-azido Mb (mainly $S = 1/2$)

Two broad signals are present in the spectrum of met-azido(3,7-DF) (Fig. 5D). The larger line widths of the signals for met-azido Mb(3,7-DF) than those for low-spin met-cyano Mb(3,7-DF) are attributed to the partial high-spin character of met-azido Mb, where the electron spin relaxation time is relatively large and Curie spin relaxation [46] also occurs. The thermal spin equilibrium [47] in met-azido Mb is manifested in negative slopes of the Curie plots for these signals.

Deoxy Mb ($S = 2$)

The signals in the ^{19}F NMR spectrum of deoxy Mb(3,7-DF) (Fig. 5E) are high frequency-shifted to >200 ppm relative to those of CO Mb(3,7-DF). On the other hand, in the ^{1}H NMR spectrum of deoxy Mb(3,7-DF), the most high frequency-shifted haem methyl proton signal is at 16.61 ppm and this value is comparable to the shift of 16.41 ppm for the resolved haem 12-methyl proton signal in the spectrum of native deoxy Mb [48]. Additionally, the difference in His F8 $N_\delta H$ proton shift between deoxy Mb(3,7-DF) and native deoxy Mb, *i.e.* 73.86 and 77.29 ppm at 25 °C for the former and latter, respectively, may be attributed to an alteration in the hydrogen bonding interaction between this proton and its proton-acceptor (Fig. 1C) [49].

Met-aquo Mb ($S = 5/2$)

The two signals in the ^{19}F NMR spectrum of met-aquo Mb(3,7-DF) are high frequency-shifted to >300 ppm relative to those of CO Mb(3,7-DF), and the line widths are >3000 Hz. These results demonstrate not only the significant effect of the strong paramagnetic contribution, but also the high sensitivity of ^{19}F NMR as to the electronic nature of haem iron. The non-equivalence of the line width between the two signals, *i.e.* 3- (2900 Hz) and 7-F (3200 Hz), arises predominantly from the difference in the contribution of the contact interaction to T_2 relaxation [50].

Haem Disorder

The nature of the molecular recognition between the haem and protein in *b*-type haemoproteins is not sufficiently specific to yield a single orientation of the prosthetic group within the protein matrix [41]. Although their crystal structures have invariably shown that the haem possesses a unique orientation within the protein, a solution NMR study has clearly demonstrated that the haem in these proteins is in two different orientations that differ by 180° rotation of the haem plane, about the 5,15-H *meso*-proton axis, relative to the protein (see the inset in Fig. 3). This phenomenon occurs in virtually almost all native *b*-type haemoproteins and is known as the haem orientation disorder [41,51–54]. The dominant component in Mb exhibits the same haem orientation as that found in the crystal structure, called the normal form; a protein with a reversed haem orientation is called the reverse form. Although the haem orientation disorder in proteins has been studied mainly by ^{1}H NMR spectroscopy [15,41,51–54], characterization of the effect of the haem orientation on the electronic structure of the active site in a physiologically relevant form of a protein is often hampered by the resolution of the signals. Due to the virtues of ^{19}F NMR spectroscopy, the haem orientation disorder in the proteins in various states can be most readily detected and characterized, as reported previously [21].

MbO$_2$ *vs.* MbCO

Characterization of the nature of O_2 and CO binding to respiratory haemoproteins is of importance for understanding the molecular mechanisms responsible for the control of their physiological activities. Despite detailed structural [55] and spectroscopic [56] information as well as theoretical consideration [57] of the binding of these ligands to haemoproteins and iron–porphyrin complexes, little experimental evidence has been reported regarding the effects of O_2 and CO binding on the haem electronic structure of proteins. The ^{19}F NMR spectra of oxy Mb(3,7-DF) and CO Mb(3,7-DF) are compared in Fig. 8. In the spectrum of a mixture of the oxy and CO forms of Mb(3,7-DF) (Fig. 8B), the two sets of signals were separately observed, demonstrating that the timescale of the ligand exchange between O_2 and CO in the protein is slow compared with the NMR timescale [58]. The signals for the oxy form are low frequency-shifted relative to the corresponding signals for the CO one, indicating that the electron density in the porphyrin π-system of the CO form is lower than that of the oxy one. This finding unequivocally demonstrates the effect of Fe $d_\pi \rightarrow$CO π^* back-donation [59,60] on the haem electronic structure.

X-ray crystal studies [55] have indicated that the Fe–C–O unit in CO Mb prefers a linear geometry (∠Fe–C–O = 171°) to maximize the Fe $d_\pi \rightarrow$CO π^* back-donation [59,60], while the Fe–O–O unit in oxy Mb is greatly bent (∠Fe–O–O = 123°), although the orientation of the His F8 imidazole with respect to the haem is essentially the same in the two forms. The greater nonequivalency between 3- and 7-F in the oxy form, relative to that in the CO one, can be attributed to the bent Fe–O–O coordination with respect to the haem. These results also reflect the high sensitivity of ^{19}F NMR as to the haem electronic structure.

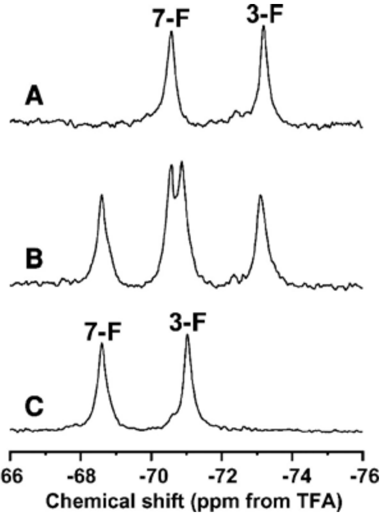

Fig. 8. 376 MHz ^{19}F NMR spectra of Mb(3,7-DF), in 90% H_2O/10% ^2H_2O, pH 7.0, at 25 °C; (A) Oxy Mb, (B) a mixture of oxy and CO Mbs, and (C) CO Mb. The signal assignments are indicated in the spectra.

Summary

A ^{19}F NMR study of Mb has been reviewed with a brief explanatory description of the characteristics of the individual spectra of Mb in various oxidation, spin, and ligation states. The ^{19}F NMR study described here provides a new means for detailed characterization of the active sites of *b*-type haemoproteins to delineate their structure–function relationships.

Polymer Structure

NMR in Dry or Swollen Temporary or Permanent Networks

Jean-Pierre Cohen Addad
Laboratoire de Spectrométrie Physique associé au CNRS (UMR C5588), Université Joseph Fourier,
38402 St Martin d'Hères Cedex, France

Introduction

NMR is a convenient tool for investigating a wide domain of polymeric properties whether investigations deal with thermodynamics or with chain dynamics. Considering here low-resolution NMR of protons attached to chains, measurements can be performed using low-cost equipment. Main magnetic interactions involved in proton relaxation in polymers are dipole–dipole interactions; for example, the magnetic interaction strength of two protons located on a methine group (–CH_2) is 10^5 rad/s in pulsation units. This interaction strength serves as a reference for characterizing dynamic polymeric properties: whether or not they are isotropic, random segmental motions detected from NMR are necessarily characterized by correlation times shorter than about 10^{-5} s [1]. The spin system response exhibits an axial symmetry; the longitudinal (spin–lattice) relaxation is induced by a quasi-resonant exchange of energy between the spin system and the molecular thermal bath and is sensitive to friction effects which occur around the Larmor frequency (10^8 rad/s) whereas the proton transverse (spin–spin) relaxation mainly reflects quantum phase coherences of nuclear spins and is sensitive to deviations from isotropic random rotations of monomeric units in networks. Although they were not observed during polymer flow NMR properties are closely related to the linear viscoelastic behavior of polymers.

Polymeric Dynamics

The description of dynamics properties of polymers observed above the glass transition temperature relies on the behavior of the relaxation modulus $G(t)$; measured from long linear chains, it exhibits two well-separated dispersions [2]. At short times, the transition dispersion is insensitive to chain length variations and associated to fluctuations of short segments while large-scale rearrangements of chain conformations are associated with the terminal dispersion of the dynamics spectrum of one chain and are described according to the reptation model [3,4]. The two dispersions are separated by a rubber-like plateau response at intermediate times; the plateau called G_N^0 and attributed to chain entanglement interactions [5] is considered as a break in dynamic fluctuations that occur along one chain. In analogy with properties of networks, the temporary plateau value is conveniently related to a mean segmental molecular weight called M_e: $G_N^0 = \rho RT/M_e$, with $M_e = 361.9A\rho(M/A\rho\langle R_0^2\rangle)$ [3], (ρ is the polymer density, A is the Avogadro number, and $\langle R_0^2\rangle$ is the Gaussian mean square end-to-end distance of one chain of molecular weight M) [6]; the plateau width is an increasing function of molecular weight.

Effect of Local Friction and Spin–Lattice Relaxation

Spin–lattice relaxation measurements are used to investigate properties of collective random motions of a few monomeric units forming short segments; these motions occur around the Larmor frequency ω_0 ($\approx 10^8$ rad/s) and are independent of chain length. The relaxation rate $1/T_1(T,\ \omega_0)$ is usually measured by applying $[180^\circ - \tau - 90^\circ]$ pulse sequences to the spin system and the relaxation of the longitudinal magnetization is described according to the equation [1]:

$$M_z(\tau) = M_0[1 - 2\ \exp\{-\tau/T_1(T, \omega_0)\}] \qquad (1)$$

This relaxation is closely related to friction properties also involved in the viscoelastic behavior observed in the transition domain; the temperature dependence of the local friction coefficient $\zeta_0(T)$ is mainly governed by free volume effect and characterized by a shift factor $a(T_{\text{ref}}^{\text{L}}, T) = \zeta_0(\theta)/\zeta_0(\theta_{\text{ref}}^{\text{L}})$ determined in the following way. First, starting from the maximum of the temperature dependence of the relaxation rate, the ratio $\omega_0 T_{1,\max}/T_1(T, \omega_0)$ is drawn as a temperature function; this ratio is a homogeneous function of the product $\omega_0\zeta_0(T)$; then, considering the temperature dependence of the ratio determined from two Larmor frequencies called, respectively, ω_0' and ω_0'', the following equation

$$\omega_0' T_{1,\max}'/T_1(T', \omega_0') = \omega_0'' T_{1,\max}''/T_1(T'', \omega_0'') \qquad (2)$$

provides the relationship $\omega_0'/\omega_0'' = \zeta_0(T'')/\zeta_0(T')$ between the friction coefficients $\zeta_0(T'')$ and $\zeta_0(T')$ corresponding to T' and T'' temperatures, respectively; starting from a reference temperature $T_{\text{ref}}^{\text{L}}$, the ratio leads to the

Graham A. Webb (ed.), Modern Magnetic Resonance, 541–543.
© 2008 *Springer.*

determination of the temperature dependence of the shift factor $a(T_{\mathrm{ref}};T)$. This analysis applies to liquid polymers as well as to permanent networks in which the glass transition temperature T_{g} is an increasing function of the cross-link density [7]. For illustration, the temperature dependence of $a(T^{\mathrm{L}}_{\mathrm{ref}};T)$ is in coincidence with that of the shift factor derived from viscoelastic measurements performed on polybutadiene [8]. This approach applies to variations of polymer concentration too.

Chain Diffusion

Chain diffusion measurements are performed by forming pulse field gradient spin-echoes [9]; the molecular weight dependence of the chain diffusion coefficient D exhibits a cross-over from the short chain dynamics described according to the Rouse model ($D\alpha M$) to the long chain dynamics described according to the reptation model ($D\alpha M^{3.4}$) [10].

Statistical Polymeric Structures and Spin–Spin Relaxation

Measurements of spin–spin relaxation are used to investigate properties of temporary or permanent polymeric networks; relaxation curves are drawn by forming Hahn spin-echoes, applying a $[90^\circ/x - \tau - \{180^\circ/x - 2\tau - 180^\circ/-x - 2\tau - 180^\circ/-x - 2\tau - 180^\circ/x - 2\tau-\}n]$ pulse sequence which eliminates both field inhomogeneity effects due to diamagnetism and possible pulse phase problems. Considering long chains, the timescale associated with large-scale rearrangements of chain conformations is much longer than the inverse of the strength of proton–proton interactions about equal to 10^5 rad/s; consequently, these processes do not induce any full motional averaging of magnetic interactions and residual spin–spin interactions result from the partial averaging process which is induced by segmental motions associated with the transition dispersion [8]. Residual proton–proton interactions are independent of molecular weight and their order of magnitude is 10^3 rad/s.

NMR Structural Parameter

The normalized relaxation function $M_x^T(t)$ consists of two contributions expressed as:

$$M_x^T(t) = (1 - A_{\mathrm{II}})(\Delta_{\mathrm{I}}, \tau_{\mathrm{I}}, t) + A_{\mathrm{II}} M_x^{\mathrm{II}}(\Delta_{\mathrm{II}}, \tau_{\mathrm{II}}, t). \quad (3)$$

The relative amplitude A_{II} is proportional to M^{-1}. Normalized $M_x^{\mathrm{II}}(t)$ relaxation functions are assigned both to protons attached to chain-end segments and to protons attached to monomeric units in dynamic interaction with end segments; normalized $M_x^{\mathrm{I}}(t)$ functions are assigned to protons attached to remaining units [8,11]. $M_x^{\mathrm{I}}(\Delta_{\mathrm{I}}, \tau_1, t)$ and $M_x^{\mathrm{II}}(\Delta_{\mathrm{II}}, \tau_{\mathrm{II}}, t)$ are mainly governed by residual dipole–dipole interactions of protons; represented by two parameters called Δ_{I} and Δ_{II}, respectively. $M_x^{\mathrm{II}}(t)$ is independent of chain length while the correlation time τ_1 is proportional to $M^{0.35}$; $M_x^{\mathrm{I}}(\Delta_{\mathrm{I}}, \tau_1, t)$ and $M_x^{\mathrm{II}}(\Delta_{\mathrm{II}}, t)$ spread over different timescales and are easily distinguished from each other. Considering the two following integrals:

$$\Phi_3 = \int_0^\infty \{\mathrm{d}M_{\mathrm{I}}(\Delta_{\mathrm{I}}, \tau_1, t)/\mathrm{d}t\}/t^{0.5}\,\mathrm{d}t \quad \text{and}$$

$$\Phi_1 = \int_0^\infty M_{\mathrm{I}}(\Delta_{\mathrm{I}}, \tau_1, t)/t^{0.5}\mathrm{d}t \quad (4)$$

the NMR structural parameter is defined as the ratio $\chi_c = \Phi_3/\Phi_1$; based on an integral treatment of relaxation curves, the determination of χ_c does not require the mathematical description of proton relaxation be thoroughly analyzed. For molten polymers observed above the glass transition temperature, the inverse of the NMR structural parameter is expressed according to the equation:

$$1/\chi_c^{\mathrm{M}}(T, c, N_e) = (T - T_{\mathrm{ref}}^{\mathrm{M}}) \times (A\chi + B\chi N_e/(M^{0.35}c^{2.1}) \quad (5)$$

N_e is the mean number of monomeric units associated with the plateau G_N^0 and Equation (5) reflects segmental properties induced on NMR by the transition dispersion; the reference temperature T_c^{M} is about 40 K above the glass transition temperature T_{g} and c is the polymer concentration (w/w) (the addition of solvent induces a dilation of the temporary network). For polybutadiene, typical numerical values are $A_\chi = (13.5 \pm 2) \times 10^{-3}$ ms/K and $B_\chi = (22 \pm 1) \times 10^{-3}$ ms/K (g/mol)$^{1/0.35}$ within the range $75 \times 10^3 < M < 500 \times 10^3$ g/mol while N_e is a function of the concentration of monomeric units in the vinyl 1–2 conformation in the chain microstructure.

Cross-Linked Long Chains

In polymeric networks formed from randomly cross-linked chains, segmental properties induced by the transition dispersion combine with properties of segments determined from the cross-linking process; for a given weight fraction of cross-linking reagent γ, these properties are represented by $1/\chi_c^{\mathrm{G}}(\gamma)$. Then, for networks the NMR structural parameter is expressed according to the equation:

$$1/\chi_c^{\mathrm{N}}(T, \gamma) = \kappa(\gamma)\mathrm{arctg}[\chi_c^{\mathrm{G}}(\gamma) \times \{(A\chi + B\chi N_e)(T - T_{\mathrm{ref}}^{G}(\gamma))\}] \quad (6)$$

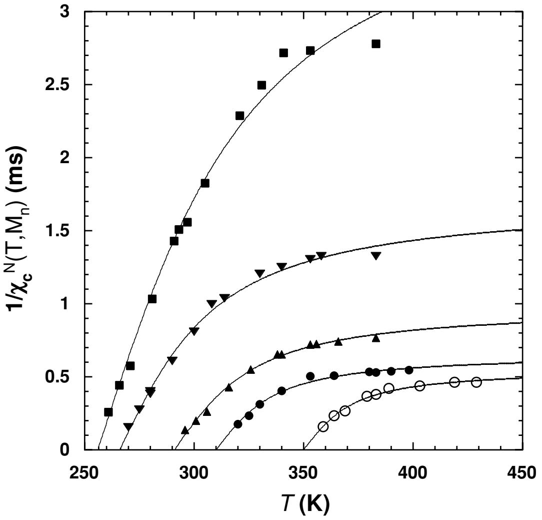

Fig. 1. Variations of $1/\chi_c^{\mathrm{N}}(T, M_n)$ corresponding to precursor molecular weights: 425 (○), 725 (●), 1000 (▲), 2000 (▼) and 4000 (■) g/mol; correspondingly, reference temperatures are: 350, 310, 291, 266, and 256 K. Theoretical curves drawn using Equation (6).

Now, the reference temperature $T_{\mathrm{ref}}^{\mathrm{G}}$ is a linear function of γ, $\kappa(\gamma)T_{\mathrm{ref}}^{\mathrm{G}}$ and $1/\chi_c^{\mathrm{G}}(\gamma)$ are determined experimentally using Equation (6). Both $\kappa(\gamma)$ and $1/\chi_c^{\mathrm{G}}(\gamma)$ are found to be linear functions of $1/\gamma$ showing that the mean segmental spacing between cross-links is proportional to $1/\gamma$. Furthermore, considering a given network and its maximum swelling ratio $Q_{\mathrm{m}}(\gamma)$, at constant temperature $1/\chi_c^{\mathrm{N}}(\gamma)$ is proportional to $Q_{\mathrm{m}}(\gamma)^2$ because swollen polymeric strands obey Gaussian properties.

Calibrated Polymeric Networks

Well-defined mesh sizes are obtained when polymeric networks synthesized from calibrated telechelic segments are characterized by a polydispersity index close to one. Then, the NMR structural parameter is a function of polymeric precursor molecular weight as illustrated in Figure 1; $1/\chi_c^{\mathrm{N}}(T, M_n)$ was determined from end-linked polypropylene oxide chains using triisocyanate as a cross-linking reagent [7]. $1/\chi_c^{\mathrm{N}}(T, M_n)$ again obeys Equation (6) in which $\kappa(M_n) = 0.95 \times 10^{-3} M_n$ ms and $1/[\chi_c^{\mathrm{G}}(\gamma)\{A_x + B_x N_e\}] = 15.71 + M_n \times 10^{-2}$ Kelvin (M_n is in g/mol).

Furthermore, considering a given network and its maximum swelling ratio $Q_{\mathrm{m}}(M)$, at constant temperature $1/\chi_c^{\mathrm{N}}$ is proportional to $Q_{\mathrm{M}}^{1,5}$ because swollen segments obey both excluded volume properties and a packing condition [3,7].

Conclusion

Using low-resolution spectrometers, proton relaxation properties observed from high polymers above the melting point as a function of temperature, solvent concentration, and molecular weight or cross-link density in networks are given a quantitative analysis.

Crystalline Structure of Ethylene Copolymers and Its Relation to the Comonomer Content

Qun Chen
The Key Laboratory for Optics and Magnetic Resonance of MOE, Physics Department,
East China Normal University, Shanghai 200062, China

Ethylene copolymers are a large group of polymer material with a lot of industrial applications [1]. They usually consist of two types of monomers. One is the ethylene unit and the other one is the comonomer unit like methyl methacrylate, vinyl acetate, vinyl alcohol, etc. These two monomer units distribute, randomly in most cases, along the polymer chain, forming ethylene segments with different length. Once the length of some ethylene segments exceeds a critical value, i.e. the so-called minimum crystallizable sequence length at a certain temperature [2], these segments tend to aggregate and form crystals, while the segments with the length smaller than the minimum crystallizable sequence locate in the amorphous region. The comonomer units, which often lack the ability of crystallization, are either expelled from the crystals or embedded in the crystals as defects when the volume of the comonomer unit is small. Similar to other semicrystalline polymers, the bulk samples of ethylene copolymers usually comprise the crystalline, the amorphous, and the interfacial region, which lies between the crystalline and amorphous regions. The structures and the dynamics of these different morphological regions, which have large impact on the macroscopic properties of the material, have been the topics with a lot of research interests.

Solid-state high-resolution ^{13}C NMR spectroscopy has been turned out to be an especially useful technique in probing the phase structure of ethylene copolymers. In the recent years, there have been a number of researches in this field [3–11]. In the following section, some of these works will be introduced to illustrate the possible application of solid-state high-resolution ^{13}C NMR to the investigation on phase structures of ethylene copolymers.

Polymorphism of Ethylene Copolymers

Similar to the behavior of polyethylene, the ethylene segments in the copolymers can be crystallized in different forms, namely, the orthorhombic form and monoclinic form. The orthorhombic form that is thermodynamically favored for long ethylene segments, is dominant for most ethylene copolymers. However, it has been revealed by solid-state high-resolution ^{13}C NMR that for many ethylene copolymer systems [3–7], the ratio of the content of the monoclinic crystal relative to that of the orthorhombic crystal increases steadily with the increase of the comonomer content. Figure 1 illustrates the ^{13}C cross-polarization, high-power dipolar decoupling and magic angle spinning (CP/MAS) spectra of ethylene vinyl acetate copolymers (EVA) with different composition [5]. The numbers after EVA in the figure represent the weight percentage of the VA comonomer in the samples. Among the signals shown in the spectra, peaks at 33.4, 32.4, and 30 ppm are corresponding to the methylene carbon of the monoclinic crystal, orthorhombic crystal, and the amorphous phase. The chemical shift of the monoclinic signals is marked by a dashed line. The assignment of the remaining signals in the spectra, which is not related to the current topic, will not be described here. In the spectra of the EVA05 and EVA12, the intensity of the monoclinic crystals is quite weak, while the signal of the monoclinic crystals can be distinguished easily in the spectra of the EVA18, EVA28, and EVA40 samples. By applying curve fitting to all five spectra, the relative content of each phase component can be obtained. It is found that with the increase of the VA content, the relative contents of the monoclinic crystals in the crystalline region increase while the degree of the crystallinity decreases. Similar results are also observed in the works on ethylene–dimethylaminoethyl methacrylate copolymers (EDAM) [3,4], ethylene–butene, and ethylene–octene [6], but is not observed for ethylene–vinyl alcohol copolymer [7]. All these observations demonstrate that the crystalline structures depend on the comonomer content is a general phenomenon for ethylene copolymers with relatively large side group in their comonomer units. The explanation for such a phenomenon is as follows: For random ethylene copolymers, there exist ethylene segments with different length. Upon crystallization, ethylene segments with the same or near length tend to aggregate and form crystals with different lamellar thickness. The crystallization behavior of the ethylene segments with relative long length is similar to that of polyethylene and tends to

form orthorhombic crystals that are thermodynamically stable. On the other hand, for shorter ethylene segments, due to the influence of the side group of the comonomer unit on both ends of the segment, monoclinic crystalline form is not only dynamically favored, but also thermodynamically stable. It is apparent that the percentage of the shorter ethylene segments increases with increasing the comonomer content, leading to the increase of the relative content of monoclinic crystals in the crystalline region. This interpretation is supported by the fact that in the variable temperature ^{13}C CP/MAS spectra of EDAM, the signal of monoclinic crystals disappears at relatively lower temperature, comparing to that of orthorhombic crystals in the heating process [4]. This reveals that the thickness of the monoclinic crystals is relatively small compared with that of the orthorhombic crystals, suggesting that monoclinic crystals do mainly correspond to the shorter ethylene chains.

Polymorphism of ethylene copolymers can also be studied by WAXD, IR, Raman, and other techniques [6,7,10]. With comparison to these techniques, the advantage of solid-state high-resolution ^{13}C NMR lies in the following two aspects. Firstly, in the ability of discriminating small signals of monoclinic crystals, solid-state high-resolution ^{13}C NMR excels the other techniques. Figure 2 shows the partially decayed ^{13}C spectra of EVA28 acquired by using a Torchia's pulse sequence [12], in order to measuring the ^{13}C spin-lattice relaxation time (T_1) of the sample. It is apparent that with the increase of the variation time, the peaks related to the amorphous region relax rapidly, leaving only the peaks corresponding to the orthorhombic and monoclinic signals in the spectra. The existence of the monoclinic crystal, therefore, can be discriminated clearly. This result demonstrates the powerfulness of solid-state NMR technique, in terms of acquiring useful information from the intricate spectrum. Secondly, our recent work on high-density polyethylene [13] has shown that the cross-polarization enhancement ratios of different crystals in the CP/MAS spectrum, which are key factors in determining the quantitative degree of the method, are almost the same. This observation indicates that the relative ratio of crystals in different forms of ethylene copolymers determined by ^{13}C CP/MAS methods is of high quantitative degree.

The Biexponential ^{13}C T_1 Relaxation Behavior of the Crystalline Region

In the studies on polyethylene and ethylene–octene copolymers, Axelson et al. [14,15] found for the first time that the crystalline regions of these polymers exhibit multi-exponential ^{13}C T_1 relaxation behavior. Two or even three ^{13}C T_1s can be obtained by analyzing the relaxation

Table 1: Specifications of EDAM and EMA copolymers

Samples		Mol%	T_m/°C
EDAM	DA3032	10.7	65.5
	DA3002	6.9	83.6
	DA3023	3.9	92.3
	DA3014	3.6	99.3
EMA	EMA6.5	2.2	102
	EMA9	3.1	93
	EMA27	10.8	64
	EMA29	11.7	48

curves of the crystalline region. The value of the longer ^{13}C T_1 varies from several tens of second to thousands of second, depending on the lamellar thickness. The values of the shorter ones are usually in the order of one second or even less than one second. The origin of such a phenomenon has been a subject with strong research interests for many years [16–18]. Recent studies on several series of ethylene copolymers provided additional information for illustrating the mechanism of multi-exponential relaxation behavior of the crystalline region of polyethylene and ethylene copolymers [5,8]. Meanwhile, it was demonstrated that the multi-exponential relaxation behavior itself can be utilized to probe the phase structure of the corresponding polymer systems.

Two series of ethylene copolymers, namely EDAM and ethylene–methyl acrylate (EMA) were investigated by measuring ^{13}C T_1 of the crystalline regions. The comonomer contents of these samples are listed in Table 1. Figure 3 shows the ^{13}C T_1 relaxation curves of the crystalline component, including the contribution of both orthorhombic and monoclinic crystals, for melt-quenched EDAMs. It can be found that for all the samples, the relaxation curves exhibit biexponential relaxation behavior. Similar results can also be observed for EMAs and for aforementioned EVAs either melt-quenched or isothermally crystallized. This result suggests that the biexponential relaxation behavior is independent of the crystallization condition, the comonomer structure, and the comonomer content. A careful study on EVA28 that has a relative higher content of monoclinic crystal, reveals that the biexponential relaxation behavior is not caused by the coexistence of two different crystalline forms, i.e. the orthorhombic and monoclinic crystalline forms. By carrying out curve fitting on the relaxation curves, two ^{13}C T_1s as well as the relative contents of the components to which each T_1 corresponds can be attained. It is found that, under same crystallization conditions, the relative content of the crystalline component with shorter T_1 generally increases with the increase of the comonomer contents. Meanwhile the content of the shorter T_1 component for a melt-quenched sample is generally higher than that of its isothermally crystallized counterpart, as is demonstrated in Figure 4. It is also found that the values of the longer T_1, which varies from several tens of seconds to several seconds, are closely dependent on the comonomer content, or in other words, dependent on the average lamellar thickness.

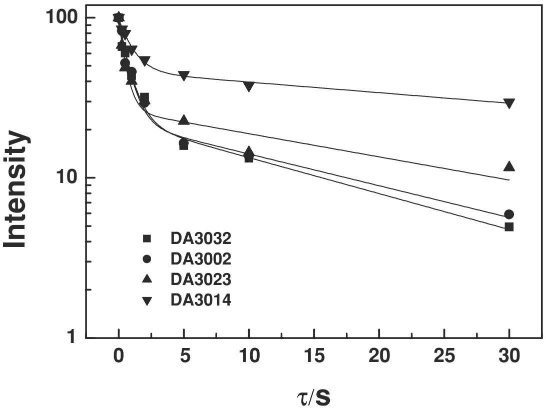

Fig. 3. ^{13}C T_1 relaxation curves (semilogarithmic) of the crystalline components for melt-quenched EDAM samples acquired by Torchia's pulse sequence, where the real lines represent the results of curve fitting in terms of two components with different ^{13}C T_1s.
Source: Ref. [8]; Fig. 2 in the original literature.

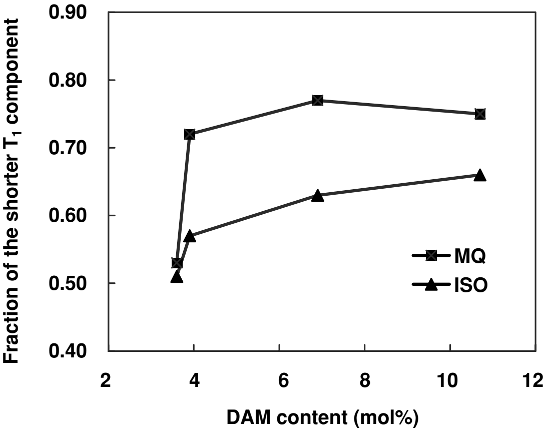

Fig. 4. The fraction of the shorter T_1 component vs. DAM molar content for EDAM samples.
Source: Ref. [8]; Fig. 3 in the original literature.

The above results strongly indicate that the crystalline components with longer and shorter ^{13}C T_1s are corresponding to the internal and the surface parts of the crystalline region, respectively. The interpretation for such a phenomenon is as follows: Both the increasing of the comonomer content and melt-quench will lead to a decrease of the lamellar thickness. The decrease of the lamellar thickness will, in turn, lead to an increase of the relative content of the surface part of the crystalline region. The surface part can also be termed as mobile crystalline or intermediate crystalline component located between the amorphous and the internal part of the crystalline regions [17,18]. The molecular chains in the surface part of the crystalline region should have all trans conformation, because the chemical shift of the component is just the same as that of the internal part of the crystalline region. They should have higher mobility comparing with those within the internal crystalline region, as demonstrated by their remarkably shorter ^{13}C T_1 compared with that of the internal component of the crystalline region.

A pulse sequence that can be considered as a combination of Goldman–Shen's [19] and Torchia's pulse sequences as depicted in Figure 5, was designed to give further evidence for the above interpretation of the biexponential relaxation behavior of the crystalline region. The strategy of the method can be described by a study on EMA29 membrane sample [8]. The first delay window (D6) on the ^{1}H channel is set to be 50 μs. During this delay window, most magnetization in the crystalline region is dephased, while there are still a large amount of magnetization remained in the amorphous region. After D6, ^{1}H magnetization is flipped back to Z-axis. During the second delay window (D7), the magnetization starts to spin-diffuse from the amorphous region to the crystalline region, due to the magnetization gradient existing between these two regions. When D7 is set to be 20 ms, it is demonstrated that a certain part of ^{1}H magnetization has transferred into the crystalline region. However, equilibrium distribution of ^{1}H magnetization has not been reached. In other words, the magnetization diffused from the amorphous region is relatively enriched in the surface area of the crystalline region, comparing with the equilibrium state of ^{1}H magnetization. After D7, the magnetization is flipped back again to XY plane to allow cross-polarization to happen. Subsequently, ^{13}C spin-lattice relaxation can be measured according to Torchia's methodology, i.e. recording ^{13}C CP/MAS spectra with different τ values. What should be kept in mind is that the ^{13}C T_1 of the crystalline region measured under such initial conditions emphasizes the contribution of the surface part of the crystalline region. For EMA29 membrane sample, the relaxation curve of the crystalline region acquired in such a way is shown in Figure 6, together with the relaxation curve of the same region determined by the conventional Torchia's method. It can be found straightforwardly that the relative content of the shorter T_1 component obtained by the new pulse sequence under aforementioned conditions is much higher than that obtained by the conventional Torchia's sequence. Such a result unambiguously supports the conclusion that the crystalline component with shorter ^{13}C T_1 is mainly corresponding to the surface part of the crystalline region locating between the amorphous and the internal part of the crystalline region.

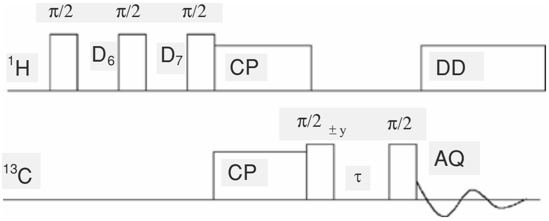

Fig. 5. The Goldman–Shen/Torchia's pulse sequence used for interpreting the mechanism of the biexponential ^{13}C T_1 behavior of the crystalline region.

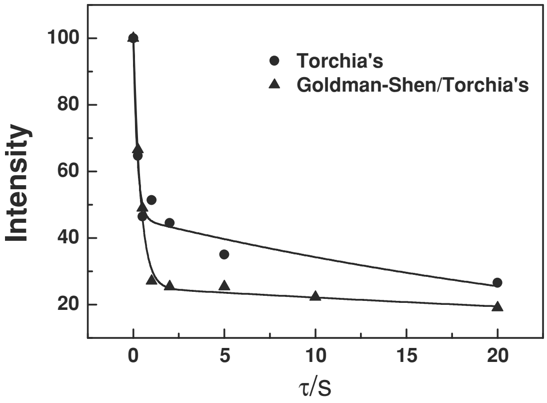

Fig. 6. ^{13}C T_1 relaxation curves of the crystalline component of EMA29 membrane sample acquired by Torchia's and Goldman–Shen/Torchia's pulse sequence.
Source: Ref. [8]; Fig. 8 in the original literature.

The pulse sequence depicted in Figure 5 can also be used in an alternative way to estimate the thickness of the intermediate part. The first delay window on ^{1}H channel is set to be 50 μs once again to eliminate most of the ^{1}H magnetization of the crystalline region. The pulse interval τ at ^{13}C channel is set to be 1.5 s, which serves as a T_1 filter to remove the signals of the amorphous region and the surface part of the crystalline region, leaving only the signal of the internal part of the crystalline region in the resulted spectrum. The spin-diffusion window D$_7$ is

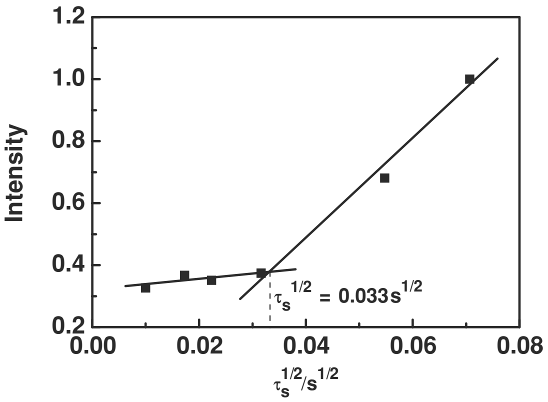

Fig. 7. Plot of the crystalline signal intensity as a function of $\tau_s^{1/2}$ measured by a modified Goldman–Shen/Torchia's pulse sequence. The dashed line indicates the turning point at which the signal starts to increase significantly.
Source: Ref. [8]; Fig. 10 in the original literature.

allowed to vary during the experiment and its length is represented by τ_s. It can be easily visualized that when τ_s increases, the ^{1}H magnetization will diffuse gradually from the amorphous region to the surface part of the crystalline region and subsequently to the internal part of the crystalline region. When τ_s is short, theoretically there should be no apparent signal enhancement in the obtained ^{13}C spectrum with the increase of τ_s. The signal starts to increase only when τ_s is long enough to allow the ^{1}H magnetization to diffuse into the internal part of the crystalline region.

A series of ^{13}C CP/MAS spectra of EMA29 membrane sample are acquired at different τ_s values by using the above method. The intensity of the crystalline signal is plotted in Figure 7 as a function of the square root of τ_s. It is apparent that there exists a turning point on the curve. The intensity of the signal is hardly changed before the turning point, while further increase of τ_s leads to a rapid increase of the signal intensity. Such an increase is undoubtedly due to the fact that after certain time of spin-diffusion the ^{1}H magnetization has already transferred into the internal part of the crystalline region. The influence of ^{1}H spin-lattice relaxation on the signal intensity, in this case, can be safely neglected, because the ^{1}H T_1 of the sample is as long as 0.5 s. Even when τ_s takes its largest value in the experiment, i.e. 5 ms, the intensity enhancement due to ^{1}H spin-lattice relaxation is still lower than 1%. The value of τ_s at the turning point, i.e. $\tau_s \approx$ 1.09 ms, is undoubtedly corresponding to the time that the ^{1}H magnetization of the amorphous region takes to pass across the surface part of the crystalline region. The thickness of the surface part can then be estimated by the following equation [20]:

$$L^2 = 4D\tau_s/3$$

where D is the spin-diffusion coefficient, L is the thickness of the component, and τ_s is the spin-diffusion time. The thickness of the surface part of the crystalline region obtained through calculation is about 0.85 nm, when D is 5.0×10^{-12} cm^2/s.

In conclusion, the above investigations on the relaxation behavior of ethylene copolymers have demonstrated that by measuring the ^{13}C T_1 of the crystalline region, the solid-state high-resolution ^{13}C NMR can be employed to study the content and nature of the surface part of the crystalline region of ethylene copolymers, providing us with unique phase structural information about these industrially important materials.

Introduction

Biodegradable plastics are currently receiving much attention for use as a commodity consumed with ecological advantages over nondegradable ones. Biodegradability is well known for some kinds of polymers including natural polymers such as cellulose, chitin, lignin, and bacterially synthesized aliphatic polyesters, and chemically synthesized polymers such as aliphatic polyesters and polyvinyl alcohol. Among them, aliphatic polyesters are the most promising materials for fibers and resins [1,2].

NMR spectroscopy is widely used in the structural analysis of biodegradable aliphatic polyesters, including stereo- [3,4] and comonomer-sequence [5–9], conformation [10,11], and dynamics in solution [10,12,13] and in the solid state [14–16]. Biodegradability is just a property of polymers. So, the procedure of structural analysis of biodegradable polyesters is no different from that of common vinyl polymers. Some of the structural characteristics of biodegradable polyesters, especially, of the bacterially synthesized ones are, however, totally different. For example, the bacterial copolyesters usually have an extraordinary broad chemical composition distribution, which adds a dimension in the analysis of the structure–property relationship [17–19]. The deuterium distribution in poly(3-hydroxybutyrate) [P(3HB)] biosynthesized from deuterated carbon sources indicates the conversion from a C–H to a C–D bond and from a C–D to a C–H bond in bacteria [20]. Due to limitations of space, we cannot review all of these characteristics. Instead, we focus here on the structural characteristics of a bacterial copolyester, i.e. isomorphism in poly(3-hydroxybutyrate-*co*-3-hydroxyvalerate) [P(3HB-*co*-3HV)]. In the characterization of this phenomenon, high-resolution solid-state NMR spectroscopy provides an exclusive method for determination of the chemical composition in each of the coexisting phases.

Isomorphous Behavior of Bacterially Synthesized Copolyesters

In P(3HB-*co*-3HV), relatively high crystallinity around 60% is preserved even at intermediate comonomer compositions, though the crystalline lattice of P(3HB-*co*-3HV) changes from the P(3HB) type to the P(3HV) type at ca. 40% 3HV [21,22]. Only the P(3HB) crystalline lattice is observed for P(3HB-*co*-3HV) with low 3HV content, while only the P(3HV) lattice is observed for the copolymers with high 3HV content. These observations are consistent with the hypothesis of isodimorphism [21], i.e. 3HB and 3HV units cocrystallize both in the P(3HB) lattice and in the P(3HV) lattice. The crystalline unit cells of P(3HB) [23,24] and P(3HV) [25] are both orthorhombic, $P2_12_12_1$-D_2^4. The chemical structures of 3HB and 3HV monomers differ only by the length of a methylene group in the side chains. Similarity in the chemical and crystalline structures must be responsible for the cocrystallization of 3HB and 3HV units.

Even in an isomorphous copolymer, the compositions in the crystalline and amorphous phases are not necessarily the same as the whole composition [26,27]. High-resolution solid-state ^{13}C NMR spectroscopy is a powerful tool for the determination of the compositions in each of the coexisting phases. So, the isomorphous behavior of P(3HB-*co*-3HV) has been analyzed by high-resolution solid-state ^{13}C NMR spectroscopy [28–30]. Figure 1a–c shows the ^{13}C cross-polarization magic-angle sample-spinning (CPMAS) NMR spectra of P(3HB-*co*-3HV)s. For the samples with low 3HV content, the resonances from the 3HV units in the crystalline phase are relatively small which gives a large margin of error in the calculated composition. In such cases, P(3HB-*co*-3HV) samples of which HV units are specifically labeled with ^{13}C were used [30,31]. Here, P(3HB-*co*-3HV) with and without ^{13}C label is denoted as P(3HB-*co*-3HV)^{E} and P(3HB-*co*-3HV)^{N}, respectively. The spectrum shown in Figure 1c is of P(3HB-*co*-13% 3HV)^{E} of which 3HV methine position contains 12% ^{13}C. The rate of the enrichment of this sample was selected so as to make the areas of the 3HB and 3HV methine peaks comparable.

Figure 2 shows the expanded spectra of the methine resonances of P(3HB-*co*-21% 3HV) and P(3HB-*co*-58% 3HV). The former crystallized in the P(3HB) type lattice, while the latter forms the P(3HV) type lattice. These spectra demonstrate the difference in chemical shift of each

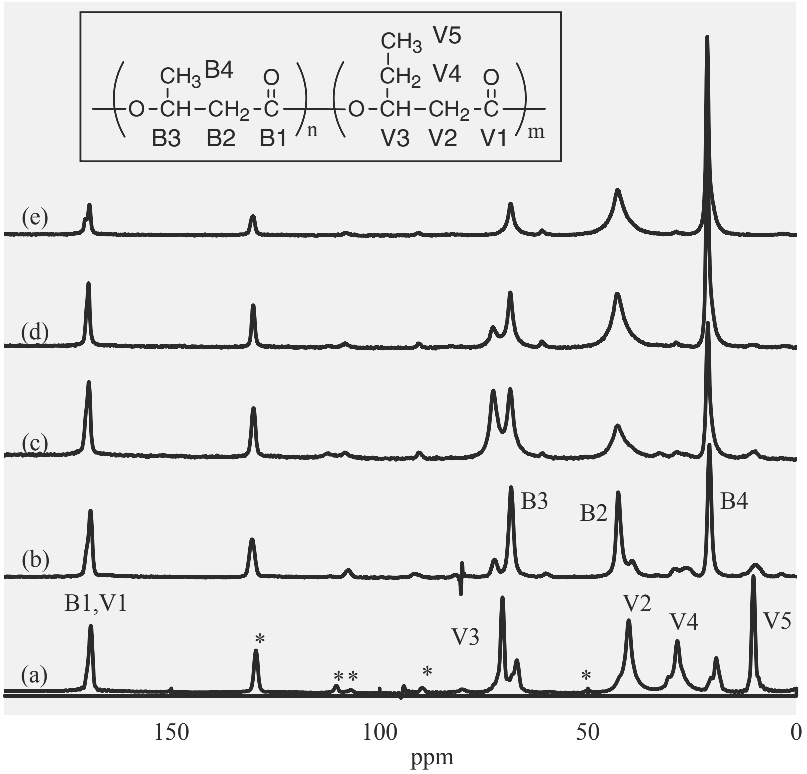

Fig. 1. NMR spectra (100 MHz ^{13}C CPMAS) of (a) P(3HB-*co*-58% 3HV), (b) P(3HB-*co*-21% 3HV), (c) P(3HB-*co*-13% 3HV)^{E}, (d) 1/1 blend of P(3HB)^{E}/P(3HB-*co*-13% 3HV)^{E}, and (e) P(3HB)^{E}. Peaks marked with * are due to the spinning sideband.

of the methine [$B3$, $V3$] carbons between the P(3HB) and P(3HV) lattices. This indicates the difference in the environments of the respective carbons. Assuming a two-phase model, the methine [$B3$, $V3$] resonances are, respectively, resolved into the crystalline and amorphous peaks by a curve fitting procedure. The composition in the crystalline phase can be determined from the relative areas of the resolved peaks.

The relation between the composition in the crystalline phase and the overall composition for P(3HB-*co*-3HV) crystallized in the P(3HB) lattice at 90°C is shown in Figure 3. The solid line in the figure indicates the case where both of the crystalline and amorphous phases have the same composition. It is obvious that the 3HV content in the crystalline phase, $f_{\mathrm{V}}^{\mathrm{c}}$, is smaller than the whole composition, f_{V}, in the P(3HB) crystalline lattice. Figure 3 also shows that the ratio of $f_{\mathrm{V}}^{\mathrm{c}}$ to f_{V} changes. The ratios for the samples with low and high 3HV contents are one-half and two-thirds, respectively. This change was interpreted as a evidence of the structural transition from sandwich lamella to uniform lamella [30]. In the uniform lamella, the comonomer units are assumed to be distributed uniformly. In the sandwich lamella, the comonomer units exist only in the edges and the core is composed entirely of the major units. In P(3HB-*co*-3HV) with low 3HV content where long 3HB sequences are abundant and the entropy gain upon the cocrystallization of comonomers is little, the 3HV units must have a marked tendency to be excluded from inside of the crystalline lamella to the surface where the distortion of the crystalline lattice by the contamination of the HV units can be easily relaxed. So, the sandwich lamella model can be assumed to better describe the isomorphism of P(3HB-*co*-3HV) with low HV content. On the other hand, in P(3HB-*co*-3HV) with high 3HV content, the 3HV units can get into the P(3HB) crystalline lattice because the entropy gain upon the cocrystallization compensates the excess free energy of 3HV cocrystallization.

When the extent of cocrystallization in the P(3HB) lattice has been compared with that in the P(3HV) lattice, more 3HB units cocrystallize in the P(3HV) lattice than 3HV units in the P(3HB) lattice [28,29]. Wide angle X-ray

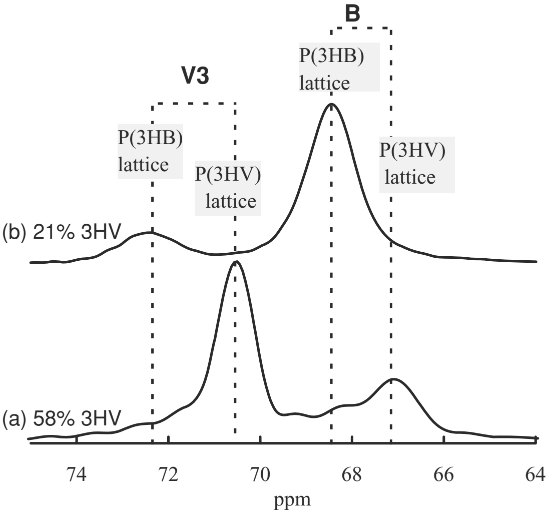

Fig. 2. Expansion of the methine resonances (B3 and V3) of the spectra shown in Figure 1a and b.

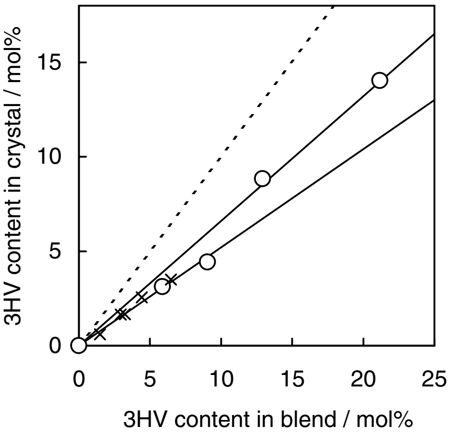

Fig. 3. 3HV content in the crystalline phase of P(3HB-*co*-3HV) copolymers (○) and blends (x) of P(3HB) and P(3HB-*co*-3HV) as a function of overall composition. The broken line indicates the case where both the crystalline and amorphous phases have the same composition. The solid lines indicate the cases where the HV contents in the crystalline phase are one-half and two-thirds of the whole HV content.

diffraction (WAXD) studies show that for the crystals in the P(3HB) lattice the *d*(110) spacing extends as the 3HV content of the overall copolymer increases [21]. On the other hand, no expansion of *d* spacings was observed for the P(3HV) lattice [22]. Thus, the less bulky minor component probably cocrystallizes more easily than the more bulky one.

The effect of crystallization temperature on the extent of cocrystallization has been also investigated [32,33]. The 3HV content in the P(3HB) lattice and the 3HB content in the P(3HV) lattice decrease as the crystallization temperature is increased. The degree of cocrystallization is lowered as the crystallization temperature becomes higher.

The possibility of the isomorphism was also examined for the copolymers of 3HB with 3-hydroxypropionate [3HP] [34,35] and 4-hydroxybutyrate [36]. The similarity in the chemical structures between the comonomers in these copolymers awakened the expectation of the occurrence of isomorphism. Particularly in the former, the difference between the comonomers, 3HB and 3HP, is only in the side chain by a length of methylene group, which is the same as that between the comonomers of P(3HB-*co*-3HV). However, the rapid decrease of the crystallinity (determined by DSC and WAXD) and the absence of the crystalline peaks for one of the comonomers in high-resolution solid-state NMR spectra demonstrate the absence of the isomorphism. This fact indicates the rareness of copolymer isomorphism.

Cocrystallization and Phase Segregation in P(3HB)/P(3HB-*co*-3HV) Blends

The occurrence of isomorphism in P(3HB-*co*-3HV) also induces an expectational hypothesis of the cocrystallization of P(3HB) and P(3HB-*co*-3HV) in their blends. Actually, the cocrystallization occurs when the 3HV contents of P(3HB-*co*-3HV) is small [37–39]. Figure 4 shows the

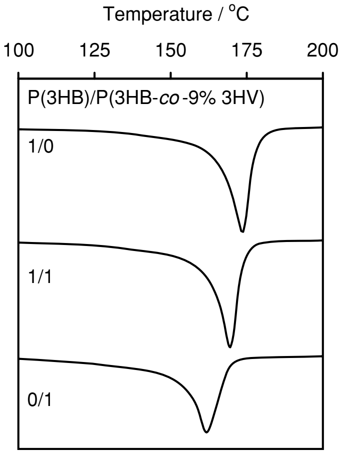

Fig. 4. DSC melting thermograms of P(3HB), P(3HB-*co*-9% 3HV) and their 1/1 blend.

DSC melting curves of P(3HB), P(3HB-*co*-9% 3HV), and their 1/1 blend. The width of the melting peak of the blends is smaller than the difference of the melting temperature of P(3HB) and P(3HB-*co*-9% 3HV). The peak top position (melting temperature) of the blend is right between those of the blend components. These observations suggest that P(3HB-*co*-9% 3HV) cocrystallizes with P(3HB) in this blend.

The cocrystalline phase of P(3HB)/P(3HB-*co*-3HV) is composed of 3HB units from P(3HB), 3HB units from P(3HB-*co*-3HV), and 3HV units from P(3HB-*co*-3HV). Therefore, the complete description of the phase structure of P(3HB)/P(3HB-*co*-3HV) blends needs the determination of both the 3HV and P(3HB) contents in the crystalline phase.

Similar to the case of isomorphous copolymers, high-resolution solid-state ^{13}C NMR can be a usable tool for the determination of the extent of cocrystallization in the polymer blends. The analysis is, however, impossible for the normal P(3HB)/P(3HB-*co*-3HV) blend samples. In high-resolution solid-state ^{13}C CPMAS NMR spectra of P(3HB)/P(3HB-*co*-3HV), the peaks from P(3HB) completely overlap with those from 3HB units of P(3HB-*co*-3HV). Therefore, Yoshie *et al.* [30] made the contrast between P(3HB) and P(3HB-*co*-3HV) by ^{13}C-labeling of the methylene position [$B2$] of P(3HB) [31]. Further, they also used ^{13}C-labeling of the methine position of HV units [V3] when the total 3HV content in the P(3HB)/P(3HB-*co*-3HV) blend is small. Figure 1c–e shows ^{13}C CP-MAS NMR spectra of P(3HB-*co*-13% 3HV)^{E}, 50/50 P(3HB)^{E}/P(3HB-*co*-13% 3HV)^{E}, and P(3HB)^{E}. Assuming a two-phase model, the main chain methine and the main chain methylene resonances are decomposed into the crystalline and amorphous peaks by curve fitting procedure.

The peak areas of the crystalline resonances from the backbone methylene [B2, V2] and the backbone methines [B3, V3] for P(3HB)^{E}/P(3HB-*co*-3HV)^{E} blends are given by

$$A_{\mathrm{B2}} = kr^{h}_{\mathrm{B2}} f^{\mathrm{h}}_{\mathrm{B2}} P^{\mathrm{h}}_{\mathrm{B}} + kr^{\mathrm{c}}_{\mathrm{B2}} f^{\mathrm{c}}_{\mathrm{B2}} P^{\mathrm{c}}_{\mathrm{B}} \tag{1}$$

$$A_{\mathrm{B3}} = kr^{\mathrm{h}}_{\mathrm{B3}} f^{\mathrm{h}}_{\mathrm{B3}} P^{\mathrm{h}}_{\mathrm{B}} + kr^{\mathrm{c}}_{\mathrm{B3}} f^{\mathrm{c}}_{\mathrm{B3}} P^{\mathrm{c}}_{\mathrm{B}} \tag{2}$$

$$A_{\mathrm{V3}} = kr^{\mathrm{c}}_{\mathrm{V3}} f^{\mathrm{c}}_{\mathrm{V3}} P^{\mathrm{c}}_{\mathrm{V}} \tag{3}$$

where k is a constant; A, r, and f are peak areas; ^{13}C population and CP efficiency, respectively: superscripts c and h indicate copolymer [P(3HB-*co*-3HV)^{E}] and homopolymer [P(3HB)^{E}] in the blend, respectively; subscripts B2, B3, and V3 identify the carbon site; P_i^j is a content of i unit from copolymer (j = c) or homopolymer (j = h) in the crystalline phase. From the definition, $P^{\mathrm{h}}_{\mathrm{B}} + P^{\mathrm{c}}_{\mathrm{B}} + P^{\mathrm{c}}_{\mathrm{V}} = 1$. In the present case, we can assume that $f^{\mathrm{h}}_{\mathrm{B2}} = f^{\mathrm{c}}_{\mathrm{B2}} = f_2$ and $f^{\mathrm{h}}_{\mathrm{B3}} = f^{\mathrm{c}}_{\mathrm{B3}} = f^{\mathrm{c}}_{\mathrm{V3}} = f_3$ because the chemical structures of 3HB and 3HV are similar so that the dynamics of the main chain of these units are similarly restricted in the crystalline region. Since the B2 and B3 carbons in P(3HB-*co*-3HV)^{E} and the B3 carbon in P(3HB)^{E} are not ^{13}C-labeled, $r^{\mathrm{c}}_{\mathrm{B2}} = r^{\mathrm{c}}_{\mathrm{B3}} = r^{\mathrm{h}}_{\mathrm{B3}} = r_n$(^{13}C natural abundance) ≈ 0.011. Then, the HV content in the crystalline phase P^{c}_{V} can be estimated from Equations (2) and (3) as

$$P^{\mathrm{c}}_{\mathrm{V}} = \frac{A_{\mathrm{V3}}}{\dfrac{r^{\mathrm{c}}_{\mathrm{V3}}}{r_{\mathrm{n}}} A_{\mathrm{B3}} + A_{\mathrm{V3}}}. \tag{4}$$

The ratio of A_{B2} to A_{B3} is given by

$$\begin{aligned} R &= A_{\mathrm{B2}}/A_{\mathrm{B3}} \\ &= f_2 \left(\frac{r^{\mathrm{h}}_{\mathrm{B2}}}{r_n} P^{\mathrm{h}}_{\mathrm{B}} + P^{\mathrm{c}}_{\mathrm{B}} \right) \Big/ f_3 \left(P^{\mathrm{h}}_{\mathrm{B}} + P^{\mathrm{c}}_{\mathrm{B}} \right). \end{aligned} \tag{5}$$

Considering that $P^{\mathrm{c}}_{\mathrm{B}} = P^{\mathrm{c}}_{\mathrm{V}} = 0$ for pure P(3HB)^{E} and $P^{\mathrm{h}}_{\mathrm{B}} = 0$ for pure P(3HB-*co*-3HV)^{E}, we can determine the P(3HB) content in the crystalline phase of P(3HB)^{E}/P(3HB-*co*-3HV)^{E} by the comparison of the peak area ratio of the blend, R^{blend}, with those of P(3HB)^{E}, R^{PHB}, and P(3HB-*co*-3HV)^{E}, $R^{\mathrm{PHB\text{-}HV}}$, as follows:

$$P^{\mathrm{h}}_{\mathrm{B}} = \left(1 - P^{\mathrm{c}}_{\mathrm{V}}\right) \frac{R^{\mathrm{PHB\text{-}HV}} - R^{\mathrm{blend}}}{R^{\mathrm{PHB\text{-}HV}} - R^{\mathrm{PHB}}}. \tag{6}$$

If $r^{\mathrm{h}}_{\mathrm{B2}}$ is set to be much larger than the natural abundance, R^{PHB} and R^{blend} would be much larger than one and give a relatively large experimental error in $P^{\mathrm{h}}_{\mathrm{B}}$. In order to minimize the error, $r^{\mathrm{h}}_{\mathrm{B2}}$ of P(3HB)^{E} should be carefully selected.

For the blend of P(3HB) and P(3HB-*co*-3HV) with 3HV less than 13%, the P(3HB) content in the crystalline phase, $P^{\mathrm{h}}_{\mathrm{B}}$, is similar to the blend composition, i.e. complete cocrystallization occurs in these blends. P(3HB) and P(3HB-*co*-3HV) chains are equally introduced into the crystalline phase. On the other hand, for P(3HB)/P(3HB-*co*-15% 3HV) and P(3HB)/P(3HB-*co*-21% 3HV) blends, $P^{\mathrm{h}}_{\mathrm{B}}$ is unambiguously larger than the whole blend. At the growing front of the crystalline phase, phase segregation proceeds where P(3HB) chains preferentially enters the crystalline phase. So, the composition in the cocrystalline phase for P(3HB)/P(3HB-*co*-3HV) blends changes depending on the 3HV content of P(3HB-*co*-3HV). The P(3HB-*co*-3HV) content in the cocrystalline phase decreases as the 3HV content of P(3HB-*co*-3HV) increases. These results indicate that the composition in the crystalline phase is determined by the competition of phase segregation and crystallization.

The HV content in the crystalline phase, P_V^c, for $P(3HB)^E/P(3HB\text{-}6\%\ 3HV)^E$ and $P(3HB)^E/P(3HB\text{-}co\text{-}13\%\ 3HV)^E$ blends is also shown in Figure 3. This figure indicates that P_V^c of these blends is approximately one-half of that in the whole blend, which corresponds to the case of the P(3HB-*co*-3HV) copolymers. The coincidence in this ratio indicates the similarity in the structures inside the crystalline phase of the complete-cocrystallizable P(3HB)/P(3HB-*co*-3HV) blends and P(3HB-*co*-3HV) copolymers.

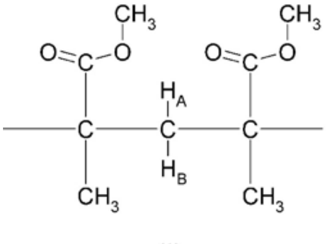
Two-Dimensional NMR Analysis of Stereoregularity of Polymers

A.S. Brar and Gurmeet Singh

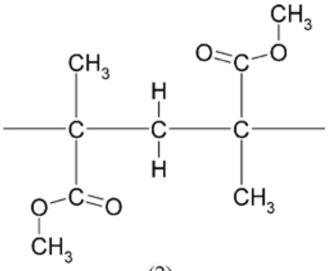
Department of Chemistry, Indian Institute of Technology, Delhi, New Delhi 110016, India

Poly(Methyl Methacrylate)

Analysis of couplings by 2D HSQC, TOCSY, and HMBC spectroscopy enable the unambiguous and comprehensive assignments of the carbon and proton resonances of vinyl polymers [1–4].



(1)



(2)

α-Methyl, methylene, carbonyl, and quaternary carbon resonances are configuration sensitive [5]. Unlike the α-methyl, quaternary, and carbonyl carbon resonances, methylene carbon and proton resonances do not follow chemical shift order so are consequently difficult to assign. The assignments of methylene resonances thus provide a good base for 2D NMR analysis. The main structural difference between meso (1) and racemo (2) diad of PMMA is that in the case of meso diad, methylene proton H_A is flanked by two carbonyl groups and H_B by two methyl groups, while in racemo configuration both the protons have symmetrically placed substituents. The non-equivalent methylene protons H_A and H_B of meso diad show two different couplings with the methylene carbon, giving rise to two cross-peaks in 2D HSQC. Non-equivalent H_A and H_B give a cross-correlation peak in 2D TOCSY spectrum. The two equivalent methylene protons of racemo diad couple with the methylene carbon giving a single cross-peak in 2D HSQC spectrum.

2D HSQC spectrum of methylene region showing carbon resonances ranging from 51.0–55.5 ppm coupled with proton resonances ranging from 1.4 to 2.1 ppm is shown in Figure 1. Cross-peaks I, II and III correspond to *r* centered tetrads having single cross-peaks in 2D HSQC spectrum, assigned to rrr, mrr, and mrm tetrads, respectively. Cross-peaks IV/V and VI/VII correspond to rmr tetrad and are higher order sensitive. Owing to *m* centered methylene group, couplings IV/VI and V/VII were assigned to H_A and H_B protons, respectively. The non-equivalent H_A and H_B protons of rmr tetrad show a cross-relation peak in 2D TOCSY spectrum labeled "b" in Figure 2. The cross-peaks VIII and IX were attributed to H_A and H_B of mmr tetrad and the non-equivalent protons gave cross-correlation peak "a" in 2D TOCSY spectrum.

The proton resonances assigned using 2D HSQC spectrum and confirmed by 2D TOCSY spectra were applied to analyze the 2D HMBC spectrum. Cross-peaks 1 and 3 were assigned to the couplings between α-methyl protons of rr triad with methylene carbon of rrr and mrr tetrads, respectively. Cross-peaks 2, 4, and 7 were attributed to couplings between α-methyl protons of mr triad with methylene carbons of rmr, mrr, and mrm tetrads, respectively. Couplings between α-methyl protons of mm triad with methylene carbon of mmr and mmm triad resulted in cross-peaks 5 and 6, respectively. Cross-peak 8 was assigned to the coupling of methylene proton of the rmr tetrad with methylene protons of the adjacent mrm unit. Similarly, cross-peak 9 was assigned to the coupling between methylene carbon and protons of the adjacent rrr tetrads in the rrrr pentad. Cross-peaks 10/12 and 11/13 were assigned to the couplings between methylene protons of the rmr tetrad with methylene carbon of the mrr unit in the rmrr pentad. The cross-peak 14 was assigned to the coupling of mrr methylene carbon with rrr protons in

Methyl Acrylate (A)/Methyl Methacrylate (B) Copolymer

Analysis of the methylene, α-methyl and methine carbon and proton resonances of the methyl acrylate/methyl methacrylate copolymers can be done by the analysis of HSQC and TOCSY spectra. Assignments of the complex and overlapping carbonyl carbon resonances of the methyl acrylate/methyl methacrylate copolymers is a complicated and speculative procedure. The carbonyl carbon assignments based on the experimental analysis of their couplings with methylene protons and α-methyl protons (assigned using the 2D HSQC and TOCSY spectra) using HMBC spectra can be done to overcome any speculation in the resonance analysis (Brar *et al.*, unpublished work).

2D HSQC spectrum of A/B copolymer of composition $F_A = 0.58$ is given in the Figure 4 and the assignments are listed in Table 1. The methylene protons H_a and H_b of both the AmB and ArB centered tetrads are non-equivalent as shown in Scheme 1, thus resulting in two cross-peaks by coupling with the methylene carbon in the 2D HSQC spectra. 2D TOCSY spectrum is given in Figure 5 and the assignments of cross-correlation peaks are given in Table 2. H_a and H_b of AmB and ArB being non-equivalent also give cross-correlation peaks in the 2D TOCSY spectrum, enabling to differentiate between cross-peaks of AmB and ArB in the 2D HSQC spectra. AA and BB diad centered tetrads show compositional and conformational sensitivity. The reasoning given above in conjunction with the analysis of change in the intensity of cross-peaks with copolymer composition can be applied to assign the resonances.

Methine group of methyl acrylate can be assigned up to triad level of compositional sensitivity in the copolymer, based on the 2D HSQC assignments. Cross-peaks 25, 26, and 27 are assigned to BAB, BAA, and AAA triads. 2D TOCSY studies were used to ascertain these assignments by analyzing 1, 3 bond order couplings between methylene protons and methine protons of A monomer in AA and AB centered methylene cross-correlation peaks VII to X in Figure 5.

The assignments of the couplings marked on the HMBC (Figure 6) are listed in the Table 3. The HMBC spectral analysis enabled to assign the carbonyl carbon resonances by analyzing the three bond couplings with α-methyl protons of the same methyl methacrylate monomer unit, enabling to assign the B unit centered triads. The rest of carbonyl carbon resonances were analyzed from the couplings of methylene protons with the carbonyl carbon. On the basis of the 2D HMBC spectral analysis, the carbonyl carbon resonances were assigned as shown in the Figure 7.

Introduction

The techniques of solid-state NMR have been still growing and now varieties of methods exist for the structure characterization. The multiple-quantum coherences are particularly useful in NMR for the precise analysis of the local structures in disordered as well as ordered polymers. In this chapter, we show some examples of the quantitative conformation characterization of disordered and amorphous solid polymers by the advanced solid-state multiple-quantum NMR spectroscopy.

Characterization of Conformations in Atactic Polymers by Two-Dimensional Experiments [1–3]

The characterization of the microscopic structure of polymers in the solid state is crucial in polymer science. Although the crystal structures have been determined by wide-angle X-ray diffraction (WAXD) for many polymers, the structures for some polymers are still controversial. Atactic poly(acrylonitrile) (aPAN) is one of the examples. The WAXD measurements of oriented aPAN fibers show only diffuse patterns along the meridian. The conformational disorders are suggested and several models have been proposed for the crystal structure [4], however, the details have not been characterized. In this section, we show the precise determinations of the conformations in aPAN by two-dimensional solid-state double-quantum NMR spectroscopy (2D DOQSY) [1,2,5,6] and two-dimensional solid-state heteronuclear multiple-quantum correlation NMR spectroscopy (2D HMQC) [3] for the labeled samples in Figure 1. These solid-state NMR measurements give quantitative torsion angles even in such a disordered solid polymer.

The 2D DOQSY experiment correlates the sum of the chemical shifts of two labeled spins, $(\omega_a + \omega_b)$, and the individual chemical shift, ω_a or ω_b. Since the chemical shift without sample spinning is orientation-dependent, the resulting 2D spectrum determines the torsion angles between the relevant two spins through their relative orientation. Figure 2a shows the experimental ^{13}C 2D DOQSY spectrum of $^{13}CH_2$-carbon labeled atactic PAN ($^{13}CH_2$-aPAN, see Figure 1a) [1]. The spectral patterns depend on the two successive torsion angles intervening between the two labeled $^{13}CH_2$ sites and therefore these two torsion angles can be characterized. From the best fit simulation in Figure 2b, the trans/gauche ratio is determined as 90:10%.

More precise information can be obtained by ^{13}C 2D DOQSY experiments of ^{13}CN-carbon labeled atactic PAN (^{13}CN-aPAN, see Figure 1b) [2]. Figure 3 shows the experimental and simulated ^{13}C 2D DOQSY spectra of ^{13}CN-aPAN. This experiment has three advantages compared with the experiment for $^{13}CH_2$-aPAN. First, due to the much wider chemical shift anisotropy (CSA) span of ^{13}CN carbons (363 ppm) compared with that of $^{13}CH_2$ carbons (~45 ppm), significantly better angular resolution is obtained as shown in Fig. 3b and c. Second, the axially symmetric chemical shift tensors of the $^{13}C{\equiv}N$ carbons probe specifically the $^{13}C{\equiv}N$ triple bond directions and the orientation of the chemical shift tensor is well-defined without ambiguities. Third, the torsion angles of meso and racemo dyads can be determined simultaneously and selectively even if their conformations are the same. This experiment observes the correlation between the relevant two $^{13}C{\equiv}N$ triple bond directions and the different CN–CN orientational correlations are given for meso and racemo dyads. An example is shown in the simulated spectra of Figure 3b and e. The meso and racemo patterns with the same trans–trans backbone conformation are drastically different.

The experimental 2D DOQSY spectrum in Figure 3a does not give sharp ridges, which clearly shows the torsion angles are widely distributed. It is also found that the average torsion angles are significantly deviated from the ideal 180° trans state for meso-dyads. The best-fit simulation in Figure 3d indicates that the two $^{13}C{\equiv}N$ bond directions in meso trans–trans dyads make an average angle θ_{CNCN} of 20° with the standard deviation of the Gaussian distribution, $\sigma = 25°$. This CN–CN correlation can be translated into the backbone torsion angles. The typical average torsion angles for meso trans–trans dyads

are (+160°, +160°) and (±170°, ∓170°) with $\sigma = 20°$ for the both torsion angles.

The torsion angles of (180°, 180°) with $\sigma = 10°$ and those of (+170°, +70°) with $\sigma = 10°$ for racemo trans–trans dyads and meso trans-gauche dyads, respectively, are also suggested from this experiment. These torsion angles are more accurately determined from the following ^{2}H-^{13}C 2D HMQC NMR experiments [3], since 2D DOQSY spectra for these two patterns are similar as shown in Figure 3e and f.

The ^{2}H-^{13}C 2D HMQC NMR experiments also have the above-mentioned three advantages. Figure 4b and c exemplifies the good angular resolution. The distinction of meso and racemo dyads is shown in Figure 4b and e. Different from the 2D DOQSY experiments, the HMQC pattern of racemo trans–trans dyads is significantly different from that of meso trans-gauche dyads. Therefore, 2D HMQC is complementary experiment and the most accurate analysis is possible for racemo trans–trans dyads.

Figure 4a shows the experimental 2D HMQC spectrum of α-hydrogen deuterated and ^{13}CN-carbon labeled atactic PAN (^{2}H/^{13}CN-aPAN, see Figure 1c). From the best-fit simulation in Figure 4d, the torsion angles for racemo trans–trans dyads is found to be centered at (180°, 180°). Even for the racemo trans–trans dyads, the torsion angles are found to be distributed with $\sigma = 10°$.

The PAN studied here is atactic. Therefore, meso and racemo dyads are statistically distributed along one polymer chain, which cannot be separated. Moreover, due to the existence of these dyads, the conformation is disordered. The combination of the above-mentioned two-dimensional solid-state NMR experiments enables us the determination of backbone torsion angles of meso and racemo dyads "separately" and "quantitatively" with the accuracy of ± 5–10° even in such a disordered atactic polymer. The results show that the torsion angles in meso trans–trans dyads are deviated from the ideal trans and the distributions are wider than those in racemo trans–trans dyads. The difference in meso and racemo dyads would be originated from larger steric hindrance and larger electric dipole replusion between CN groups in meso trans–trans dyads.

Strictly speaking, the conformations determined as trans and gauche here extend beyond a single conformational region due to the wide torsion angle distributions. A knowledge about the intermolecular CN–CN alignments is also obtained. See references [2,3] for further details.

Selective Observation of Respective Conformers in Polymers by Zero-Quantum (ZQ) Experiments [7]

The backbone conformation in amorphous polymers is also important to characterize and the 2D DOQSY

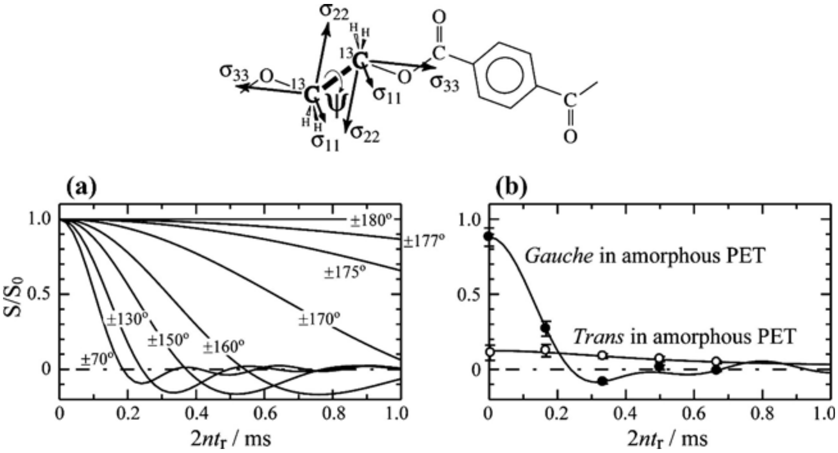

Fig. 5. (a) The torsion angle dependence of calculated ZQ-CSA-dephasing curves. (b) ZQ-CSA-dephasing curves for trans and gauche conformers in doubly $^{13}CH_2$-labeled amorphous PET.

experiment is also used for the quantification of the $O^{13}CH_2-^{13}CH_2O$ torsion angles of poly(ethylene terephthalate) (PET) [6]. The DOQSY experiments determine trans/gauche ratio and the average torsion angle of the gauche conformer quite precisely. However, the precise torsion angle could not be obtained for the trans conformer and the distinction of amorphous trans and crystalline trans was difficult. We recently develop two solid-state NMR methods, ZQ-CSA-dephasing NMR and (DQ-2SQ)-CSA-dephasing NMR, for identifying and quantifying conformations of ^{13}C-labeled polymers under (MAS) [7]. The new NMR methods can distinguish the two trans states quantitatively. Here, we show the conformational analysis of the $O^{13}CH_2$-$^{13}CH_2O$ moieties in amorphous and semicrystalline PET by the ZQ-CSA-dephasing method. This method is based on ZQ dephasing under the recoupled CSA, and the observed magnetization is dephased by the relative orientation of relevant two ^{13}C sites. The amorphous trans component, which cannot be detected by traditional CP/MAS experiments due to complete overlap with dominant gauche signal, is clearly observed by this method.

Figure 5 shows the ZQ-CSA-dephasing curves for doubly $^{13}CH_2$-labeled amorphous PET. Signals of near-trans conformations decay more slowly than those near gauche, which enables (1) selective observation of amorphous trans and gauche components, (2) the determination of trans/gauche ratio, and (3) the quantification of torsion angles of respective components. The angular resolution is especially high for near-trans conformations as shown in Figure 5a. From the decay curves, it is determined that the trans fraction is 12% and the torsion angle is distributed with $\sigma = 16^\circ$ around 180° for amorphous PET. In semicrystalline PET (the data not shown here), the crystalline trans:crystalline gauche:amorphous trans:amorphous gauche = 23:0:20:57%. The trans fraction in the amorphous regions of semicrystalline PET, 26%, is found to be significantly higher than the 12% in amorphous PET.

The new methods shown here also can be used for the definite conformational assignment of respective resonance lines in MAS NMR spectra. The CP/MAS experiment is a versatile method because the spectra (the isotropic chemical shifts) contain a large amount of information, such as conformation, hydrogen bonds, intermolecular packing, dynamics, etc. However, the origin of the change of the isotropic chemical shifts is often unclear and the reliable analysis cannot be carried out without ambiguity. The ZQ-CSA-dephasing NMR or (DQ-2SQ)-CSA-dephasing NMR gives direct relation between the isotropic chemical shifts and torsion angles. Once the assignment is done, conformation analysis can be easily carried out by simple CP/MAS experiments without the need of isotopic labeling. Then, the CP/MAS method would become more useful tool than ever.

Polymer Microstructure: The Conformational Connection to NMR

Alan E. Tonelli
Fiber and Polymer Science Program, North Carolina State University, Raleigh, NC 27695-8301, U.S.A.

Introduction

Of the nuclei (^{1}H and ^{13}C), which both possess nuclear spin and are common to synthetic polymers, ^{13}C is by far the more sensitive NMR spin probe of polymer microstructure. ^{13}C NMR spectra suffer neither from a narrow dispersion of chemical shifts nor from extensive homonuclear, scalar spin–spin coupling, which both complicate the analyses of ^{1}H NMR spectra. It is the sensitivity of ^{13}C resonance frequencies or chemical shifts, δ^{13}C, to the microstructures of polymers, which makes ^{13}C NMR so useful as a structural probe.

For example, the 25 MHz ^{13}C NMR spectra presented in Figure 1 [1] are for three polypropylene (PP) samples with different stereoregularities: isotactic PP, with all meso = m diads, syndiotactic PP, with all racemic = r diads, and atactic PP with a random distribution of m and r diads. The microstructural sensitivity of ^{13}C NMR is plainly evident in the distinct spectra observed for these PP samples. While the ^{13}C resonances of PPs are spread over an ∼30 ppm range, all ^{1}H resonances observed for PPs are within 1 ppm of each other. In addition, the absence of homonuclear (^{13}C–^{13}C) and the easy removal of heteronuclear (^{13}C–^{1}H) scalar couplings further simplify the ^{13}C spectra. Both of these advantages result in the kind of microstructural sensitivity seen in the methyl carbon region of the PP spectra, where for the atactic PP sample all 10 possible pentad stereosequences (mmmm, rrrr, mmmr, rrmr, etc.) are distinctly observed. At higher fields, we will subsequently show that the methyl carbon resonances show sensitivity to even longer stereosequences (heptads: mmmmmm, rrrrrr, mmrmmr, etc.) [1,2]. The ^{13}C NMR spectra of PPs are thus sensitive to stereosequences extending over at least four (pentads) and six (heptads) bonds in both directions along the PP backbone. This long-range sensitivity to microstructural detail makes ^{13}C NMR the most valuable tool for determination of polymer structures.

The ^{13}C nucleus occurs at a natural abundance of only 1.1% and has a small magnetic moment, about one-fourth that of the proton. Both factors tend to mitigate against the observation of high-resolution ^{13}C NMR spectra. However, the decrease in the observational sensitivity of the ^{13}C nucleus can be compensated for by employing a greater number of spectral accumulations during the Fourier transformation (FT) recording of spectra, leading to suitable signal-to-noise ratios. Though requiring the application of several observational techniques [3,4] to overcome the inherent insensitivity of the ^{13}C nucleus, ^{13}C NMR spectroscopy can be and is used to greater advantage for probing the molecular structures of organic molecules, including polymers. The reason is the much greater sensitivity of ^{13}C nuclear shieldings to molecular structure, in the 200 ppm range for neutral organics compared with 10–12 ppm for ^{1}H shieldings, for example. The increased sensitivity of ^{13}C resonance frequencies/chemical shifts to local microstructural environments has generally made ^{13}C NMR spectroscopy the method of choice for investigating molecular structure.

^{13}C NMR Spectral Assignments

To realize the full potential of ^{13}C NMR in microstructural studies of polymers, the connections between constituent microstructural features and their corresponding effects on chemical shifts must be established. Traditionally, synthesis and NMR spectroscopic analysis of model compounds and polymers with known microstructures have provided the means for assigning the NMR spectra of polymers to their underlying microstructural features. These laborious approaches to the assignment of the NMR spectra of polymers could be eliminated if it were possible to predict the ^{13}C NMR chemical shifts expected for each type of carbon nucleus residing in all possible structural environments.

The magnetic field B_i required to obtain the resonance condition for nucleus i at a particular irradiating rf field (B_1) is not equal to the applied static field B_0, but is instead $B_i = B_0(1 - \sigma)$, where the nuclear screening constant, σ, depends on the chemical structural environment of nucleus i. It is the cloud of electrons moving about in the vicinity of a nucleus which shields it from the applied field B_0 by producing small local magnetic fields. Any structural feature that alters the electronic environment of a nucleus will affect its screening constant σ and lead to an alteration in its resonance frequency or chemical shift δ_i.

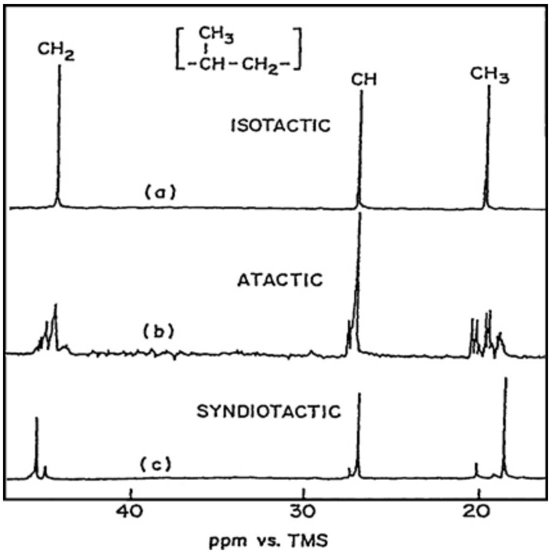

Fig. 1. 25 MHz ^{13}C NMR spectra of (a) isotactic, (b) atactic, and (c) syndiotactic PPs [1].

To date it has not been possible to make sufficiently accurate predictions of ^{13}C NMR chemical shifts even when applying the most sophisticated *ab initio* quantum mechanical methods [5–7 and especially 8]. Instead, the effects of substituents and local conformation have been used to correlate the observed ^{13}C NMR chemical shifts and the microstructures of molecules, including polymers [9,10].

^{13}C NMR studies of paraffinic hydrocarbons [11–15] have led to the following substituent effect rules. Carbon substituents attached at α-, β-, and γ-positions to an observed carbon produce a deshielding of ca. 9 ppm, a deshielding of ca. 9 ppm, and a shielding of ca. −2 to −3 ppm, respectively, compared with an observed carbon that is unsubstituted. In PP, for example, the CH_3 carbons possess 1α, 2β, and 2γ carbon substituents; the CH carbons possess 3α, 2β, and 4γ carbon substituents; and CH_2 carbons 2α, 4β, and 2γ carbon substituents. Based on $\alpha = \beta = 9$ ppm and $\gamma = -2$ ppm, we would expect the CH_2 carbons to resonate downfield from the CH carbons by $-1\alpha + 2\beta - 2\gamma = -9 + 18 + 4 = 13$ ppm, while the CH carbons should resonate $2\alpha + 2\gamma = 18 - 4 = 14$ ppm downfield from the CH_3 carbons. The pattern of ^{13}C resonances expected on the basis of these substituent effects is indeed observed (see Figure 1).

However, the extensive, though smaller, splitting of resonances belonging to the same carbon type (CH, CH_2, or CH_3) observed in the ^{13}C NMR spectrum of atactic PP (see Figure 1 and subsequently Figure 3), must be produced by the presence of different stereosequences, because the numbers and types of α, β and γ substituents possessed by each carbon type are independent of stereosequence. On the other hand, it is well known that the local conformations in vinyl polymers like atactic PP are sensitive to stereosequence [16]. The local magnetic field B_i experienced by a carbon nucleus i must be dependent upon the local conformation in its vicinity. Thus,

$$\text{Microstructure} \rightarrow \text{Conformation} \rightarrow B_i \rightarrow \delta^{13}\,\mathrm{C}_i. \quad [10]$$

γ-Gauche-Effect

To make the connection between polymer microstructures and $\delta^3 C_i$s, we need to know the dependence of the local magnetic field B_i on the local conformation. The γ-substituent effect, which shields an observed carbon nucleus, is the source of the dependence of the local magnetic field B_i on the local conformation. Because the observed carbon C^o and its γ-substituent C^γ are separated by three intervening bonds (C^o–C–$\circlearrowleft^{\varphi}$–C–$C^\gamma$), their mutual distance and orientation are variable, depending on the conformation (φ) of the central bond. Note that the distance between C^o and C^γ is reduced from 4 to 3Å on changing their arrangement from trans ($\varphi = 0°$) to gauche$^{\pm}$ ($\varphi = \pm 120°$).

Grant and Cheney [17] first suggested the conformational origin of the γ-substituent effects on δ^{13}Cs. In their model, it is the polarization of the C^o–H and C^γ–H bonds, resulting from their compression caused by proton–proton (o–γ) repulsion, that leads to a shielding of both carbons. More recently, Li and Chesnut [18] presented evidence that correlate shielding γ-effects with attractive van der Waals forces and not repulsive steric interactions, though their results still suggest that their gauche arrangement is required for shielding. Using both semi-empirical and *ab initio* quantum mechanical calculations Seidman and Maciel [19] concluded that the γ-substituent effect is conformational in origin, but cannot be attributed solely to the proximity of the interacting C^o and C^γ carbons. Thus, it seems apparent that the γ-substituent effect on δ^{13}Cs has a conformational origin and is, as we will shortly demonstrate, useful in characterizing both the local microstructures and conformations of polymers.

For a carbon nucleus to be shielded by a γ-substituent, we have suggested that they must be in a gauche arrangement. The methyl carbons in butane and higher *n*-alkanes have a single γ-substituent, while the methyl carbons in propane have none, but the same number and kinds of α- and β-substituents. The methyl carbons in liquid butane and higher *n*-alkanes resonate at ∼13 ppm, while in liquid propane the methyls resonate at ∼15 ppm [1]. In their solids the *n*-alkanes crystallize in the fully extended all trans conformation, and so there the methyl carbons of butane and the higher *n*-alkanes are not gauche to their γ-methyl or methylene carbon substituents. Thus, we would expect that δCH_3 (solid C_nH_{2n+2}, $n \geq 4$) = δCH_3 (liquid propane). VanderHart [20] has observed the methyl carbons in the solid n-alkanes with $n = 19, 20, 23$, and 32 to resonate at ~15 ppm, just like the methyls in liquid propane which have no γ-substituents.

If we know how much gauche character (P_g = fractional population of $\phi = \pm 120^\circ$ conformations [10,16]), then we can estimate the γ-gauche shielding (γ_{c-c}) produced at the methyl carbons in butane, for example. When the observed shielding $\Delta\delta CH_3 = \delta CH_3(\text{butane}) - \delta CH_3(\text{propane}) = 13.2 - 15.6 = -2.4$ ppm is divided by the gauche character of the intervening bond ($P_g = 0.46$), $\gamma_{c-c} = \Delta\delta CH_3/P_g = -2.4/0.46 = -5.2$ ppm. Similar application of this procedure to 1-propanol and 1-chloropropane yields the following γ-gauche shielding effects: $\gamma_{c-o} = -7.2$ ppm and $\gamma_{c-cl} = -6.8$ ppm [10]. Thus, the shielding produced at a carbon nucleus by a γ-substituent in a gauche arrangement can be comparable in magnitude (-5 to -7 ppm) to the $+9$ ppm deshielding produced by the more proximal α- and β-substituents. More important, however, is the conformational dependence of the γ-substituent effect on ^{13}C NMR chemical shifts. Any structural variation in a molecule which effects its local conformation can be expected to be reflected in its δ^{13}Cs via the γ-gauche-effect.

The conformationally sensitive γ-gauche-effect permits us to draw the connection between a polymer's microstructure and its ^{13}C NMR spectrum:

$$\text{Microstructure} \rightarrow \text{Conformation} \rightarrow B_i \rightarrow \delta^{13}C_i.$$

The connection between the microstructures and the conformations of polymers may be readily established [16]. The γ-gauche-effect establishes the connection between the local polymer conformation and the local magnetic field experienced by a ^{13}C nucleus, so finally

$$\text{Microstructure} \xrightarrow[\text{Effect}]{\gamma\text{-gauche}} \delta^{13}\text{Cs}. \ [10]$$

Example of the γ-Gauche-Effect

Observation of nonequivalent δ^{13}Cs for the isopropyl methyl carbons in several branched alkanes (see Table 1) clearly illustrates the conformational connection between observed δ^{13}Cs and molecular structure (microstructure). Even though the isopropyl methyl carbons have the same α, β, and γ substituents, we note in Table 1 (second column) that their observed nonequivalence progressively diminishes as the number of carbons separating the terminal isopropyl group from the asymmetric center is increased. This behavior can be understood [21] if we focus attention on the source of the nonequivalent δ^{13}Cs observed for 2,4-dimethyl-hexane (2,4-DMH).

We have illustrated in Figure 2 the likely conformations (staggered) about the C_2–C_3 backbone bond in 2,4-DMH, since these determine whether or not the isopropyl methyl carbons C^{sc}, C^{bb} are γ-gauche to the asymmetric carbon C_4. From the probabilities of the trans (t), gauche$^+$ (g$^+$), and gauche$^-$ (g$^-$) conformations (P_t, P_{g+}, P_{g-}), we

obtain $P_t + P_{g+}$ and $P_{g+} + P_{g-}$ as the probabilities for gauche arrangements between C^{sc} and C^{bb}, respectively, and their γ-substituent C_4. The conformational model developed by Mark [22] for ethylene-propylene copolymers may be used to obtain $P_t = 0.38$, $P_{g+} = 0.01$, and $P_{g-} = 0.61$, so C_4 is γ-gauche to C^{sc} with probability 0.39 and to C^{bb} with probability 0.62. The nonequivalence between C^{sc} and C^{bb} is expected to be $\Delta\delta^{13}C = (0.39 - 0.62) \times \gamma_{c-c} \sim -0.23 \times (-5\,\text{ppm}) = 1.1\,\text{ppm}$.

The observed nonequivalence (1.0–1.1 ppm) [23–25] is in close agreement with the value expected from the γ-gauche conformational calculation. The temperature dependence of the magnetic nonequivalence is also successfully reproduced, leaving little doubt that its origin is the conformationally sensitive γ-gauche-effect.

From the Newman projections in Figure 2b it might be expected that the t and g^- conformations would be equally populated. However, it is well known that rotational-state probabilities for the bonds in linear chain molecules depend on the conformations, or rotational states, of neighboring bonds [16]. The asymmetric center at C_4 produces intramolecular interactions which depend simultaneously on φ and neighboring bond rotations (see Figure 2a), which render $P_t \neq P_{g-}$. The values of P_t and P_{g-} approach each other as the asymmetric center is further removed from the terminal isopropyl methyl carbons. This expectation is borne out in Table 1, where it is both observed and predicted that the magnetic nonequivalence of isopropyl methyl carbons vanishes once they are separated from the asymmetric center by more than four carbons.

It is apparent from this example that the microstructural sensitivity of ^{13}C NMR chemical shifts can have a conformational origin. $\delta^{13}Cs$ depend on the local magnetic field, which is influenced by the local conformation in the vicinity of resonating carbon nuclei. The local conformation is determined by the neighboring microstructure. Hence, the microstructural sensitivity of ^{13}C NMR has its basis in the dependence of the local conformation on microstructure.

PP Stereosequences From ^{13}C NMR

To predict the ^{13}C chemical shifts observed at 90 MHz for the methyl carbons in atactic (a)-PP (see Figure 3), which show sensitivity to heptad stereosequences, we simply have to calculate the trans and gauche probabilities for the backbone bonds in each of the 36 heptad stereosequences (mmmmmm, rrrrrr, mmrmmr, rmrmrm, . . .). When this is carried out with the Suter–Flory rotational isomeric state (RIS) conformational model for PP [26] and the resultant probabilities of finding CH_3 in a gauche arrangement with its γ-substituents (CHs) are multiplied by $\gamma_{CH3-CH} = -5.2$ ppm, we obtain the δCH_3s shown as the stick spectrum in Figure 3.

Because the γ-gauche-effect method of calculating $\delta^{13}Cs$ only leads to relative stereosequence-dependent chemical shifts, we are free to translate the calculated shifts as a group to achieve the best agreement with the observed $\delta^{13}Cs$.

This has been done in Figure 3, where the agreement between observed and calculated $\delta^{13}CH_3s$ has been used to make the stereosequence assignments indicated there. The γ-gauche-effect method of assigning resonances in the methyl carbon region of the ^{13}C NMR spectrum of a-PP to heptad stereosequences has been achieved without recourse to the syntheses and study of PP model compounds or stereoregular PPs and without assuming a particular statistical model to describe the expected frequencies of stereosequences produced during polymerization. Having assigned all heptad stereosequence-dependent ^{13}C NMR resonances in a-PP [27], integration of the resonances provides us with a detailed accounting of how much of each stereosequence is present. Such information is needed to test various statistical models of PP polymerization [28]. Furthermore, the close agreement between observed and calculated chemical shifts provides strong confirmation of the Suter–Flory RIS conformational model for PP [26].

^{13}C NMR of Solid Polymers

There exist two interactions between nuclear spins and their neighbors or with the applied magnetic field that result in severe broadening of their solid-state NMR spectra when recorded under conditions that produce

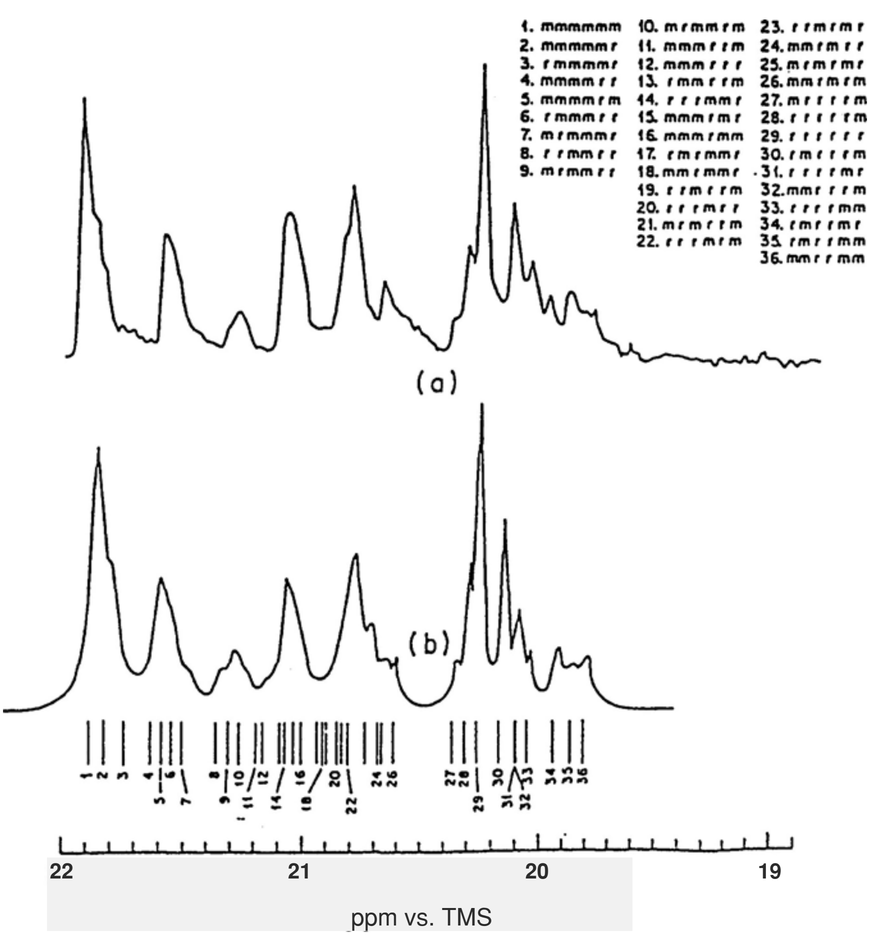

Fig. 3. (a) Methyl carbon region of the ^{13}C NMR spectrum of the same atactic PP shown in Figure 1, but recorded at 90 MHz in *n*-heptane at 67 °C. (b) Simulated methyl carbon spectrum obtained from chemical shifts calculated using the γ-gauche-effect method, as represented by the line spectrum below, and assuming Lorentzian peaks of <0.1 ppm width at half-height [1,2].

high-resolution NMR spectra for their solutions. Both of these nuclear interactions, direct through space dipolar coupling and anisotropic electronic shielding of nuclei from the applied magnetic field, are also present in the liquid. They do not lead to resonance line broadening there because they are averaged to zero by the rapid and essentially isotropic motions occurring in the liquid. In rigid solid samples like glassy or crystalline polymers, the motional averaging of these nuclear interactions are incomplete and produce spectra like the one shown in Figure 4a [29].

As a result of their dipolar interactions with nearby abundant protons, the ^{13}C resonance line widths observed in rigid organic polymers are typically tens of kHz [30]. Since the range of ^{13}C NMR resonance frequencies, or chemical shifts, observed [31] in a given polymer is usually less than 200 ppm, which at an applied field strength of 4.7 T (50 MHz for ^{13}C) corresponds to a frequency range of 10 kHz, ^{13}C NMR spectra of solids whose lines are broadened by ^{1}H dipolar coupling (ca. 20 kHz) cannot resolve their chemically shifted, resonance frequencies. Without removing this ^{13}C–^{1}H coupling, ^{13}C NMR spectra of solid polymers, like poly(butylene terephthalate) (PBT) in Figure 4, cannot provide useable structural information. The ^{13}C NMR spectrum of PBT shown in Figure 4b was recorded by applying an rf field B_1 at the resonance frequency of protons, with a field strength of 50 kHz, in a direction perpendicular to the applied field

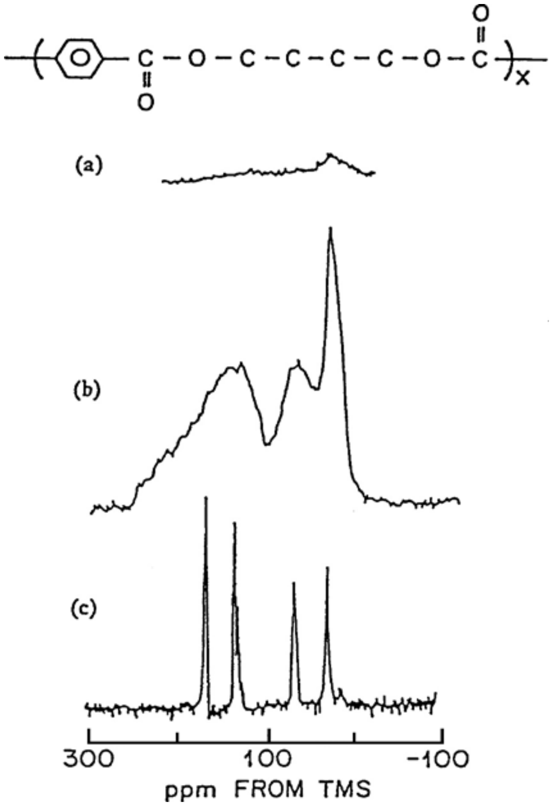

Fig. 4. ^{13}C NMR spectra of bulk poly(butylenes terephthalate) (PBT) obtained with low-power dipolar decoupling (DD) (a), high-power DD (b), and high-power DD with rapid sample spinning at the magic angle (MAS) (c) [29].

B_0 (analogous to the broadband ^1H scalar J decoupling of ^{13}C NMR solution spectra). Note the substantial increase in spectral resolution {compare (a) and (b) in Figure 4 produced without and with high-power ^1H dipolar decoupling (DD) [32]}, though falling far short of the resolution observed in spectra recorded in solution. The remaining line broadening in solid-state spectra is due primarily to chemical shift anisotropy (CSA).

CSA reflects the anisotropy inherent in the distribution of electronic currents about nuclei which screen (σ) them from the applied magnetic field B_0. The local magnetic field experienced by a nucleus is anisotropic and therefore three-dimensional, so the nuclear screening constant σ is in fact a tensor [33]. Rapid molecular motion experienced by polymer segments in solution results in the observation of motionaly averaged, isotropic chemical shifts, $\sigma_{i.}$ If a solid powder sample is rotated rapidly about an axis making an angle 54.7° (the magic angle) with respect to the applied field B_0, the anisotropic chemical shift tensor powder patterns (see Figure 4b and c) are reduced to their isotropic averages. CSA of ^{13}C nuclei in different structural environments vary from ~30 ppm for CH_2 carbons to ~200 ppm for aromatic carbons [30]. Magic-angle sample spinning MAS at a few kHz reduces the CSAs of the aromatic and carbonyl carbons in PBT to their isotropic averages, leading to the high-resolution spectrum seen in Figure 4c.

The first truly high-resolution ^{13}C NMR spectra of solid polymers were reported by Schaefer and Stejskal [34]. They combined for the first time the previously developed techniques [32,35] of high-power proton DD, rapid MAS spinning, and cross-polarization (CP) [35], which permits a dramatic reduction in the spectral acquisition time, to obtain these spectra. In this way, ^{13}C NMR can be utilized to probe the conformations, packing, and motions of solid polymer samples.

Application of Solid-State ^{13}C NMR to Polymers

Syndiotactic polystyrene (s-PS) is a highly stereoregular, semi-crystalline vinyl polymer that normally melts at ~270 °C [36,37]. s-PS shows a large number of crystalline polymorphs [38–41] obtained by melt crystallization and solvent-exposure techniques. However, s-PS assumes only two distinct crystalline conformations [all trans, planar zig-zag (...tttttttt...) and 2_1-helical (...ttggttgg...); t = trans and g = gauche], which are characterized by fiber repeats of 5.1 and 7.5Å, respectively.

Figure 5 presents the high-resolution CPMAS/DD ^{13}C NMR spectra of two s-PS crystalline polymorphs [42], one with s-PS chains adopting the...tttttttt... conformation (a) and the other the...ttggttgg... conformation. We note in spectrum (b) that two CH_2 carbon resonances appear at 38 and 49 ppm, while in spectrum (a) only a single CH_2 carbon resonance at 49 ppm is evident. In the...ttggttgg...polymorph half of the CH_2 carbons are gauche to both of their γ-substituent CH carbons, while the other half are trans to both γ-CH carbons. We expect, as was also observed for s-PP crystallized in the 2_1-helical...ttggttgg...conformation [43], two CH_2 resonances separated by ~2 × 5.2 ppm ~10 ppm in agreement with spectrum (b). Also the single CH_2 resonance observed for the...tttttttt... polymorph in (a) comes at nearly the same frequency (~49 ppm) as the most downfield CH_2resonance observed for the...ttggttgg...polymorph in spectrum (b). These and other ^{13}C NMR observations of solid polymers [10] further confirm the validity of the conformtionally sensitive γ-gauche substituent effects on ^{13}C chemical shifts, with extension of their applicability to solid polymer samples. This strongly implies that the ^{13}C chemical shifts observed for solid polymers are in general primarily influenced by

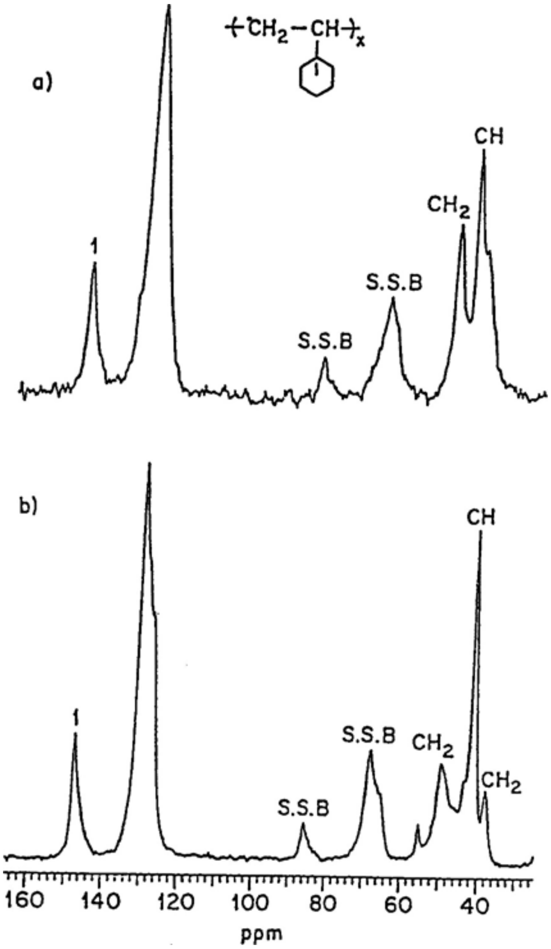

Fig. 5. CPMAS/DD ^{13}C NMR spectra of form I (. . . tttttttt. . .) (a) and form II (. . . ttggttgg. . .) (b) s-PS crystalline polymorphs [42].

Table 2: ^{13}C spin-lattice relaxation times, T_1(s), for the crystalline carbons in s-PS polymorphs [42].

Sample	C_1	C_{2--6}	CH_2 (∼49 ppm)	CH	CH_2 (∼38 ppm)
S_a	78	60	83	65	
$S_{\alpha1}$	400	120	400	200	
$S_{\alpha2}$	140	134		280	
S_0	74	54	58	59	55
$S_{\delta1}$	32	24	30	28	30

the conformations adopted by their rigid backbones and usually only to a much smaller extent by the crystalline packing of their chains [44].

Though all of the crystalline polymorphs of s-PS exhibit distinct X-ray diffraction patterns, they exhibit only one or the other of the two ^{13}CPMAS/DD ^{13}C NMR spectra seen in Figure 5, which correspond to their distinct . . . tttttttt. . . and . . . ttggttgg. . . crystalline conformations with fiber repeats of 5.1 and 7.5 Å, respectively. As a consequence, we can conclude that among all the crystalline polymorphs observed for s-PS only two chain conformations are represented. Apparently differences in packing of s-PS chains in these two crystalline conformations result in the variety of crystalline polymorphs observed for s-PS by X-rays [38–41].

However, CPMAS/DD ^{13}C NMR can still be utilized to distinguish among these many crystalline polymorphs. In Table 2 the ^{13}C spin-lattice relaxation times (T_1s), which reflect motions on the NMR (MHz) timescale [31], observed at room temperature [42] for several of these polymorphs are presented. Samples $S_{a,}$ $S_{\alpha1}$ and $S_{\alpha2}$, and S_0 and $S_{\delta1}$ represent amorphous, . . . tttttttt . . . crystalline, and . . . ttggttgg. . . crystalline s-PSs, respectively. Clearly, the T_1s observed for the . . . tttttttt . . . polymorphs are longer (2–10 times longer) than those for the . . . ttggttgg . . . polymorphs. Even amorphous s-PS has longerT_1s than the . . . ttggttgg. . . polymorphs. When the T_1 results are coupled with the observation of small solvent peaks in the CPMAS/DD and MAS/DD spectra of the S_0 and $S_{\delta1}$ samples (Not presented here [42]), we can conclude that small quantities of the solvents used to induce crystallinity in these s-PS samples are retained in both their crystalline and amorphous glassy regions. Solvent incorporated in the crystalline regions of the . . . ttggttgg . . . polymorphs may act as defects causing the crystalline chains to be at least as mobile as those in the completely disordered, glassy portions of these samples.

Summary

By means of several examples, we have illustrated the types of detailed microstructural, conformational, and motional information that can be obtained from the high resolution, solution, and solid-state NMR spectra of polymers. The microstructures of polymers, including stereo- and regiosequences, comonomer composition and sequence, and geometrical isomerism and branching, can be most effectively identified from NMR spectra, usually ^{13}C, recorded from their solutions. This is facilitated by establishing the connection/assignment of observed ^{13}C resonances to their underlying microstructures via the γ-gauche-effect, which permits the microstructurally sensitive local conformation in the vicinity of a given

^{13}C nucleus to be related to its observed resonance frequency. Through knowledge of the conformational characteristics of polymers and their sensitivity to polymer microstructure we may more easily assign the NMR solution spectra of polymers and thereby determine their microstructures. Application of CPMAS/DD techniques also yield high-resolution spectra for solid polymer samples. Consequently, CPMAS/DD-observed resonance frequencies and relaxation times can be analyzed to learn about the structures/packing, morphologies, conformations, and mobilities of polymer chains in their bulk samples, as well.

Solid-State NMR Characterization of Polymer Interfaces

Peter A. Mirau
Air Force Research Laboratories, Polymer Branch, Wright-Patterson AFB, Dayton, OH 43433, U.S.A.

Overview

Polymer blends and composites have emerged as technologically important advanced materials with mechanical, optical, and electrical applications. It has been shown that the properties of polymers can be improved with the addition of particles ranging in size from nanometers to microns. As the volume fraction becomes large or for composites with nanometer-sized particles, the fraction of interfacial material becomes large enough to influence the properties. In many nanocomposites, the improved properties are thought to result from the favorable properties of polymers at the interface.

The interfacial characterization of polymers is an extremely important and challenging problem. Solid-state NMR is well suited for polymer characterization because the chemical shifts, relaxation times, and dipolar couplings are sensitive to the structure and dynamics on a very local length scale [1–3]. Most composites contain both bulk and interfacial material, and the challenge for NMR studies is to separate the spectral contributions from the polymers in these different environments. This is often accomplished by taking advantage of differences in the NMR properties (chemical shifts, relaxation times, dipolar couplings, or line shapes) between the bulk and interfacial polymer. In other cases, polymers at the interface can be observed via magnetization exchange from the particle surface.

The easiest systems to study are those where chemical shift differences are observed between the bulk and interfacial polymers, and the chemical shifts, line shapes, and relaxation times can be separately measured. If there are no clear chemical shifts differences for the bulk and interfacial polymer, then some other means must be used to separate their spectral contributions. In favorable cases, it is possible to take advantage of differences in the molecular dynamics of the bulk and interfacial polymer to identify and characterize the interface. In other cases, it is necessary to identify the interfacial polymer by magnetization exchange from the surface or to introduce NMR-active nuclei into the system at the interface.

Solid-State Proton NMR Studies

Solid-state proton NMR has a number of advantages for studying polymers at surfaces and interfaces. Protons have a high sensitivity and are present at high concentrations in most materials, making it feasible to study interfaces that may be present at low concentrations. The difficulty in using proton NMR is that the lines are often broad in solids, due to the proton–proton dipolar couplings. This leads to proton line widths that are larger than the proton chemical shift range (∼10 kHz at 500 MHz) [3], and some means of averaging must be used to observe a high-resolution spectrum. The lines in solids can be averaged by several means, including chain motion, multiple-pulse decoupling, or by rapid magic-angle sample spinning [4]. The line widths can be reduced from 50 kHz to ∼0.5 kHz with multiple-pulse decoupling [5], but these methods are often difficult to implement. The lines can also be narrowed by rapid magic-angle sample spinning provided that the spinning frequency is on the order of the dipolar couplings. Commercial probes have recently been introduced that can spin samples as fast as 30 kHz, leading to substantial line narrowing in the proton [6] and fluorine spectra [7,8] of polymers. For polymers above T_g the dipolar couplings are partially averaged by molecular motion and slower (10–15 kHz) spinning is often sufficient for line narrowing [9].

Solid-state proton NMR has been used to study the structure and dynamics of polymers at the interface in composites with poly(methyl silsesquioxane) that are candidate materials for low dielectric constant layers in electronic circuits [10]. Figure 1 compares the solid-state proton NMR spectrum of the bulk poly(ethylene oxide-*b*-propylene oxide-*b*-ethylene oxide) copolymer and the 15 wt% poly(methyl silsesquioxane) composite [11]. Three groups of signals are resolved in the proton spectrum observed with 15 kHz magic-angle sample spinning, the signals at 3.5 and 1.0 ppm from the main-chain and methyl signals of the triblock copolymer, and the signals near 0 ppm from the poly(methyl silsesquioxane) methyl protons of the matrix. The dipolar couplings for

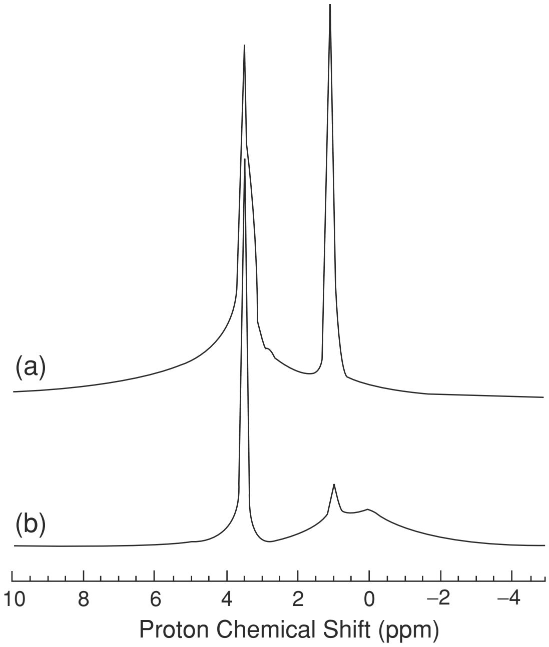

Fig. 1. The 500 MHz solid-state proton NMR spectra of (a) the poly(ethylene oxide-*b*-propylene oxide-*b*-ethylene oxide) triblock copolymer and (b) the 15 wt% composite with poly (methyl silsesquioxane). The spectra were obtained with 15 kHz magic-angle sample spinning.

rigid (crystalline or glassy) protons are in the range of 30–50 kHz and sharp lines are not typically observed in the spectra acquired with 15 kHz magic-angle sample spinning. The fact that such high-resolution spectra are observed shows there is substantial molecular motion both in the bulk triblock copolymer and the composite.

The relative intensities of the methine/methylene protons at 3.5 ppm and the methyl protons at 1 ppm can be calculated from the molecular weights of the ethylene oxide and propylene oxide blocks (4532 and 2262 g/mol for the ethylene oxide and propylene oxide blocks, respectively). The data for the bulk triblock copolymer show a peak intensity ratio of 2:1, which is much less than the expected value of 8:1. This shows that a large fraction of the ethylene oxide is crystalline and cannot be observed with 15 kHz magic-angle sample spinning. In the composite, however, the peak intensity ratio is closer to the expected value, showing that composite formation suppresses the formation of crystallinity in the ethylene oxide block, and that both polymer blocks are mobile in the composite.

Since a high-resolution proton spectrum is observed for the composite, the two-dimensional (2D) exchange (or NOESY) spectroscopy can be used to probe the structure in the solid state [12]. The 2D exchange spectrum for the 15 wt% composite obtained with a 0.1 s mixing time and 15 kHz magic-angle sample spinning shows three peaks along the diagonal that can be assigned to the polymer main-chain and methyl peaks at 3.5 and 1.0 ppm, and the poly(methyl silsesquioxane) methyl peak at 0 ppm. The off-diagonal intensity shows that there is spin exchange between all these peaks, but it is difficult to determine which block is in close contact with the poly(methyl silsesquioxane) matrix by direct examination of the contour plots.

A better insight into the spin exchange process can be obtained by examining the cross sections through the 2D spectra at the frequencies of the main-chain peak at 3.5 ppm and the methyl peak at 1.0 ppm, as shown in Figure 2 [12]. The largest peaks in the cross sections are due to diagonal signals. The cross section through signal at 3.5 ppm (which is due mostly to the ethylene oxide methylene protons) shows only a small amount of exchange to the propylene oxide methyl or poly(methyl silsesquioxane) signals. Cross sections through the propylene oxide methyl signal at 1 ppm shows very efficient spin exchange to the poly(methyl silsesquioxane) methyl signal at 0 ppm. These and other experiments show that the polymer domains in the composite adopt a core-shell

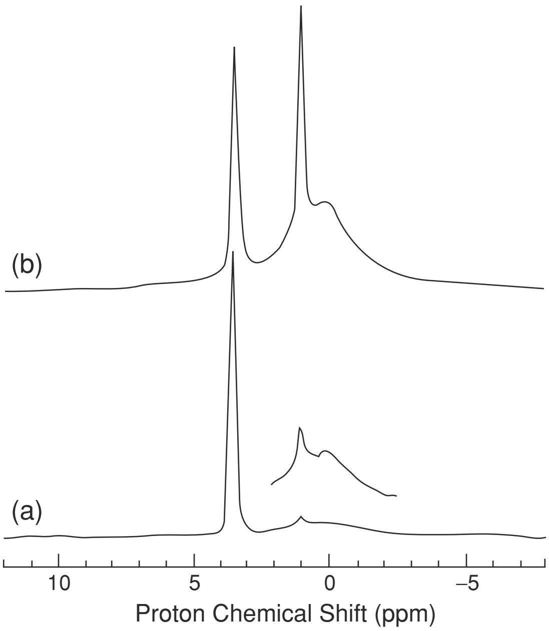

Fig. 2. Cross sections through the 2D exchange spectra of the 15 wt% composite of poly(ethylene oxide-*b*-propylene oxide-*b*-ethylene oxide) and poly(methyl silsesquioxane) at the frequency of (a) the main-chain peak at 3.5 ppm and (b) the propylene oxide methyl peak at 1 ppm.

structure with the ethylene oxide at the center and the propylene oxide at the interface with the poly(methyl silsesquioxane).

High-resolution solid-state proton NMR with rapid magic-angle sample spinning has also been used to study the structure and dynamics of the interfaces in alternating layers of electrostatically adsorbed polyelectrolyte multilayers. This is illustrated in Figure 3 which shows the proton NMR spectra of poly(diallyldimethylammonium chloride) and poly(4-styrene sulfonate), the polyelectrolyte complex (PEC) precipitated from solution, and the sample prepared using layer-by-layer deposition on colloidal silica acquired with 30 kHz magic-angle sample spinning [13]. The layer-by-layer complex is prepared by alternately coating the silica particle with the anionic or cationic polymer. The spectra for the PEC and the layer-by-layer deposited sample show the peaks from both polymers, including the aromatic peaks near 7 ppm and the methyl proton peaks near 3 ppm. Residual water signals are also observed at 4.9 and 3.85 ppm in the layer-by-layer sample for water in the polymer domains and at the silica surface.

The structure of the PEC and layer-by-layer samples can be probed by measuring the proton dipolar couplings between the layers. NOESY experiments cannot be used in these studies because of the overlap of the aliphatic signals from the poly(4-styrene sulfonate) and the poly(diallyldimethylammonium), so proton–proton double-quantum correlation spectroscopy is used [14]. The idea behind this experiment is to apply a series of pulses to reintroduce the dipolar couplings that are averaged by rapid magic-angle sample spinning in one dimension of a 2D NMR experiment. Protons that are close in space can be identified by the correlation of the single- and double-quantum frequencies.

Figure 4 compares the 2D double-quantum spectra for the PEC and the layer-by-layer complex with four layers. Since this experiment measures the correlation of the single- and double-quantum spectrum, the frequencies in the indirectly detected dimension are twice as large as those in the directly detected dimension. Furthermore, the only peaks that appear in the spectrum are those with strong dipolar couplings. The autocorrelation peaks ($\omega_1 = 2\omega_2$) arise from pairs of protons with the same

chemical shift that also have strong dipolar couplings. The peaks near $\omega_1 = 14$ ppm and $\omega_2 = 7$ ppm arise from couplings between styrene aromatic protons, while peaks between 2–6 ppm in the ω_1 dimension and 1–3 ppm in the ω_2 dimension arise from nearby aliphatic protons. The peaks of interest (note arrow in Figure 4) in both spectra arise from dipolar couplings between the aromatic protons of poly(4-styrene sulfonate) and the methyl protons of poly(diallyldimethylamomnium chloride) at the interface.

Solid-State Heteronuclear NMR Studies

The structure and dynamics of polymers at surfaces and interfaces can also be studied using nuclei other than protons that may be at or near the interface. The heteronuclear signals can arise from nuclei that are naturally at the interface or from NMR-active nuclei introduced at the interface. We can probe the structure and dynamics at the interface using cross polarization and sampling the magnetization only from those polymers close enough to cross polarize the heteronuclei at the surface.

Figure 5 shows how silicon–proton 2D heteronuclear correlation NMR [15,16] can be used to characterize the interface in polymer composites of vycor glass and poly(ethyl acrylate) [17]. Vycor is a porous glass with 4-nm sized pores that have been filled with monomer and photopolymerized. The heteronuclear 2D experiment correlates the high-resolution proton spectrum with the silicon spectrum from the interface. The pulse sequence begins with evolution of the proton spins under multiple-pulse decoupling. After an optional mixing time the proton magnetization is transferred to the surface silicons using multiple-pulse cross polarization to quench spin diffusion during magnetization transfer [15]. Figure 5a shows the heteronuclear correlation spectrum with a short (50 µs) spin diffusion delay time between the proton evolution and the multiple-pulse cross polarization [17]. With such a short cross-polarization time, the surface silicons are cross-polarized only by protons within a few Å of the surface. Figure 5a shows that the protons nearest the

surface have a chemical shift near 5 ppm and are assigned to hydroxyl protons and a layer of water molecules at the surface. With a longer spin diffusion delay time (Figure 5b, 50 ms) the surface silicons are correlated with the proton signals from the poly(ethyl acrylate). These and other experiments show that the polymer in the porous glass is separated from the silica surface by a 5 Å layer of water.

Solid-state heteronuclear correlation NMR has also been used to study the structure and dynamics of polymer-clay nanocomposites [18]. Polymer–clay composites can adopt a variety of structures, ranging from completely exfoliated to morphologies where the polymer is intercalated between the clay sheets [19,20]. The intercalated morphology is of interest because the polymer is confined to a very narrow space (1–3 nm) between the relatively rigid clay sheets. Polymer–clay composites for NMR studies were prepared by intercalating poly(ethylene oxide) between the layers of hectorite, a synthetic clay with a low iron content. The proton NMR spectrum with fast magic-angle sample spinning shows the presence of a peak at 0.35 ppm that can be assigned to hydroxyl protons in the silicate layers of the clay [18]. This peak makes it possible to probe the structure in the vicinity of the clay using silicon–proton cross polarization and proton spin diffusion. Figure 6 shows the heteronuclear correlation spectrum of the intercalated nanocomposite with a 30 ms spin diffusion delay time [18]. The cross peaks to the poly(ethylene oxide) protons at 3.5 ppm can only arise from the close proximity of the polymer and the clay sheets. The results from a study of the interaction of poly(styrene-*b*-ethylene oxide) block copolymers with hectorite clay shows that the ethylene oxide block intercalates between the clay sheets while the polystyrene block is excluded [21].

Dynamics at the Interface

Many NMR methods have been developed to study the molecular dynamics of polymers over a wide range of frequencies, ranging from picoseconds to seconds [1,2,22]. The difficulties in studying the dynamics of polymers at the interface are mostly in selectively observing the interface. Once a pulse sequence has been used to select for interfacial material or a composite is prepared with an NMR-active nuclei at the interface, then the standard NMR experiments can be used to characterize the dynamics.

The NMR relaxation times, line shapes, and dipolar and quadrupolar coupling constants are sensitive to the molecular dynamics of polymers. The proton line shapes can be measured with a high sensitivity, but they tend to be rather featureless and difficult to model quantitatively. Quadrupolar line shapes from deuterons introduced at the interface are much more sensitive to the rate and amplitude of molecular motions [23]. The line shape measurements are usually sensitive to motions on the kHz timescale, while the relaxation times are generally sensitive to faster motions [3]. 2D spin exchange experiments are sensitive to very low frequency molecular motions [24].

Figure 7 shows the solid-state deuterium NMR spectra of methyl-deuterated poly(methyl acrylate) in the bulk and as a thin film coating silica particles [25]. At 25°C the deuterium spectrum is similar to that expected for a methyl group in a relatively rigid matrix. Rapid methyl group motion partially averages the deuterium quadrupolar coupling from 120 to 37.5 kHz [26] but there is insufficient molecular motion in poly(methyl acrylate)-d_3 to completely average the quadrupolar coupling. For the bulk sample (Figure 7a) the powder pattern disappears as the sample is heated and a motionally averaged signal is observed at temperatures above the glass transition temperature.

Figure 7b shows the deuterium spectra of the same polymer coated as a 2–3 nm thick film on silica particles [25]. The spectra at 25 °C are similar to those in the bulk but differences are observed as the temperature increases. The most notable features are the peak near zero frequency that is observed at lower temperatures in the surface-coated sample and the powder pattern with the 37.5 kHz coupling that is preserved until much higher temperatures. These results show that the surface-coated samples have at least two dynamic components. The component with dynamics faster than the bulk that gives rise to the center peak is assigned to polymer at the air interface,

while the polymer with reduced mobility is assigned to polymer at the silica interface. The more mobile polymer at the air interface disappears when the sample is overcoated with protonated poly(methyl acrylate).

The averaging of the proton line widths by molecular motion is a rough measure of the dynamics that can be measured using 2D wide line separation spectroscopy (WISE) [27]. The 2D WISE experiment correlates the proton line width with the heteronuclear chemical shift. The proton spectrum is typically not well resolved and this method allows us to measure the proton line width associated with resolved peaks in the carbon, silicon, phosphorus, or nitrogen spectra.

Figure 8 shows cross sections through the 2D WISE spectra for bulk poly(ethyl acrylate) and the polymer confined to the 4 nm pores in Vycor glass [17]. These spectra were recorded at ambient temperature, which is far above the glass transition temperature for the poly(ethyl acrylate). Under these conditions the dipolar couplings are partially averaged by molecular motion and a 5 kHz line width is observed in the proton dimension. A more complex line shape is observed for the Vycor composite, with broad and narrow components. The broad component is associated with the polymer at the interface that has a restricted mobility, while the sharper component is associated with bulk-like poly(ethyl acrylate) at the center of the 4 nm pore. 2D WISE NMR has also been used to study the dynamics of poly(ethylene oxide) and poly(ethylene oxide-*b*-styrene) intercalated into clay nanocomposites [21].

Double-quantum NMR has also been used to study the poly(ethyl acrylate) dynamics as the interface [28]. The dipolar couplings are partially averaged by motion above T_g for bulk poly(ethyl acrylate), and double-quantum coherences are difficult to observe. However, they can be observed in the Vycor composites where the dynamics are restricted at the polymer–glass interface. The

double-quantum peaks disappear when the glass surface is coated with trimethylsilyl groups.

Outlook and Conclusions
